The Influence of Treatment Upon Early Neurosyphilis. Therapeutic Shock vs. Neurorecurrence.—An acute process in the nervous system undetected, and treated abruptly with arsphenamine, gives rise to symptoms from the affected group of structures which should be classified as Herxheimer reactions. These Herxheimer reactions may develop upon subthreshold processes, as in the case of a clinically inconspicuous involvement of the eighth nerve, for example, and may result in serious and permanent damage. Sudden deafness, *a period of coma, convulsions, seventh nerve paralysis, may all* follow the first injection of arsphenamine in a patient whose neurosyphilis

Fig. 405

OPTIC NEURORECURRENCE WITH NORMAL SPINAL FLUID AND BLOOD FOLLOWING INSUFFICIENT ARSPHENAMIN TREATMENT. RAPID RECOVERY AND APPARENTLY COMPLETE CURE. REINFECTION (?) (PRIMARY AND SECONDARY LESIONS) FOURTEEN MONTHS AFTER FIRST EXAMINATION. SECOND REINFECTION (?) FOUR YEARS AFTER FIRST EXAMINATION

Laborer aged thirty-two years.

7/24/20 Examined.

History of Penile Lesion with secondaries six months before.

History of Treatment: Five intravenous arsphenamin injections and potassium iodid by mouth, no mercury.

Vision Began to Fail one month after last arsphenamin injection.

Eye Examination: Violent rapidly progressing neuroretinitis.

Physical Findings negative.

Wassermann Reaction on the Blood negative.

Spinal Fluid negative.

Diagnosis: Neuroretinitis, probably syphilitic.

Rapid Improvement under mercury succinimid and iodid, followed by arsphenamin.

Further Treatment: Four arsphenamin courses as for an early infection. Forty injections of mercury succinimid, 200 4-gram inunctions, 345 gm. sodium iodid intravenously.

11/22/21 Re-examined. Multiple penile lesions developing two weeks after drunken spree.

Physical Findings: Several scattered papules on penis of several weeks duration.

Induration of Old Scar: No erosion or other sign of activity.

Spirocheta pallida demonstrated eight days after examination *in small penile lesion*.

Wassermann Reaction on the Blood strongly positive.

Maculopapular Secondaries on Trunk and Arms Appeared Twenty Days After Examination.

Wassermann Reaction on the blood again strongly positive.

Condition of the Eyes: Normal except for organized exudate of healed neuroretinitis.

Spinal Fluid negative.

12/27/21 Was Seen with Chancre of the Cervix.

9/27/23 Slight serologic relapse (Kolmer 21) spinal fluid normal. One month later negative.

7/21/24 Eight months later penile lesion (5d) followed by typical macular secondaries.

Discussion

1. *Grave Involvement of a Cranial Nerve* in the neurorecurrences of early syphilis may be associated with a negative Wassermann reaction on the blood and negative spinal fluid.

2. **It Is Remotely Conceivable That the First Neuroretinitis Was Nonspecific,** but its rapid response to mercury succinimid and iodid with the history would seem to establish the first syphilitic infection.

3. **Was the Second Infection a Relapse (Monorecidive), a Reinfection or Superinfection?**

The induration of the old primary scar suggests a relapse. On the other hand, spirochetes could not be found in this induration, but they were demonstrable in one of the chancres at a distance from the original lesion. While specific exposure was denied, the patient had been drunk and irresponsible at approximately the proper time for a new infection to have occurred. It is not possible however to state categorically that this is not a primary relapse with a second crop of secondaries.

4. **Reinfection Cannot Be Proved** without more definite history of exposure and chancre less obviously in the immediate neighborhood of the original primary.

5. **A Superinfection is Easily Conceivable** but not probable in this case.

6. **The Course of the Second Infection Has Been Very Different from the First.** No tendency to involve the optic nerve is thus far apparent.

7. **If This is a Relapse of the Original Infection** the original involvement of the optic nerve (neurorecurrence) would scarcely appear to be due to a neurotrophic strain of organism, but rather to the effect of insufficient treatment (especially lack of mercury as such).

8. The second "reinfection," in view of the previous serologic relapse suggests recurrence but may be a superinfection.

has not been detected by careful history and examination and provided for by heavy-metal preparation. Such accidents are hardly to be regarded as neurorecurrences in a strict sense though expressive of kindred neurosyphilitic lesions. They can in the majority of cases be avoided by proper study of the case before treatment is begun, and an intelligent and cautious initiation of treatment.

Neurorecurrence. An Effect of Inadequate Treatment.—Neurorecurrence is not to be confused with a therapeutic shock or Herxheimer reaction, nor is it to be regarded as evidence that "arsenic" has "predisposed" the nervous system to spirochetal invasion. It is merely a sudden relapse of an imperfectly extinguished infection in a structure peculiarly inaccessible and difficult of sterilization and in a patient whose resistance has been prevented from developing by improper treatment. Neurorecurrence may assume all of the clinical forms of early syphilis of the nervous system. Its relation to arsenical therapy is discussed in Chapter V The remedy for neurorecurrence is more intensive treatment for syphilis, better directed in that it always employs both spirillicidal and resistance-building therapy coincidently or in immediate succession to one another and does not place the patient with early syphilis on prolonged rest periods or dismiss him from observation and treatment after a few injections of arsenical.

The definition of "neurorecurrence is by no means easy matter and assumes some importance in view of the polemic discussions, especially between Harrison and Burke dealing with the relative merits of alternating and simultaneous use of arsphenamines and heavy metals in early syphilis. Strictly and originally neurorecurrence is sudden isolated clinical manifestation or injury appearing after lapse in treatment, early in the disease, and usually involving the vascular or cranial nerve mechanisms in hemiplegia or palsy This definition takes no cognizance of what might be thought of as serological neurorecurrence, in which previously normal spinal fluid is found on subsequent examination after lapse, to show marked abnormality often of the "red flag or preparetic type, even though no clinical symptoms accompany the relapse. If the range of spinal fluid abnormality in such recurrences be extended to include all abnormal fluids, even with slight rises in cell count, the proportion of neurorecurrence will evidently appear higher than in current estimates based purely on symptomatic criteria. Thus, when an observer states that he has never seen neurorecurrence, it is necessary to know what he means by neurorecurrence. The narrower or older definition is the more widely used, the serological relapses tending to be ignored through nonuse of spinal fluid examination in certain clinical materials (e. g British), or being rated as "neurosyphilis progressive in spite of treatment. There is, too, tendency to use figures dealing ith serological neurorecurrence to illustrate contentions based on clinical neurorecurrence. W personally tend to define neurorecurrence or neurorelapse as either clinical or serological revival or outburst of nervous system involvement after lapse in treatment preceded by clinical serological (spinal fluid) normality In view of the obvious difficulty in defining the borderline of involvement in the nervous system when spirochetes may be present in an apparently normal fluid, it is probably too soon to attempt final classifications and definitions distinguishing neurorecurrence from early neurosyphilis in general.

Zimmermann, from study of the experience of the Johns Hopkins Clinic, estimates the frequency of clinical neurorecurrence at 1.8 per cent in 1400 patients with early syphilis on service which uses arsphenamine and mercury in alternation. The Cooperative Clinical Group found 2.9 per cent neurorecurrence in 3444 cases of early syphilis under observation for more than six months. Gennerich estimates that 10 per cent of those who develop meningeal neurosyphilis in the first year will show outspoken neurorecurrences. This places clinical neurorecurrence among the comparative rarities of even special practice. The frequency of the general forms of neurorelapse is indicated by Gennerich as follow r of 9 cases with general symptoms, 4 had epileptiform attacks, 3 had severe headache, and 1 each had coma (encephalitis?) and apoplexy Of the forms involving cranial nerves Zimmermann gives comparative table (Fig. 406) including his own results and Gennerich s.

Onset of Symptoms.—As a rule the onset of symptoms in neurorecurrence as in primary symptomatic neurosyphilis is sudden, but may be very gradual.

The earlier stages may not be apparent either to patient or physician. The predominance of auditory and facial nerve involvements, and combinations of the two, is apparent from the figures. The symptomatic optic nerve lesion

is, of course, much less frequent than the asymptomatic papillitis, but may cause remarkably rapid failure of vision.

Neurorecurrence in Untreated Patients and Those Receiving Only Mercury or Bismuth.—It is entirely possible for a neurorecurrence to develop

Comment At this point the patient disappeared from observation. On reporting him by name to the State Board of Health, he was obliged to resume treatment under a private physician, but no opportunity was given us to advise the physician of the gravity of the case.

Every Physician Who Takes Over a Case Treated Elsewhere Should Ask for and Receive a Full Report of the Findings of His Predecessor

Note—Six years after the last examination of the spinal fluid, without interim treatment, this patient appeared in the clinic with general paresis.

in an untreated patient whose infection is following the ebb and flow of his own defence mechanism It was well known under mercurial therapy in the prearsphenamine era. It has been observed under an exclusive bismuth

therapy as in the Breslau Krankenkassen "epidemic" (Hugo Müller) The term as previously noted may quite as properly be applied to flare-ups of asymptomatic meningeal neurosyphilis in patients who have previously been shown to have negative spinal fluids, as in Figs. 407 456

Prognosis of Neurorecurrence.—The prognosis of the early neurosyphilis with symptoms and of the symptomatic relapse of neurosyphilis varies with the structures affected. That of the eighth nerve, as studied by Alexander is good for the mild type which presents only tinnitus, slight diminution in hearing, and spontaneous nystagmus without vertigo. The prognosis of pure vestibular involvement is good, but 30 per cent lose the function of the static labyrinth. Marked cochlear symptoms, and a sudden severe onset have a bad prognosis for recovery of hearing. The outlook in optic neuritis, if the process has not been too long neglected is good, and remarkable recoveries of vision follow the institution of effective treatment. Seventh nerve lesions are more refractory and partake of the prognosis of eighth nerve lesions.

Unfavorable Reactions in Early Neurosyphilis.—Stokes has been able to watch both symptomatic and asymptomatic neurorecurrence appear while the patient was on reasonably effective arsphenamine or heavy metal therapy Such cases may perhaps best be regarded as 'progression in spite of treatment."

One patient, while on large inunctions following 8 injections of arsphenamine, developed combined seventh and eighth nerve lesion. Another developed full-fledged meningeal neurosyphilis while actively under treatment with arsphenamine. Still another comparatively late case, was made definitely and rapidly worse by arsphenamine and was only controlled by huge dosage of mercury by inunction and iodides by mouth and intravenously There is unquestionably type of meningeal flare-up which can be provoked into activity by injudicious prodding of a seemingly quiescent case with arsphenamine, sometimes to subside again when the drug is pushed or others substituted. All these considerations indicate that the problem of neurorecurrence is not simple one, dependent merely on one factor such as the inadequate use of arsphenamine. There seems at times to be definite and even irresistibly unfavorable trend, and not even treatment effectively given can always stop it. Heavy-metal treatment is, of course, most valuable as builder of the systemic resistance which prevents neurorecurrence, but it cannot be offered as an absolute preventive.

Occasionally a case will appear in which the arsenicals will evidently be entirely out of place in the therapy and under such circumstances heroic bismuth, mercurial, and iodide therapy hard though it may be for the patient, may be necessary to control the situation. A resort to fever therapy in such cases may be particularly helpful (O'Leary)

Precocious Tertiarism in the Nervous System.—Precocious tertiarism the allergic response of tissues in the early stage of syphilis, which results in gummatous lesions years before their expected period in the chronology of the disease, may occasionally be seen in early syphilis of the nervous system For example, J.H.S. has seen a case of brain gumma with negative spinal fluid develop within the first year of a fairly well treated infection. The vascular accidents, reported as early as three months after infection (Gennerich) are very possibly precocious gummatous and thrombotic involvements of cerebral vessels.

Ultimate Prognosis.—The ultimate prognosis of early neurosyphilis can not as yet be exactly defined, for one has only to observe its possibilities for relapse and for symptomatic progress without serological signs over a period of years to realize that there are no criteria of cure on which complete reliance

Fig. 408.

ANESTHETIC RASH"

Woman, aged twenty-six, married, telephone operator

Note the small horny papular lesions in the centers of these palms and t the flexures of the fingers. The center of each palm was markedly erythematous ith scattered patches of deeper color nd with the more easily visible horny lesions superposed. The patient gave the following history

A year nd three months before coming to the clinic large bluish lumps had p peared in both groins These lasted approximately tw months, nd then the patient went to hospital t seek relief for general ill health. She wa xamined and told that an operation wa necessary which was then performed. The patient describes it as "right ovary pack and adhesions. The lumps subsided rapidly after operation.

Approximately two days after the operation measle-like eruption broke out, first ver the arms, then over the entire body The patient inquired as t its nature and states that sh was told it was an 'anesthetic ash. Her convalescence as otherwise uneventful, but after she left the hospital her mouth became sore. She went t the surgeon ho had performed the operation for relief and states that he ished t treat her mouth ith nitrat of silver In view of the fact that she had mucous patches in the commissures hen she examined at the clinic it seems probable that this part of her secondary manifestations. She later saw her home physician, who urged her t have her tonsils removed. Coincidently ith the ppearance of the mouth lesions the eruptive lesions on the palms also developed and ere present to varying degree throughout the following eight or nine months

During the year that she pparently having secondaries on the skin, mucous membranes, nd palms this patient seen by 3 surgeons and 1 general practitioner She as not given an thing that would suggest systemic treatment for syphilis, she did not receive ny diagnosis, nd so fa could be ascertained from the patient account no diagnosis made Inquiry t the explanations offered for the various lesions present elicited the reply "They used to pinch my hands this y and said just your condition after operation So far can be ascertained nobody suspicion was aroused t the point of taking W sserma reaction at any time

Upon examination in the clinic in ddition t the palmar lesions, involuting mucous patches ere found from which no spirochetes could be obtained, and the W sser mann reaction on the blood strongly positive The spinal fluid findings ere as follow

Wassermann reaction strongly positive with 0.4 0.6, and 1

100 small lymphocytes.

20 large lymphocytes

can be placed. The tabular summary of prognostic grading of spinal fluid findings gives a close practical approximation to the type of case in which a given type of treatment may be expected to produce a satisfactory result (Chapter IV) The question is often raised, and has usually been answered in the affirmative by such observers as Fordyce and Wile, as to whether the patient who seems to have escaped involvement in the earliest months of the infection can confidently hope to remain free of neurosyphilis throughout the course of his disease. We have ourselves taken this view in earlier studies, but with increasing qualification as we note the development of late serological relapse in both blood and spinal fluid in patients protected seemingly by every resource of modern treatment, including pregnancy An illustration of such a case is shown in Fig. 435 Lomholt (1036) Livingood and Beerman (1941) and Kopp and Solomon (1941) have supplied further clinical evidence in support of this position. The question as to whether a patient who has acquired syphilis can ever be released from the need for a periodic examination of the nervous system and the spinal fluid test, like the entire problem of the extent and character of observation in seemingly arrested syphilis, cannot be conclusively answered at this time. Moore's observations for the Co-operative Clinical Group indicate that once true latency is attained a negative spinal fluid need not be reexamined more than once, if at all. The tendency under war time pressure is increasingly to dismiss as permanently recovered and free from risk of neurosyphilitic relapse patients who following adequate modern treatment in early syphilis or the achievement of latency in later syphilis, have obtained a negative spinal fluid examination. To this statement we would certainly add the exception that the recurrence of a positive serologic test on the blood or the intervention of trauma (head trauma especially) should call for a reexamination of the spinal fluid.

Fig. 408.

TO DETECT EARLY SECONDARY SYPHILIS

1. Properly follow up all doubtful genital lesions.
2. Strip the patient for examination. See everything in good light.
3. Expect symptoms in women, signs in men.
4. Trust the blood serologic reaction, but don't call everything syphilis in the patient whose blood serologic reaction is positive.
5. Use the darkfield carefully if there are vailable lesions.
6. Accept the repeatedly negative blood serologic reaction as eliminating all but 1 per cent or less of eruptive secondary syphilis.
7. Be more suspiciously minded gynecologist or otolaryngologist. Use the blood serological test routinely
8. Know the clinical characteristics of secondary syphilitic lesions.
9. Take more blood serological tests on young adults ith headaches, persistent sore throats, "rheumatism," and pseudotuberculous symptoms.
10. Keep early neurosyphilis always in mind.
11. Give your patient summary of your findings in writing when or before he goes to another physician, to supply the evidence for his diagnosis when his signs have vanished.

CHAPTER XIII

THE CLINICAL ASPECTS OF RELAPSE, REINFECTION AND PROGRESSION IN EARLY SYPHILIS

The Importance of Relapse.—Syphilis, as we have already remarked is the relapsing disease par excellence The ability to recognize relapse, to know when and where to look for it, to understand its influence on the transmission of the disease, and to control it, becomes an essential part of the equipment of every physician who assumes charge of a syphilitic patient.

The literature of relapse is still obscured and study of the subject retarded by an over shadowing interest in the subject of reinfection, due largely to the bearings of the latter on the question of cure. The subject of early infectious relapse is one of great practical importance, for the maintenance of infectious foci through relapse in improperly treated early syphilis is undoubtedly an important bar to the conquest of the disease. Mucocutaneous relapse in particular stands in a numerical ratio of 1 to 16 to early syphilis itself as disseminator of the disease. It is one fifth as important numerically as the chancre among infectious lesions, while reinfection is only one fifty-seventh as important as the chancre numerically in the potential transmission of syphilis.

The immunological relations of relapse and reinfection have been discussed in Chapter I They should be reviewed as a preliminary to full under standing of the relapse problem

The Forms of Relapse.—The physician should be on the lookout, especially in the earlier years of his patient s infection, for one or more manifestations of the following relapse categories.

1 **Mucocutaneous relapse.**

2. **Serological Relapse.**—These two exceed all others in frequency and constitute, according to the large material of the Cooperative Clinical Group, 12.1 and 15 1 per cent respectively of the total number of early cases studied and under treatment for six months or more (5244)

3 **Ocular recurrences** (3.3 to 0.3 per cent depending on method of treat ment) include iritis, iridocyclitis, keratitis, neuroretinitis. The form of ocular relapse seen most often in Negroes is iritis.

4 **Neurosyphilitic relapse** either in the form of neurorecurrence in the strict sense (see p 017) (2.9 per cent) or of asymptomatic neurosyphilis develops following a previous normal spinal fluid (3 4 per cent)

5 **Bone and joint lesions** (0 4 per cent) as forms of relapse, include particularly periostitis and osteitis. Headache for example, is not infrequently (especially in Negro patients according to Moore) an expression of cranial osteitis as a form of relapse.

6 **Visceral lesions** (0 05 per cent) especially hepatitis.

7 **Birth of a syphilitic child** to an apparently healthy and serologically negative mother who has syphilis.

8 **Infection of a sex partner** with syphilis in the absence of detectable clinical or serological relapse in the patient.

The relative frequency of these forms of relapse can only be partly estimated but the percentage data given here from the Cooperative Clinical Group investigation are believed to be representative.

Mucocutaneous Relapse.—This particular field of relapse, in many respects the most important of all, especially from the standpoint of the public health, has been specially studied in the University of Pennsylvania Clinic by Besancon, Schoch, Ireland and Stokes, by the Cooperative Clinical Group and by Kern. The following summary is drawn largely from the first two sources.

Statistical estimation of the incidence of infectious recurrence and mucocutaneous relapse is influenced greatly by the stage of syphilis represented by the material under consideration. For example, if patients under observation for less than six months are excluded, it was found in the Cooperative Clinical Group surveys that the proportion of mucocutaneous relapse to the total of cases was materially affected In the collected material of this group among 5952 cases, regardless of observation period, mucocutaneous relapse occurred in 6.05 per cent of patients, 86 per cent of them relapsing once 11 per cent twice, 2 per cent three times and 1 per cent four times. In patients observed for six months or more, the incidence was 12 1 per cent. Infectious relapse is more frequent in males than females, and in Negroes than in white patients. The Negro woman in particular is conspicuously a subject of infectious relapse.

The frequency of relapse is influenced by the age sex and color of the patient, the age of the infection, the stage of syphilis at which treatment begins, the mass of treatment received the system of treatment (simultaneous versus alternating) and the prolongation and scheme of treatment employed. Relapse tends to be more frequent in the younger patient (33.3 per cent for patients under sixteen years and 30.9 per cent for patients between sixteen and twenty years as compared with 23 per cent in patients over forty) The influence of the age of the infection is of great importance not only in the control of infectiousness in patients themselves but in the differentiation of relapse from reinfection. Within the first six months of the infection, 25 7 per cent of relapsing patients have relapsed, and in the second six months 29.2 per cent, making a total of 54.9 per cent within the first year (Cooperative Clinical Group) By the end of the second year after infection, 84 7 per cent of relapsing patients have relapsed. In relation to treatment, 45 per cent of relapses occurred within six months after treatment was stopped, 73 6 per cent by the end of the first year 91 per cent by the end of the second year Thus it is evident that infectious relapse is largely concentrated into the first two years of the infection or after the cessation of treatment. The Cooperative Clinical material included 33 cases in which relapses occurred from three to seven years after infection and eight instances of relapses more than seven years after infection. Relapse may occur as early as three weeks after the onset of the infection.

The most widely quoted figures on the time of onset of cutaneous and mucosal relapse are based on the transmission of syphilis in marriage in the prearsphenamine era. Fournier found that 84 per cent of women were infected in the first three years of their husbands' disease, and 66 per cent within the first year. Tschestjakow from Tarnowski' clinic, is quoted as finding 80 per cent of relapse within five years in 1000 patients· 16.7 per cent within the fifth to the tenth years; 2.8 per cent in the tenth to the fifteenth years; and 0.5 per cent in the fifteenth to the twentieth years. Gennerich, in 1914 in 30 patients receiving so-called abortive cures, noted 5 relapses within one year and regarded 5 additional cases as reinfections. Gennerich and Zimmern, in reporting long series of reinfections, observed monorecidives or relapses of the chancre as early as thirty-one days after the seventh injection of arsphenamines. Gennerich also found in 30 patients with early secondary syphilis, 40 per cent had recurrence of the disease in from one and one-half

t three years. Hudelo and Rabut noted in their series of 51 monorecidives that 63 per cent appeared within the first year and from that point on the percentage occurring in successive years fell from 20 in the second year to 2 per cent (1 case) in the sixth and seventh years respectively Caesar observed a monorecidive three years after the first chancre which, while not in the same site, was in the same lymphatic drainage. The most delayed monorecidive in our experience was recurrence on the finger five years after primary lesion in that site, followed by the development of an ulcerative sore throat five weeks later

Various forms of relapse of the secondary eruption have been observed at varying intervals. Saenz reported maculopapular eruption with a monorecidive or recurrence of the chancre three months after the original primary lesion, following 6 injections of neoarsphenamine and 6 of an arsenic and mercury preparation. Barbacci observed recurrent roseola seven months after 12 injections of neoarsphenamine. W have observed delayed or recurrent secondaries from four months to four years after suspension of treatment begun in either the primary or the secondary stage. Infectious recurrences in the mouth have appeared in our experience as lat as eleven years after infection, and Nielsen reported finding *Spirochaeta pallida* in what appeared to be recurrent lesions nine years after infection. Pariser (1930) found six cases of infectious relapse occurring two and a half or more years after onset of infection among 120 cases encountered in our University of Pennsylvania Clinic from July 1, 1937 to December 31 1938. One of the six had relapse ten years and nine months after the infection was first discovered and another had a recurrence of infectious lesions six years and four months after her original infection. There was no evidence of reinfection in either case. Kern (1941) observed seven relapses in cases, adequately treated, *from three to eight years after infection among 81 patients with infectious relapse at*

From Felix Pinkus, Urol. & Cutan. Rev 1912.

the Vanderbilt University Hospital Clinic One-third of his cases relapsed less than six months after the last treatment, two-third relapsed ithin one year after cessation of treatment, and only 17 per cent relapsed more tha t years after treatment. Pinkus (1912) found 2 per cent of 2,856 Berlin women had infectious lesions (containing spirochetes) ten or more years after thei infections. (Fig 410.) The percentage rose t 4 if one considered only the period seven years after infection.

The American figures of Moore and Kemp compare very closely with our own t the time of relapse in cutaneous and mucosal lesion in early syphilis. These uthors, in 85 cases (our series 56 cases) found that the erage lapse from treatment was 8 1 months (University of Pennsylvania *series 8.5 months*) W *observed t recurrences in the second month. They found* comparatively few before the third month.

In our Pennsylvania series 24 per cent relapsed in the first six months after onset of the infection and 31 per cent in the second six months, making total of 55 per cent within the first year of the infection and 93 per cent before the end of the second year of the infection.

Duration of Noninfectiousness.—It would appear from the foregoing figures that noninfectiousness, at least so far as it concerns cutaneous and mucosal relapses, has an expected duration in perhaps the first year of the disease of from one to two months after cessati n of treatment. No such figures, of course, can be absolute for we have in our series a patient whose chancre during a two-weeks lapse from treatment after seven injections of bismuth arsphenamine sulphonate, recovered its trde and grew mightily

The great danger of infectiousness from relapse falls in the first two years, and modern treatment has not apparently modified this established dictum materially for those patients who receive too little of it or who, for reasons not as yet apparent, are predisposed to relapse. The "safety period" after a trivalent arsenical then, if such exists at all, is perhaps one to two months and

Fig. 411.

RECURRENCE OF MEATAL CHANCRE (MONORECIDIVE) ONE MONTH AFTER ONE ARSPHENAMIN INJECTION

Male, aged forty-one married, miner

The lesion consists of an induration about the meatus slightly raised and superficially eroded. Marked inguinal adenitis.

The patient gave a history of a primary lesion developing nine or ten days post coitu at the site of the present recurrence. His physician made a darkfield diagnosis, told him he had syphilis, instructed him in regard to treatment, and gave him his first arsphenamin injection. The lesion immediately cleared up and the patient did not report for further treatment.

One month later the lesion reappeared, and the patient, in a panic, came to the clinic.

There were no signs of secondaries. The Wassermann reaction was *negative* and has always remained so during three years of observation and treatment.

By darkfield examination a few spirochetes were demonstrable in the recurrent chancre. Enormous numbers of exceedingly active organisms were obtained by glandular aspiration, from the inguinal bubo.

Discussion.—There is no intrinsic reason why a syphilis incompletely aborted should not start over again from the beginning, or repeat any individual stage or succession of stages.

The darkfield examination of infectious relapses is often more valuable than the Wassermann test in making or confirming the diagnosis. Note that this patient has never had a positive Wassermann reaction and that aspiration of the glands eliminates saprophytic spirochetes, so that the patient had an undoubted early relapsing syphilis.

is not to be relied on when as in marriage, an infected partner may desire to resume unprotected intercourse or habitual intimate contacts during rest periods, either as a matter of preference or with conception in view

The Forms of Mucocutaneous Relapse.—The recurrence of the chancre in situ, called a "monorecidive" (Fig 411) is the simplest and usually the earliest form of relapse It is often spoken of loosely as "chancre redux," a

term which is undesirable because of the ease with which it is confused with the pseudochancre redux, the long-familiar term for the gummatous recurrence at the site of a primary lesion many years before. The monorecidive or recurrent chancre may ape in every particular the primary lesion of the disease. It may be accompanied or followed by a revival of the satellite adenopathy and it should contain *Spirochaeta pallida* demonstrable by dark field if it is to be completely differentiated from pseudochancre redux. A local reaction at the site of the chancre without the actual complete recrudescence of the lesion may accompany the recrudescence of secondary manifestations of the disease. The ease of confusion of the monorecidive with the chancre of reinfection is attested by the practically universal acceptance of the criterion, and a reinfection to be credited as such must not occur in the site of or in the lymphatic drainage of the original primary lesion.

Fig. 412.—Mucous Membrane Recurrences in Spite of Treatment. Beginning Leukoplakia.

A, Active mucous patch near left labial commissure. This is common site for such lesions.
B, An involuting mucous patch of the lip in the same patient entirely concealed until the lip is everted. A faint, silvery leukoplakia is developing about the lesion. The patient own fingers are controlling the lip, which should not be touched by an examiner with ungloved hands.

The chancriform solitary indurated papule or giant papule mentioned in the reports of Gennerich and Zimmern, Hell, Hudelo and Rabut, and Balzer is a papular recurrent lesion entirely outside the zone of primary involvement, and in many cases, at least, to be interpreted, we believe, as a lesion of the secondary stage, even though its appearance is identical with that of the primary lesion. Balzer includes the chancriform papule with the monorecidive under the term of pseudoreinfection and this term is adopted in Bernard's summary of the subject of reinfection.

Secondary recurrences which either chronologically or morphologically mimic the lesions of the early secondary stage in the normal evolution of the disease, form the next group of relapse lesions. They are rarely confused with the lesions of reinfection except in those cases in which the size and erosion of a single papule in an appropriate site give the impression of a chancre with its ensuing secondaries. The fact that such a papule may not be erosive and hence may give the impression of a late and partially healed primary lesion

Fig. 413.—An eroded mucous patch on the under surface of the upper lip in a patient with an unrecognized and untreated syphilitic infection. The patient spat spirochetes while a submucous resection was performed before the lesion was recognized. The postoperative blood Wassermann reaction was strongly positive.

A B

Fig. 414.—Scrotal mucous patches and papular syphilid of the sole of the foot three years after infection in a "supposedly cured" case.

The chancre was apparently diagnosed by inspection without darkfield or Wassermann test and the patient was given 10 arsphenamine injections with complete involution of lesions.

First Relapse.—Scrotal recurrences four months later. Wassermann positive, spinal fluid not examined. Lesions disappeared under another course of 10 arsphenamine injections, 5 intramuscular mercurial injections, and 20 inunctions.

Second Relapse.—A year later the second relapse occurred and he was given 5 neoarsphenamine injections at five-day intervals.

Third Relapse.—Four months later an eruption appeared on the scrotum and soles of the feet, accompanied by sore throat. At this time the patient asserts that his physician told him it was impossible for him to have syphilis because he had been adequately treated for it.

This eruption and the mucous lesions were seen in the clinic three months later. At that time he had mucous patches at the upper poles of both tonsils; the lesions shown in the photographs; mucous patches on the scrotum from one of which *Spirochaeta pallida* was recovered (A); a strongly positive blood Wassermann reaction, and a spinal fluid with a strongly positive Wassermann reaction 0.2 and 1 cc., positive Nonne and 6 lymphocytes, colloidal test negative.

The discovery of this infectious relapse is to be credited to the follow-up system. This is the typical course of the mucous relapser. No physician need feel any hesitation in diagnosing syphilitic recurrences merely because the patient has had prolonged and energetic treatment. Part of the eruption on the sole is trichophytic (organism found in vesicle top). The syphilitic part vanished under treatment.

with active secondaries, increases the possibilities of confusion. Secondary recurrences appear as mucous erosions or patches (Figs. 412, 413 414) as

Fig. 415.—An illustration of the triviality of cutaneous recurrences.

Fig. 416.—Scattered annular lesions in relapse following 30 neoarsphenamine injections and several courses of mercury salicylate injections. The patient had been discharged as cured. The relapse developed within thirty days. There as no evidence of reinfection.

moist papules and condylomas as dry papules in erodable sites (Fig 417) as macular papular (Figs. 415 416 417 418 419 420) annular (Figs. 418 419 420) pustular grouped follicular and corymbose lesions (Fig 421) and as

alopecia. The later recurrent secondary lesions tend toward destructive characteristics, though destructive characteristics may be likewise the result of a premature allergy induced by *insufficient treatment (Fig 423) It is,* of course, conceivable that any of these groups of lesions may be expressions of a superinfection without primary manifestations, a possibility still theoretical for man.

In addition to the monorecidive, the chancriform papule and the secondary recurrence, it is possible to include in discussion of relapse the so-called delayed generalized secondary manifestations, which include the appearance from

Fig. 417—Dry Papule of the Penis—A Potentially Infectious Recurrence.

The mucous surface of this papule was the thinnest imaginable without actual erosion. The lesion was associated with similar recurrences of the scrotum (Fig. 416) and mucous lesions in the mouth.

The primary infection in this case occurred in November, 1918, although he gave history of supposed syphilitic infection sixteen years ago.

At the time of his first appearance in the clinic he had tremendous outburst of mucous lesions, papular secondary lesions, and apparently precocious gumma of the nasal septum as relapse following 6 arsphenamine injections and mercury by mouth. He responded promptly to another 6 arsphenamine injections and then disappeared from observation. Nine months later he took 3 more injections and again disappeared. Six months after his second disappearance he returned with the scrotal recurrences here illustrated, and with mucous lesions in the mouth. During his lapses in treatment he had evidently had repeated herpetic and moist lesions and had developed syphilitic laryngitis with an ulcer of the false cords.

This is the typical course of an infectious relapsing type of case. It is particularly alarming and serious defect in the inadequate treatment methods so often applied to early syphilis, that the symptomatic response is so striking that the patient as ell as the physician is entirely thrown off guard, and the patient sometimes sustains an almost indefinite prolongation of his infectious recurrent period t the grave danger of the public. Only systematic examination will disclose lesions of this sort. They are practically symptomless.

a clear sky in a previously treated and apparently latent or "cured" case, of the extensive outburst of secondary manifestations which should have formed part of the clinical picture or progression of the disease months or years before. Delayed secondaries are, then, essentially a subdivision of secondary relapse, in which the first crop of secondary lesions failed to appear They may be regarded in a sense as lesions of progression in spite of treatment, rather than of relapse. This brings out the fundamental essential of any working definition of cutaneous and mucosal relapse, which is *an appearance or reappearance of lesions after treatment has been suspended* Without previous treatment, relapse

for the purposes of general definition does not exist all other lesions being regarded as progression

Fig 418.—The Annular Scrotal Recurrence.

This is classical picture of type of recurrence relatively unfamiliar because of the omission of routine inspection of the surface of the scrotum in many examinations. When dry the lesion is fleshy with little or no scale. The appearance of scale in the photograph is due to wrinkling of the shiny slightly indurated border This is the same patient described in connection with Fig. 417 The Wassermann reaction t this time was positive. The possibility of annular lichen planus and annular psoriasis should not be overlooked in differential diagnosis in the presence of negative Wassermann reaction.

A B

Fig 419 —T see an annular recurrence on the scrotum, it is necessary t *put the skin on stretch*. This patient was treated by an army technic pparently told he wa cured, married, and infected his wife.

Fig. 420.—Apparently typical annular recurrences on the shaft of the penis. They are typical lesions of lichen planus, however and not of syphilis. There were lesions elsewhere, including the mouth. (See Fig. [illegible].)

Fig. 421.—The most disconcerting relapse in our experience. It came on in the midst of course of injections, after the patient had had four courses totalling 26 arsphenamine (606) injections, with no rest intervals and with alternating courses of injections. The blood Wassermann reaction was negative until the relapse occurred.

evidence of infectious relapse, direct his search? The sites on which mucocutaneous relapse lesions may be expected to appear are presented in Figs. 424–426 from the study by Stokes, Besancon and Schoch and in Fig. 427

Fig. 422.—Two successive relapses in the same patient following neglect of treatment. The first took the form of neurorecurrence ith hemiplegia. The second was a cutaneous relapse of an indurated papular type. Both occurred within the first eighteen months. Reinfection excluded.

Fig. 423.—This patient infection was of nine months duration. When his chancre was one week old he had received single dose of neoarsphenamine, and the lesion disappeared. Nothing further was done

Three months later the throat swelled and became so sore he could not eat. The physician, apparently not recognizing the condition, treated it locally for several weeks, and then gave him 3 injections of neoarsphenamine following which his throat cleared up.

Another four months now passed without incident. Then red spots and lumps developed on his arms, legs, and scalp These became crusted ulcers and the enormous gumma shown above developed over the tibia.

This patient result of inadequat treatment had advanced as far in the course of his infection in nine months he might be expected to in nine years. His condition had become so refractory that t was only ith difficulty that response could be secured with arsphenamine and mercury This patient as seen before the days of bismuth

Th blood Wassermann re ction was repeatedly negative.

Several types of relapse lesion are likely to be present in any given case. Sixty-one per cent of the relapse lesions observed by us were infectious, or

disease. It should be borne in mind that these high figures were not the result of case selection but represent the typical situation in practice. Morphologically speaking, the mucous patch is the most important relapse lesion numerically. Condylomas and moist papules combined form the second largest

category Dry papules in erodable sites were largely penile in location. Nearly half the annual lesions occurred on the genitalia and this *ipso facto* should render annular lesions on the genitalia open to suspicion. Monorecidives or recurrences of the chancre and chancriform papule formed 13 per cent of the infectious recurrences. The anogenital region is the exclusive site of relapse

Fig 427

REGIONAL DISTRIBUTION OF THE COMMONER RECURRENCES ON THE SKIN AND MUCOUS MEMBRANES

Scalp.—Recurrent moth-eaten alopecia. Papular and pustular or even rupial recurrences at the hair margin. Circinat and gyrat groups of small ulcers suggesting acne necrotica, but with a configuration and arrangement that can only be recognized on clipping the hair Psoriasiform syphilids resembling psoriasis and seborrheic dermatitis of the scalp.

Face.—Thinning of the eyebrows, usually outer third. Rosaceiform papular lesions of the nose Hypertrophic nodular lesions suggesting lupus vulgaris. Mottled chin, a maculopapular syphilid of the secondary type. Annular recurrences about the chin, cheeks, and forehead. Fissure at the nares.

Lips, Mouth, Tongue, Pharynx.—Mucous patches, especially on the lip, t the commissures, etc. (see "Summary of Infectious Lesions) Deeper erosions along the margin of the tongue Papular recurrences on the dorsum of the tongue often denuded of papillae but not eroded. Late recurrences suggesting unusually destructive mucous lesions, usually several in a group, with a suggestion of arciform configuration. Lingual fissure Diffuse pharyngitis. Laryngitis, both simple and erosive with lesions on cords and epiglottis and varying degrees of hoarseness and phonia.

Neck.—Leukoderma colli, a mottled or macular depigmentation on a background of hyperpigmentation. This is the "pigmentary syphilid." It may occur on back, thorax, abdomen, or arms. It may be associated with the macular trophic secondary syphilid. Visible adenopathy can sometimes be made out in the neck.

Thorax and Back.—Mucous patches, moist papules and small condylomas under the breasts and in the axillae. Macular papular follicular corymbose and rupial relapses and recurrences. Pustular recurrences unusual Grouped follicular (large) papules and their scars. Extensive circinat gyrate urticarial and erythema multiforme-like lesions. Psoriasiform annular and gyrat recurrences. Atrophic macular syphilid, leukoderma. Disseminate late nodular lesions.

Abdomen.—Same as thorax. In addition, pudendal alopecia (especially women) and moist lesions t the umbilicus and in the groins.

Anus and Genitalia.—Relapse or recurrence of the chancre Dorsal lymphangitis of the penis, pipe-stem. Mucous patches, erosions, moist papules. The papular annular and erosive scrotal recurrences on both anterior and posterior surfaces. "Dry papule of the penis. Condyloma latum, especially with macular and papular eruptions and recurrences. Psoriasiform recurrences. "Syphilitic herpes progenitalis.

Palms and Soles.—P pular psoriasiform recurrences. Papular varioliform recurrences. "Eczematoid syphilid with indurated border and atrophic center Annular syphilid of the palms. Hyperkeratotic papular syphilid (syphilis cornée) Arciform and gyrat papular configurations of the type of lat syphilids. Verrucous syphilid. Moist papules and condylomatous lesions between the toes.

Nails.—Syphilitic onychia and paronychia. Symmetric spade nails.

Extremities.—Papular recurrences, flexor surfaces of forearms and wrists. Grouped follicular recurrences, extensor surfaces of forearms. Psoriasiform recurrences papular annular and gyrate Occasionally pigmentary residua. Syphilitic erythema nodosum.

lesions in 41 per cent of patients, the mouth alone in 17 % and of the anogenital lesions, 75 per cent occur on the penis or vulva the ideal sites for dissemination of the disease. That a large proportion of initial infections may occur on the genitalia may conceivably mean that the tissues in the regions of primary inoculation carry an appreciably higher spirochetal population, much as does the skin in the case of staphylococci about a boil. It may point

conceivably to an elective localization of the organism in this region of the body quite as much as to the effect of external conditions such as moisture dirt, and friction commonly accepted as chiefly influential in relapse by earlier observers. Half the lesions in the Pennsylvania series were infectious at the time of first observation Physical examination with special emphasis on inspection of the lip, penis, scrotum, and vulva, and not the blood serologic reaction is, therefore the chief method for the detection of infectiousness.

Darkfield and Serological Findings in Mucocutaneous Relapse.—*Spirochaeta pallida* is found by darkfield examination in mucocutaneous relapse with approximately the same frequency as it is in early primary syphilis, namely from 70 to 80 per cent of lesions (75 per cent

Fig. 428.

DARKFIELD DIAGNOSIS OF A MUCOUS RECURRENCE EIGHT DAYS AFTER THE HEALING OF AN ABORTED PRIMARY LESION

Young woman whose husband exposed her to infection while he was in florid secondaries.
Noted lesion on right labium minus.
Told by physician that husband had syphilis.
No darkfield, no Wassermann.
Physician gave her 2 intramuscular injections of what seems to have been soluble mercurial salt.
Patient left for Rochester at once.
Indurated Papule Left Labium Involuting on Arrival.
Darkfield Negative 3 examinations day for six days.
Wassermann every other day negative.
Primary lesion healed by seventh day Depressed scar
Eight days later although still Wassermann negative, patient reported new lesion on the labium.
Darkfield Positive. Many typical *Spirochete pallida*.
The lesion was some distance from the healed primary and was apparently either monorecidive or mucous patch.
Treatment Was Begun at Once.

DISCUSSION

1. Granted that the physician in charge of this case did not have the co-operation from the patient that he should, he was none the less culpable in that he had not sterilized the husband with arsphenamin at once when he knew him to be infected and infectious

2. He began treatment of the wife without an adequate diagnosis. No darkfield examination.

3. His treatment was ineffective. In such cases arsphenamin must be begun at once, and bismuth in whatever form should follow it.

4. Was the husband the source of the wife infection? Not necessarily The woman primary lesion may have been merely an indurated recurrence of latent infection (previous marriage or other exposure) The promptness with which new mucous lesion followed the supposed primary suggests this. The negative Wassermann is somewhat against it. A latent infection producing recurrences might be Wassermann negative or be reversed to negative by the amount of treatment this patient received. The husband is, therefore, probably the source of the wife infection.

of Kern cases). In the Pennsylvania series the blood serological reactions were positive in 86.8 per cent; in the Cooperative Clinical Group series in 81 per cent. In spite of this high proportion of positive serological reactions emphasis should be placed on seronegative relapse as something which definitely can occur (see Fig. 428). Pautrier, in 1930, cited twelve authors who had reported on seronegative, darkfield-negative cutaneous and mucosal relapse, and adds 1 case of the same type as a genuine rarity from his own experience. The seronegative monorecidive has been reported by Hudelo and Rabut, who in a series of 54 monorecidives, found 21 to be seronegative. In our 7 cases in the Pennsylvania series, 1 was seronegative but positive to darkfield examination, and 4 of 7 monorecidives were darkfield positive.

The Relapsing Type of Secondary Syphilis—Delayed Secondaries.—The question as to whether there exists a definite relapsing type of early

syphilis, so far as mucocutaneous lesions are concerned can probably be answered in the affirmative The patient who is prone to develop relapse lesions may exhibit recurrent secondaries appearing from one to two years after the primary lesion (Fig. 430) with or without treatment in the early secondary stage, *cf* Pariser (1939) This group was distinctly recognizable in the Cooperative Clinical investigation and included 121 patients who had developed recurrent secondary lesions after the first year of the disease. Of

this number 17 per cent had had a previous crop of secondaries which had failed to confer immunity These patients likewise exhibited an increased tendency to serological relapse, amounting to 20 per cent as compared with 12 per cent in seronegative primary syphilis.

In practice every patient who has passed through the normal secondary incubation period of six weeks to two months since the appearance of his primary lesion without showing any signs of secondary eruption deserves watching from the standpoint *of a possible delayed secondary* and chronic

relapsing type Particularly if he is a user of alcohol, in our experience he may prove to be an inveterate recidivist, developing showers of infectious lesions without warning over a period of a number of years, and this in spite of what appears to be thoroughgoing treatment

CSF negative.

1 This patient, observed carefully for four more years, has shown no further tendency to relapse following 12 more injections of arsphenamin, [illegible] additional injections, 23 Hg. succinimid injections, and 317 gm. sodium iodid intravenously
2. This was a typical example of repressed secondaries.

Fig 431 —A corymbose papular relapse after 14 injections of neoarsphenamine, without mercury The original secondary eruption was macular The patient husband had also had macular eruption, diagnosed "heat rash, and finally recognized as syphilid when he insisted on having blood test, after hearing public lecture by health officer on the subject of venereal disease.

The Transition from Recurrent to Late Syphilids.—The earlier in the course of a syphilitic infection a relapse occurs, the more closely the lesions

correspond to those of the secondary period, both in individual characteristics and in their wide distribution. With the passage of time in the course of the disease these recurrences tend to assume more and more the characteristics of late syphilids in that they are fewer in number and more destructive in character. Thus one sees extraordinary combinations in relapse including showers of nodular infiltrative and destructive lesions widely distributed over the body and even involving the mucous membranes, each individual lesion or group of lesions having distinctly gummatous and late syphilitic characteristics. Recurrences of this type were accepted parts of the course of

FIG. 432.—THERAPEUTICALLY RESISTANT SYPHILIS.

This patient presented a seronegative darkfield positive penile chancre, January 23, 1931. On February 20, 1931, after 6 injections of arsphenamine (606), total of 2.3 Gm., the penile lesion was still present and the BWR negative.

The arsphenamine was continued at weekly intervals, and on March 13, 1931, it was noted that the patient had developed several psoriasiform papules on the right leg which were darkfield positive. These lesions resisted treatment with neoarsphenamine twice weekly until April 13, 1931, when the patient was placed on intramuscular injections of boiled milk with subsequent rapid involution of the lesions.

Total treatment from January 23, 1931, to April 13, 1931, consisted of 9 injections "606," total of 3.5 Gm., 4 injections of tartroquiniobine, total of 8 cc., and 4 neoarsphenamine injections, total of 2.4 Gm. The blood serological tests were always negative. Patient was continued on combined therapy until May 29, 1931, when he was lost sight of.

a syphilitic infection in the old mercurial days and it is only the comparatively symptomless course of the disease under modern treatment which makes them objects of astonishment and admiration for us. In Figs. 416, 421, 433, 434 lesions of this type are illustrated.

The so-called neurosyphilid of Unna, or circinate roseola, is a comparatively rare lesion which for the most part appears as a recurrence, often years after initial infection, and even at times in association with late nodulo-ulcerative syphilids. This type of roseola is usually situated upon the trunk or extremities in the form of distinct or imperfect erythematous or erythematopapular rings, at times concentric with a tendency toward gyrate configuration. Combes (1930) reported a case and reviewed the literature. Hall and Schaerrer (1934) observed the neurosyphilid

of Unna in patient with congenital syphilis and considered it as an abortive type of late granulomatous cutaneous syphilis.

Effect of Inadequate Treatment on Recurrences—Precocious Tertiarism. —It is essential to recall that the chronology of syphilis with respect to early and late manifestations, can be sharply disturbed by improperly conducted treatment. The allergy or "*Umstimmung*" induced by inadequate treatment, especially with the trivalent arsenicals, has been discussed from the immunological standpoint in Chapter I. *Its clinical manifestations are illustrated in* such lesions as that of Fig 423 in which the patient is advanced to the stage of late gummatous and highly destructive manifestations profoundly resistant

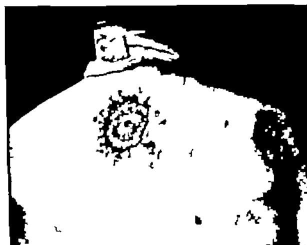

Fig 439.—An example of the type of recurrence which assumes late destructive characteristics as result of the allergy that follows inadequate treatment. The lesions approach the corymbose type.

The patient stated that she had default primary lesion, and that when her secondary eruption appeared in May 1919 her physician had given her one injection of arsphenamine and told her that nothing further would be necessary because one dose would cure.

Her first cutaneous relapse occurred six months later in the form of disseminated eruption. The Wassermann reaction on the blood being positive, she received second arsphenamine injection, and the eruption disappeared.

Her second recurrence followed, year later as shown bove. There were ulcerative lesions of late type in the larynx in addition to the skin lesions. The blood Wassermann reaction was positive, the spinal fluid negative. She had not at any time received mercury That she was not arsenic fast was evidenced by prompt response to intensive treatment.

The blood Wassermann reaction in such patients may be negative.

to treatment, through the simple but disconcerting intermediation of an insufficient amount of an arsenical Aside from the fact that the arsenicals in sufficient amounts are chief effective agents for the control of infectiousness, the risk of inducing precocious tertiarism furnishes of itself an additional reason why arsenical treatment in early syphilis should always be adequate.

Causes and Prevention of Infectious Relapse.—The causes and prevention of mucocutaneous recurrence are discussed in connection with the treatment of early syphilis. (See also Fig 438.)

Serological Relapse —*In the subsequent chapter on the treatment of* early syphilis serological relapse is dealt with incidentally to the consideration

of the serological effects of treatment, but the following brief summary orients the subject for the relapse problem in general. Serological relapse, by which is meant the recurrence of a positive blood serological reaction following suspension of treatment in a patient who had become seronegative, occurs with approximately the same frequency as mucocutaneous relapse (15 1 per cent) Its frequency of occurrence as influenced by the time at which treatment for syphilis is begun, is in interesting contrast to the course pursued by mucocutaneous relapse While mucocutaneous relapse decreases in frequency when treatment is begun after the seropositive primary stage, serological relapse increases slightly in frequency the later treatment is begun In this particular serological relapse then parallels the behavior of neurosyphilis and cardiovascular syphilis, both of which are but little affected or slightly decreased in frequency when treatment is begun in the seronegative primary instead of the secondary stage There is a close correlation between

Fig. 434 —Cutaneous recurrence within year after 9 neoarsphenamine injections The patient syphilis had been identified in Wassermann follow up, apparently for he had had no recognizable chancre or secondaries, though another man exposed under the same circumstances at the same time developed typical infection.

the behavior of the serological reaction and the occurrence of clinical forms of relapse Moore and Kemp showed that the patient who underwent serological reversal very early in the course of treatment for his infection had a demonstrably low resistance to the disease and a tendency to serological relapse. On the other hand, persistent refusal of the serological reaction to reverse under effective treatment is a warning of a relapsing tendency In patients who become serologically negative in the first year of treatment, the likelihood of relapse is represented by 10 1 per cent, as contrasted with 33 per cent in those who require longer than a year to become serologically negative or who become Wassermann fast. Serological resistiveness is, moreover a definite warning of early relapse of the secondary type, either mucocutaneous or ocular in character for there were 25.5 per cent of such relapses among 1292 patients of the Cooperative Clinical Group who were serologically resistant, as compared with 5 per cent of 1902 patients with a more satisfactory

Wassermann response. This same difference is apparent, though much less marked, for central nervous system relapse, which occurred in 30.6 per cent of patients with markedly delayed serological reversal as compared with 18.3 per cent of those who had a more favorable course. A similar tendency is apparent in other forms of late syphilis (2 per cent as compared with 0.7 per cent). Taken in the aggregate the total relapses of patients always seronegative or reversed to negative within the first year was only 22.5 per cent as compared with 48.1 per cent in patients whose serological tests showed delayed reversal. The importance from the standpoint of treatment and cure of the weak positive serological test appearing in a series of negatives during the treatment of early syphilis is presented on page 672.

Relapse Lesions in Bones.—The course of relapse as it affects bony structures is probably similar to that in the skin. The earlier lesions, while they produce local edema and inflammatory changes in the periosteum with swelling and points of exquisite tenderness, do not at first give rise to deposition of new bone with the production of permanent thickening. Similarly gummatous osteomyelitic processes do not appear until comparatively late except in cases undergoing the changes of precocious tertiarism.

A physician, age thirty-three, illustrated all the critical aspects of relapse causation and therapy. A chancre and secondaries, self-treated by successive irregular courses of sulpharsphenamine and casual mercurial treatment by mouth, was complicated by an agranulocytosis which he survived. Following this, wholesale necrosis and slough of the nasal and palatine bones appeared as a precocious tertiary type of relapse, controlled by boiled milk and bismuth injections, but relapsing and extending when treatment was stopped because of reactions (fever nitritoids). Malarial inoculation suggested, was deferred until a fulminating progression of the process had removed the entire interior of the nose, opened the accessory sinuses and involved the floor of the skull. Malaria when induced, had to be terminated because of a nearly fatal recurrence of the agranulocytosis. It had been carried far enough however so that recovery began and was continued, under mercurial inunctions, bismuth, intravenous iodide and conservative local treatment of the nasal cavity. A morphinism was nipped in the bud, and despite the extent of the internal destruction, the patient's appearance was but little changed. His spinal fluid was normal.

In all probability the comparative nonrecognition of bone recurrences is the result of the fact that the osseous system is largely covered by softer tissues and concealed both from the eye and other forms of observation. Lacking destructive character therefore, the early lesions largely escape detection, the symptomatic discomfort which they produce being lost in the general complex of rheumatoid symptoms associated with the early years of the disease. Bone and joint relapses have no particularly distinctive features and are sufficiently summarized in the general consideration of syphilis of the skeletal system (Chapter XVI).

Eye Lesions.—The commonest lesion of relapse or progression involving the eye is iritis, which is considered on page 604. Neurorecurrences involving the eye and particularly the second, third and fourth nerves, are identical with neurorecurrence in general and with the ocular symptoms of basilar meningitis as presented in Fig. 404 and in the chapter on neurosyphilis.

Birth of a Syphilitic Child as Relapse.—The problem presented by the syphilitic pregnant woman is considered in connection with the immunology of the disease (p. 31), the collateral factors of treatment (p. 447) and prenatal and familial syphilis (p. 1148). It should none the less be emphasized here that the situation presented in Fig. 435 is by no means an impossible or even

an excessively rare one. It is impossible absolutely to insure the noninfectiousness of a syphilitic mother with respect to her child and even thoroughgoing treatment before or during pregnancy is not an infallible protection. Figure 349 in Chapter XXI presents a child with a mild but incontestable prenatal syphilitic infection acquired from the mother while the mother herself was supposedly under adequate treatment with neoarsphenamine and bismuth

Fig. 435 (Continued)

EXTRAGENITAL CHANCRE (LIP). MISDIAGNOSED BECAUSE OF EARLY NEGATIVE WASSERMANN SUBSEQUENT SECONDARIES WITH POSITIVE DARKFIELD AND POSITIVE WASSERMANN. SPINAL FLUID SLIGHTLY ABNORMAL TWO YEARS AFTER INFECTION. REDUCED TO NEGATIVE BY TREATMENT. GIVEN PERMISSION TO MARRY AFTER THREE YEARS. FIRST CHILD HEREDOSYPHILITIC. SUBSEQUENT TOTAL RELAPSE IN NERVOUS SYSTEM AND BLOOD AFTER FULL COURSE OF TREATMENT

Woman, aged twenty-six, examined 10/2/16.

Chief Complaint: Gland in neck and sore lip. T months duration. Sexual exposure admitted. No kissing within one month.

Examination Indurated, crusted, partly healed ulcer left lower lip. Swollen submaxillary node. Blood Wassermann reaction negative. Consultant advice "Has had some kind of medication internally Wait t weeks and repeat Wassermann. No darkfield taken.

Re-examination 9/10/17 returns with the chief complaint of epigastric pain and vomiting. Sharp hunger pains. Ulcer on lip replaced by large mucous patches. Gland still present. Darkfield showed *Spirocheta pallida*. Blood Wassermann reaction positive.

This patient summarizes all of the problems and difficulties presented by the diagnosis and treatment of early syphilis t the present day as follow

1 Her primary lesion on the lip was not diagnosed because of overdependence on the negative blood Wassermann examination and failure to make darkfield examination.

2. She was permitted to go on to mucous membrane secondaries, the blood Wassermann becoming positive but no secondary eruption developing on the skin.

3. In conjunction with her secondary manifestations she exhibited probable acute syphilitic gastritis which cleared up under treatment.

4. When her condition was finally recognized by darkfield and blood Wassermann in the fully developed secondary period, she was placed on what might properly be regarded as intensive modern treatment. The first two courses ere given with sufficient dosage, proper intervals, and proper interim mercurialization. The patient then broke treatment for several months.

5. Spinal fluid examinations were not routine part of the treatment of early syphilis in this department until 1918. Accordingly no examination of the spinal fluid was made until after the second course of treatment.

6. The fluctuating blood W ssermann reaction, however strongly positive once during the second course of treatment, warned us that this infection was not completely under control. A spinal fluid examination tw and half years after infection showed negative Wassermann and globulin, but *pleocytosis of 11 cells*. At that time we were just beginning to realize that even very slight rise of cell count, while not significant in itself in patient ith early syphilis may be warning of involvement of the nervous system and the precursor of serious neurorecurrence.

7 The patient therefore consented to resume treatment, and 9 more arsphenamin injections reduced the spinal fluid almost t normal. A weak positive blood W ssermann reaction, however gain roused us that the disease was not completely extinguished, and still more treatment as given.

8. The patient was not given permission to marry until four and half years after infection, when her spinal fluid was completely negative nd her blood Wassermann reaction had been negative continuously for one year (five tests).

9 In spite of these precautions she gave birth to heredosyphilitic child more than five years after her infection, and one year and six months after all clinical and serologic signs of the disease had disappeared.

10 Her blood Wassermann reaction as negative during her pregnancy

11. The test became eakly positi three months after the birth of the child, and was negative twice during the following fourteen months, but she did not pursue treatment.

12. Her asymptomatic neurorecurrence was heralded by weakly positive blood Wassermann which subsequently became strongly positive. A more or less routine examination of the spinal fluid was the only thing hich detected the final serious involvement of her nervous system seven years after the onset of her infection.

Fig. 436.—Spinal fluid record of   patient seen in the primary stage, normal at the outset, with   neurorecurrence (asymptomatic) after repeatedly normal fluid findings. Warning of relapse in the form of slight rise in cell count. Controlled by sodium iodide and mercury succinimide, but the use of the iodide produced toxic symptoms in   thyroid adenoma, and thyroidectomy was necessary. Death later from encephalitis (lethargic or syphilitic?) No spirochetes found in any tissue.

The general bearings of this question are given on page 1115 (prenatal syphilis chapter)

REINFECTION

Frequency of Reinfection.—*Reinfection is a comparatively rare event* in the course of syphilis today In the University of Pennsylvania series, reinfection occurred not oftener than 4 times in 2439 cases, or once in 609 cases. White reported 1 in 375 cases Driver 1 in 384 cases Cederkreutz, 1 in 1580, and Bernard, 1 in 600 Reinfection occurred in our series once in 228 cases, in comparison with the frequency of primary and secondary syphilis. Moore and Kemp gave a frequency of approximately 1 in 131 cases of primary and secondary syphilis. From the practical standpoint *it is difficult to imagine* that the incidence of subsequent exposure of persons with syphilis to risk of reinfection falls to as low a figure as 1 in 710 cases, which is the average of the foregoing figures for frequency of reinfection exclusive of those involving only early syphilis. It therefore follows that few exposed persons are reinfected and if reinfection is a criterion of cure, few indeed are cured. So-called "pseudo-reinfection" has been particularly discussed by Belzer Hecht Bernard, Lortat-Jacob Roberti, and Pouneau-Delille.

The Clinical Characteristics of Reinfection.—In Chapter V in discussing reinfection as an evidence of cure the various criteria established by the most extended surveys of this topic were outlined (Fig. 73) It is worth recalling that no reported reinfection up to the date of the review of the subject by Stokes, Schoch, and Ireland, and the Cooperative Clinical Group, had qualified for acceptance under the most stringent code. The reporting of a *valid reinfection is one of the most difficult accomplishments in the syphilological field*, and the larger part of the evidence now in existence for individual cases must rank as presumptive or suggestive rather than conclusive. A very large part of reinfection unquestionably resolves itself into relapse, and a proportion of it into the probable but not yet fully established entity of superinfection. The reports of reinfections in patients treated by intensive systems of therapy have been discussed on page 185

There *is a tendency to dismiss as largely of historic value the clinical* criteria for differentiation between the lesions in a relapse and those of an alleged reinfection (Bernard)

Hudelo and Rabut (1924) viewed the matter more as we believe it must be viewed in this country today that the "explosion of reinfections in the months following the use of '606' and '914 must be viewed as false reinfections—chancriform recidives dependent upon colonies of spirochetes isolated from the circulation by tissue reactions." The same is undoubtedly true for intensive therapy (See Chapter XIV) The negativity of the Wassermann reaction of the blood in such cases has only a relative value, for "it is frequent in the course of secondary relapses." We are therefore compelled to regard as insufficiently critical the second of the two criteria of reinfection accepted as adequate by Halley and Wasserman "After an interval following antisyphilitic treatment and at a site other than that of the primary lesion of the first infection, there must develop a lesion with the characteristics of a chancre in which the spirochetes can be demonstrated." We believe that such lesions occur also in definite categories of relapse.

The monorecidive has already been described as one of the common forms of relapse. Critically speaking, the criterion for differentiating the

chancre of an alleged reinfection, from a mere monorecidive, then, should be an interval of at least a year and preferably two years between the first and second infections (85 per cent of monorecidives fall in the first two years of a syphilitic infection which is identical of course with the general period of relapse) The site should not be identical in the two infections, and should not even be in the same lymphatic drainage. Hecht, however pointed out how little the lymphatic drainage of the genitalia, with its rich anastomoses, may mean for such a criterion In our opinion, the case illustrated in Fig. 437 is an example of the puzzling question of regional distribution of possible relapse foci about the scar of a chancre. The monorecidive like the chancre, should be darkfield-positive, but the organisms, as emphasized by Hell, are *fewer than in the original active chancre, a criterion rendered somewhat* unreliable, however by the relation known to exist between the number of organisms and the age of any primary lesion The chancre in reinfection is

Fig 437 —See case history Fig. 405. The induration in the old scar is visible at A; the lesion from which spirochetes were obtained is posterior at B.

supposed to be seronegative at the onset and later to become seropositive, while the monorecidive, being part of a recurrence, is supposed to be more frequently seropositive at first recognition Hudelo and Rabut, however found 21 seronegative monorecidives in their series of 54 Our experience with relapse in general however indicates that it tends strongly to be seropositive at the onset and that the demonstration that the blood serologic reaction is positive in a supposed reinfection less than a week old is strong evidence in favor of relapse. Occurrence in or close to the site of the original primary lesion within a year of the original infection of a lesion seropositive on first sight, is the strongest evidence albeit subject to exception, for the *identification of a monorecidive The demonstration of Spirochaeta pallida,* or their relative number does not infallibly serve to distinguish the monorecidive from a *bona fide* new chancre.

The chancriform papule an easy source of confusion with the chancre

of a supposed second infection, is a large, solitary papular recurrence in the secondary stage of the disease Its occurrence about the genitalia, where it may become eroded and swarm with *Spirochaeta pallida*, provides the characteristics for confusion. It is a curious fact that of the supposed reinfections we have observed, the best authenticated cases from the standpoint of general criteria have had lesions at least suggestive of typical Hunterian chancres to mark the onset of the second infection. On the other hand among 54 undoubted lesions of relapse studied by Stokes, Besancon and Schoch, they observed 6 typical chancriform lesions as part of relapsing secondary eruptions. Hudelo and Rabut observed 13 examples of isolated chancriform papules on the penis among the 54 monorecidives which they studied.

Figure 437 is an illustration of the difficulty in differentiating apparent reinfections from the standpoint of history from the morphological appearances of mucocutaneous relapse. A group of new primary lesions or chancriform papules may develop about the site of a primary scar sometimes with and sometimes without induration of the scar The difficulty of differentiating such lesions from secondary recurrences is obvious. Hashimoto has reported that in some of his experiments on superinfection multiple small papulo-erosive lesions without the production of a typical secondary chancre are observed. Hecht has pointed out that a similar arrangement about the scar of a chancre can be a feature of secondary recurrence, and he has suggested, furthermore, that the site of the original chancre may be specially susceptible to reinoculation on further exposure.

It must be apparent, then, that exceptional difficulties confront any observer who desires to report an "air-tight" case of reinfection, for the confusion borderline between relapse and the experimental shadowground of superinfection is still too full of uncertainties for absolutely safe pronouncements. In view of the uncertainties attaching to the terminology more and more observers are giving up the use of the term "reinfection" and substituting "second infection" for it.

Progression and Treatment-fastness in Early Syphilis.—When the patient under treatment proceeds to develop or continues to develop lesions of whatever structure the condition is spoken of as progression Obviously treatment-fastness and progression are closely related. Under the heading of drug resistance, various aspects of treatment-fastness have been discussed on pages 146 to 149 Figure 432 is an excellent illustration of treatment fastness in the form of progression of cutaneous lesions in the course of active treatment. The graver forms of progression, however are those which involve particularly the cardiovascular and the nervous systems, and these differ from the manifestations of progression in other structures in that they are comparatively much less influenced both by the mass and the method of treatment. There is about them, and particularly about cardiovascular syphilis, a certain inevitability which emphasizes the fundamental uncertainty of all statements regarding "cure." The material of the Cooperative Clinical Group covering the period from 1910 to 1930 indicated that progression in neurosyphilis, in spite of good arsphenamine and heavy-metal treatment, occurs in approximately 6 to 7 per cent of patients under a time-treatment method of appraisal. Progression of cardiovascular syphilis under similar conditions occurs in 0.8 to 1 1 per cent of cases. Progression under treatment is controllable to some extent by the mass and prolongation of treatment. Even the most thoroughgoing treatment, however does not protect neces-

sarily against the development of abnormalities in the spinal fluid (asymptomatic neurosyphilis) Much treatment prior to the development of the abnormality had been given in 45 6 per cent of 101 cases which subsequently developed abnormal spinal fluids in spite of treatment. The inevitability of cardiovascular involvement in a certain proportion of cases in spite of thoroughgoing treatment, is indicated even more strikingly by the figures 0.9 per cent progression with little treatment and 1.2 per cent with much treat

Fig. 438.

THE PREVENTION AND TREATMENT OF RELAPSE AND PROGRESSION

1 Expect relapse in 5 t 15 per cent of the run of clinic patient with early syphilis (treated by all methods including modern intensive arsenotherapy).
2. Try to forestall and recognize it by:
 (a) Frequent serological tests, taking weak positives seriously
 (b) Thorough, frequent examination of the mucocutaneous surfaces, especially of the mouth, anus and genitalia, palms and soles, within the first two years after treatment is stopped.
 (c) Instruction of the patient as t occurrence and signs.
 (d) Especial vigilance in patients who develop lat or delayed secondary manifestations.
 (e) Especial vigilance in patients whose blood serological reactions reverse t negative immediately after treatment is started.
 (f) Being on guard, especially for explosions of delayed or suppressed secondaries in patients who began treatment as seropositive primary cases or who have been inadequately treated in that stage.
3. Insist on spinal fluid examinations, with one repetition after an initial negative (7.5 per cent may show progression even in spite of treatment)
4 Prolonged treatment
 (a) With the arsenicals beyond the t entieth injection and as near t 40 injections as possible or by an effective intensive foreshortened method.
 (b) With the heavy metals, until at least one year after all signs disappear
 (c) For two years or more beyond the last sign if relapse has once definitely ppeared.
5 Make treatment continuous, not intermittent, "intensive or irregular
6 Vary the drugs used if signs of resistiveness ppear such as:
 ( ) Persistence of spirochetes or lesions beyond a "normal" period.
 (b) Recurring weak positive blood tests in series of negatives.
 ( ) Outright signs of relapse.
7 Turn to "606" if "914 has failed, or use it from the start.
8. Trust arsphenamine-bismuth more than arsphenamine-mercury combinations. But mercury inunctions and intravenous odide may occasionally succeed when As and Bi fail.
9 Employ nonspecific methods early if others fail. Nonspecific protein, malaria, fever chemotherapy are all effective if persisted in.
10. Interdict alcohol. The periodic drinker is an almost inveterat relapser
11 Utilize iodide and the rest period in late recurrences (see Serologic Fastness).
12. Mak no promises bout pregnancy

ment. All other forms of progression however are fortunately considerably more marked under insufficient than under much treatment.

At the risk both of tedious repetition and the forestalling of unconsidered material Fig 438 epitomizes briefly the general principles of prevention of relapse and progression.

It will be seen, then that the control of relapse lies less in the treatment of consequences than in the thoroughgoing attack on the infection at the outset. It is essentially preventive rather than curative No variety of drugs or methods used late can take the place of a powerful arsenical an l bismuth

therapy at the outset, very short or no rest intervals from treatment as a whole repeated courses intelligent reinforcement of the resistance mechanism with mercury bismuth and nonspecific measures complete serological and clinical control—in short, all those things which make up the rationale of effective treatment so far as we know it today The resistant infection and persistent relapser will tax the consultant's ingenuity to the utmost. The patient whose tendency to relapse resists all these measures must bow as to the inevitable. He must wear his infection out or be conquered by it.

CHAPTER XIV

THE TREATMENT OF EARLY, EARLY LATENT AND LATE LATENT SYPHILIS*

Perhaps the best approach to the modern treatment of early syphilis (and this includes early latency and even later latency) is a series of short sharp categorical and hence to some extent disputable statements indicating land marks in the progress of the past thirty-five years. Such a summary is substituted for a narrative type of historical perspective in the present edition of this work. The personalities and the play of thought dominate the summary in the second edition. Reference may be had to it by those desiring such a presentation.

The Mercurial Era.—Syphilis therapy up to 1912, it becomes increasingly apparent, left the disease syphilis to pursue its physiopathologic course comparatively little influenced at least by the milder and hence most popular forms of medication—the therapy *per os* of the widely copied French school. Even mercury intramuscularly except as the water soluble salts, and the violently reaction-producing calomel veneered the surface of a syphilitic infection, rather than attacked its roots.

The Early Arsphenamine Era.—The "therapia sterilisans" period or one-dose cure era promised by Ehrlich's theorization slowly changed under the impact of criticism from older observers of the course of syphilis under treatment. Belief that something radical, timesaving and treatment-shortening had been accomplished by 606 died hard. One dose was succeeded by successive doses as experience grew. Relatively new conceptions of "cure by stage" came into existence with curious incomprehensible off-shoots such as the doctrine of chancre-excision. "Abortive cure" essentially the systematic speculative under-estimation of the amount of treatment required by the seronegative primary stage, dates back to this era. From 1916 to 1919 the "course" conceptions of syphilis treatment established themselves together with a combined theoretical and speculative discussion of the necessity for and the appropriate use of arsphenamine and heavy metal.

The Early Evaluative Period.—From 1919 to 1922 an extensive literature unfortunately not too familiar to some claimants for priorities, constituted the initial "shake-down" of an accumulating experiential tradition. While limited to the serologic effects of treatment and the occurrence of grossly visible forms of relapse as criteria for determining effects, many of the out lines along which the new era has developed were foreshadowed in the reports of Gennerich, the German Dermatological Society (Rost 1921), Almkvist, Bering, Boas, Hoffmann, Bruck, Jadassohn, Ullmann, Hofmann-Mergelsberg, Müllern Aspegren, Haxthausen Rasch, Scholtz-Silberstein, Sathe, Mutschler, Zieler, Bruns-Riecke, Bernard, and Colonel Harrison. The stage-of-beginning-treatment conception received quite precise delineation towards the latter part of 1922. A type of foreshortened intensified therapy, that of Scholtz, was

* A bibliography for most of the material in this chapter will be found in review by Stokes, Beerman and Wammock, Am. J. Med. Sci., 206, 521, October 1943.

reported on by Silberstein in 1923, before any American contributions were in the field. When American contributions did appear however they rapidly established a series of *important conceptions, beginning with Moore and* Kemp's demonstration based on Keidel's foresighted Johns Hopkins system of the importance of continuity in treatment, and Becker's Mayo Clinic demonstration of the value of massing or intensification of arsenical therapy at the moment treatment is begun. Familiar to Americans during this period are the Pollitzer-Ormsby variation on the Scholtz intensive technic and other types of intermittent systems which lost ground after the League of Nations confirmation of the substantial superiority of continuous treatment.

The League of Nations Syphilis Commission Evaluations.*—Begun on a massive scale in 1928 with conclusions and recommendations stated in 1935 this world wide survey of technical methods in the treatment of early syphilis provides the basis for what may now be spoken of as the conservative or prolonged method for the treatment of early and latent syphilis. Under the terms of the cooperative agreement among the nations participating, each was individually encouraged to make the most of his own material in addition to contributing to the general pool. This rapidly brought American material into the foreground, and the contributions of the Cooperative Clinical Group† working under the aegis and with the statistical cooperation of the United States Public Health Service, express today what might be called the basic formula of American practice, referred to throughout this work as the USPHS-CCG data and material From the League of Nations evaluation for which Martenstein supervised the interpretations, two general systems of treating early syphilis emerged, the British-Scandinavian intermittent and the American continuous systems (see also Stokes and Usilton, 1937) A certain amount of argument has inevitably arisen over the suitability of the material for deciding the question of intermittence versus continuity but on the whole the Commission's findings seemed to justify the belief that the intermittence of the recommended intermittent system is more formal than actual and that its intensity especially in simultaneous arsenical and heavy metal administration, causes its effects to be substantially those of a somewhat less intensive but continuous technic. Enthusiasm for the newer foreshortened procedures should not be allowed to dim the significance of this great evaluative accomplishment, and the syphilologist of today may without hesitation subscribe to either of the announced conservative systems as the equal in curative effect of the more recent "hurry-up" systems of procedure with a substantially greater margin of safety

Since the League of Nations evaluation has established such substantial landmarks, it may well be used as a milestone at which to summarize the high-points of the progress of syphilotherapy since the close of the mercurial age.

* Under the direction of the League of Nations Health Organization, the following countries participated Denmark, France, Germany Great Britain, United States of America. The membership in 1928 included Jadassohn (Breslau) chairman, Madsen (Copenhagen), Colonel Harrison (London), Queyrat (Paris), Stokes (Philadelphia), Rasch (Copenhagen); Gougerot replaced Queyrat, Lomholt replaced Rasch in 1935. Statistical consultant, Westergaard (Copenhagen) Evaluation and report by Martenstein (Dresden).

† Cooperative Clinical Group composed of the heads of five syphilis clinics, Western Reserve University (H. N Cole), Johns Hopkins University (J. E. Moore), the Mayo Clinic (P A. O'Leary) the University of Pennsylvania (J H. Stokes) and the University of Michigan (U. J Wile), assisted by the United States Public Health Service (T Parran, J T Clark, R. A. Vonderlehr and L. J Usilton, statistician)

The following fundamental principles have emerged from a quarter century of revolutionary progress

1. Early and not late syphilis is the domain of systems. Bad effects follow haphazardness, short courses, low dosage and lapse from treatment in early syphilis.
2. The "stage-at-which-treatment-is-begun" principl is established with trustworthy evidence that seronegative primary syphilis is the most easily cured of all stages of the disease, seropositive primary syphilis the most uncertain or resistant and secondary syphilis midway between the two.
3. Relapse follows short treatment, especially arsenical.
   Delayed secondaries
   Neurorecurrence
   Infectious mucosal lesions
   Serologic relapse and fastness.
4. Single drug treatment is inferior to combined treatment, and heavy metal improves arsenical results and compensates shortcomings.
5. Prolongation—more injections, longer courses—gives superior results in systems dominated by the calendar interval of one week. Prolongation and increased mass through individual and total dosage were, of course, attempts to meet the resistance of the 20 per cent relapsing group among early syphilitics t large
6. Dosage theory was spotted with empiricism the concept of lower drug tolerance of the female as compared with the male the large *versus* small dose school; the crowding or time-dose problems represented by the so-called intensive method; the toxicity fears (simultaneous *versus* alternate administration of arsenical and heavy metal); the idiosyncrasy and technical error factors in reaction interpretation which held down dosage, while reports of relapse and resistance raised it.
7. Calendar servitude or the domination of the seven-day interval on a purely empirical unevaluated basis was general. Few ventured to think in terms of shorter intervals or would admit their practicality or desirability
8. Rising ppreciation of scheduling It became clear that schedules or systems critically examined by large syphilologic centers and expert experience were the sound basis for treatment methods rather than the results of blood serologic tests, thus slowly displacing the serologism of the 1920's.
9. Th vital comprehension of toxicity and therapeutic efficiency relations was dominated by the laboratory and rested on the insecure foundation of trypanosomiasis in mice rather than syphilis in man or animals. This group of conceptions, though expressed by impressive numerical indices, was essentially vague and inadequate. A true experimental basis for syphilotherapeusis did not yet exist.
10. Despite these strictures on the knowledge of the day the work of individual investigators plus the League of Nations evaluations established the following facts
    (*a*) An arsphenamine alon can cure" early syphilis in a large proportion of cases (Levaditi).
    (*b*) Heavy metal is potent ugmenting force, particularly true of bismuth; fact recently "rediscovered" by recent workers with intensive methods.
    ( ) Arsenical ther py can be crowded or "foreshortened" without fatal effect and ith good results (Scholtz-Silberstein massive divided dose system).
    (*d*) Continuity and calendar regularity are vitally important to the conservative or prolonged systems evaluated by the League of Nations. A little treatment continuously given is t ice as effective as the same amount of treatment intermittently given.
    ( ) Prolongation of treatment (in the weekly calendar or conservative systems) irons out most complications, relapse and resistance (except preparetic neurosyphilis).
    (*f*) Some important League of Nations and CCG principles the curative outlook is one-third better when treatment is begun in the seronegative primary stage than in other stages of early and latent syphilis; the good results obtained by prolonging continuous treatment for more than one year more than double those obtained by the same kind of treatment carried through less than year; intermittent and irregular treatment methods are the principal sources of delayed reversal of the blood serologic reaction; prolongation and intensification of treatment, using much arsphenamine and heavy metal, but especially much arsphenamine in the first three month promotes good results;

satisfactory results may occur with little treatment, but much treatment and over prolonged periods is twice as effective as little treatment if continuously applied, and five times as effective as treatment intermittently applied arsphenamine is the chief factor in relapse prevention, and this applies specifically t the incidence of neurosyphilis (note importance of this principle in foreshortened intensive methods). Serologic irreversibility becomes the more marked the later in early syphilis treatment is begun, and the more frequently lapse from continuity occurs whether in the form of rest intervals or otherwise weak positive serologic test interrupting series of negatives in early syphilis is distinct warning of the possibility of relapse.

Much of the effectiveness of the foreshortened intensive treatment methods was predicted by Martenstein conclusions from the general League of Nations material that the employment of comparatively heavy individual dosage of the arsenical and of bismuth or mercury with administration in rapid succession at the outset of treatment, leads to superior results. Furthermore, approximately the same amount of treatment should be administered to primary as to secondary cases.

(g) Large dosage is preferable to small; should follow weight standard, and be without sex differentiation.

(h) Many of the most serious complications of treatment are due to background causes (idiosyncratic-allergic, intercurrent infections, and technical factors rather than the drugs as such alone) In particular the combination of arsenic and bismuth is as safe as arsenic alone.

(i) Claims for the use of heavy metal alone in the treatment of early syphilis have not withstood critical evaluation. An arsenical is essential as controller of infectiousness. The effect is augmented by bismuth, and also, though probably less so, by mercury Twenty full doses each of arsenical and heavy metal approximate minimal amount of treatment for infection control (so-called 20-20 standard)

(j) The controversies over the individual merits of arsenicals (606, 914 and so forth) have been largely submerged by the overwhelming popularity of mapharsen in American practice, due largely to its low toxicity combined with high spirillicidal value. This has been overwhelmingly demonstrated in the five-day massive dose arsenotherapy (five-day drip), and its therapeutic efficacy when intensively employed has also been demonstrated by the Eagle-Hogan animal experiments.

ADDITIONAL BASIC PRINCIPLES FOR PRESENT AND FUTURE REEMPHASIS

1 The Boeck-Bruusgaard material underlies the principle that syphilis cures" itself in 40 per cent of cases.
2. A little treatment in early syphilis (Padget) raises the percentage of cure another 20 to 30 per cent.
3. Intensification and prolongation (or repetition in the case of intensive foreshortened methods) directed at the resistant 30 per cent bags another 15 to 25 per cent (depending on stage-of-beginning-treatment) for cure.
4. The remaining 5 per cent to 15 per cent represents the irreducible residue of resistance (deficient defense special strains and so forth) that nothing save time, therapeutic repetition and variation and fever if anything, will cure.
5. Nonspecific agents (fever) have important reenforcing and curative effects in early as well as late syphilis—chiefly by enhancing the effectiveness of arsenicals faster than it increases their toxicity (Carpenter Warren).
6. The spinal fluid examination is an indispensable evaluative and curative check procedure more important ultimately than blood serology
7 As to observation and discharge as cured, all patients who have had an entirely nonrelapsing course while receiving ideal treatment should be informed that cardiovascular reexamination in the five- to ten-year period is necessary
8. The syphilitic pregnant woman or the woman who has had syphilis and is believed to be cured, should have her status reviewed with every pregnancy and safety-first requires her treatment for protection of the child during each pregnancy whether seronegative or seropositive

9 Unsatisfactory results (noncure) are usually revealed by the fifth year of observation and Padget found no less satisfactory results in any case after ten or more years of observation.

PRINCIPLES ESTABLISHED BY THE CLINICAL AND EXPERIMENTAL STUDY OF FORESHORTENED INTENSIVE METHODS

The past decade of work with intensive treatment methods has contributed a number of additional important principles to our understanding of syphilotherapy

1 Hyman and his coworkers have demonstrated that an approximation to the total curative dose of an arsenical can be administered to a human being by an intravenous infusion method (drip) without necessarily disastrous effects with controllable though increased toxicity and with satisfactory therapeutic results.
2. A toxicity-therapeutic efficacy relationship has been worked out by Eagle and Hogan on the basis of animal, and more recently human clinical results. Syphilis can be cured in 80 per cent to 100 per cent of cases (stage-of-beginning factor) by a total dose of 20 to 30 mg per kilo body weight of an arsenoxide (mapharsen) alone.
3. The toxicity of such a dose is inversely proportional to the time in which this dose is given.
4 Any combination of toxicity and time relationship (that is, any margin of safety) that practical considerations may dictate is theoretically possible, the mortality rising with the shortening of the time in which the total dose is delivered.
5. The addition of bismuth ("rediscovery") greatly enhances the effect of all foreshortened intensive arsenotherapy (informally estimated by Eagle as 8 times better effect with bismuth than without)
6 Serologic signs and symptoms under foreshortened procedures disappear gradually on a now well-recognized gradient to which a quantitative serologic procedure is essential in interpretation.
7 A wide variety of time and technical variations (five-day intravenous drip *versus* ten-day multiple injection, *versus* ten to twelve weeks of two to three injections weekly *versus* twenty-six-week schedules with graded morbidity and mortality but substantially identical therapeutic outcome) can be employed as forms of "foreshortened intensive" systems in the name of various types of exigency or expediency
8. The mortality of the five-day drip is currently estimated at 1 : 200 to 1 : 300. Any schedule completed in twenty days or less will have a mortality greater than 1 : 1000 (Eagle-Hogan) ten to twelve week systems have a mortality of approximately 1 : 1500 The mortality of twenty and twenty-six-week systems is not yet definitely known. That of reasonably good performance of the standard conservative prolonged systems is estimated by Hahn (Johns Hopkins Hospital) at 1 : 1850 with optimum experience to 1 : 2800.

   It must be recalled that the mortality of conservative treatment is computed from arsphenamine and not mapharsen-treated cases. The toxicity of mapharsen is so low (one death in 3936 patients, Levin and Keddie 1942) that a material drop in mortality should follow its use in the conservative systems. Levin and Keddie estimate the mapharsen death-rate to be one-half that from neoarsphenamine
9 The foreshortened intensive procedures (up to twelve weeks) greatly reduce the incidence of neurosyphilis.
10 The justification of the foreshortened procedures except for their apparent efficacy in the prevention of neurosyphilis (spinal fluid abnormality) is in the main still one of emergency and expediency The ultimate results are obtainable by the older slower methods with less risk to life What effect this will have on their post war use remains to be seen

   In a discussion of the basic principles of system evaluation applicable to foreshortened intensive methods, Stokes (1942) wrote as follows

   Any new systems proposed should be judged basically by their ability (a) to equal or surpass the curative expectancy of the old ones, (b) to lead to less infectious relapse (c) to cure more mothers and protect more children, (d) to reduce the incidence of cardiovascular and neurosyphilis and (e) by their relative risks to the patient.

   For the evaluation of a system, time and observation are necessary to establish reduction of or absence of relapses and progression. For the former two to four years, for the latter up to ten years is a reasonable observational requirement. For decision *on relapse the patient must be repeatedly and frequently observed*, for it is . . . come

and go affair For the evaluation of cure from a decade to a lifetime the longer the better is required.

A system which under such scrutiny has shown itself at least equal to its predecessors may then proceed to claim additional advantage and support for variety of reasons, including cheapness, rapidity controllability of the lapse factor because the whole job is finished in short time, aid in the widening of availability of treatment by making possible the treatment of more persons per unit of time, personnel and equipment. Such considerations are in the main secondary to those of control of infectiousness and real curative power

If the new system equals the old or surpasses it in all these particulars it has but one more hurdle to make before achieving priority While primum non nocere is losing some of its meaning in war-torn orld, there are still arch conservatives who are inclined to examine critically the bad effects, the complications of system. Of real importance t the victim are the risks involved, the chances of damage or of death from treatment in the case of disease which with none or very little treatment gives the victim at the outset 40 to 70 per cent chance of escape from serious consequences. If an equal chance of escape with an older method offering less risk exists, only the most cogent reasons and free choice by the patient justify the selection of the more dangerous method.

THE CONSERVATIVE OR PROLONGED STANDARDS OF TREATMENT FOR EARLY EARLY LATENT AND LATE LATENT SYPHILIS

It is now in order to summarize what may be called the official' or most widely authenticated and accepted systems for use in that phase of the disease which permits of systematization in procedure. While it is impossible, with the rapid changes taking place in syphilotherapy to predict how long such systems will have a following, it should be clearly understood that they are effective, and will do all that the foreshortened systems will with a very much greater margin of safety To the British-Scandinavian intermittent system (which must be exactly followed, diagram in hand) and a slight but now for American practice, "official" modification of the American continuous (League of Nations) system, the "30-60-03" is added the as yet unproved and unevaluated but rational "Army Plan" recommended to the Surgeons General by the National Research Council and publicized in Circular Letter 74 The conservative systems are still, we believe, the backbone of modern practice, the basis of much of our present knowledge of mechanism and effects, and likely to be displaced completely only by certain radical changes in the whole chemotherapeutic attack on the disease such as are affecting the pyogenic infections, gonorrhea, etc. (the sulfonamides, penicillin)

It is recommended that

(a) In cases hich remain or become serologically negative during, or by the end of the first course four such courses be administered, with intervals of three to five weeks between any two courses.

(b) In cases which have not become seronegative by the end of the first course, in addition to the amount of treatment shown in (a), further courses should be administered until the patient has received as minimum three beyond that which has ended with negative serum reactions. At the option of the individual clinician, this treatment may be prolonged as may be considered necessary

(c) Cases presenting signs of clinical relapse of an early type should be dealt with on principles similar to those enunciated in (b).

For nonpregnant females, treatment should be administered on the plan outlined for men, with the exception that the single dose of neoarsphenamine should be reduced by 0.15 Gm. and that of arsphenamine by 0.1 Gm.

In the event of any reduction in the amount of treatment being indicated, it is recommended that this be effected by reducing the number of arsenical injections rather than by reducing the individual dose or increasing the intervals.

Fig. 430A.

THE BRITISH-SCANDINAVIAN (LEAGUE OF NATIONS) SYSTEM

Plan of Unit Courses of Injection

Week	Neoarsphenamine (Gm.)	or	Arsphenamine (Gm.)	and	Insoluble Compound of Bismuth Containing Bismuth Metal* (Gm.)
1st	0 6 to 0 75	or	0 4 to 0 5	and	0 20 to 0 24
2nd	0 6 to 0 75	or	0 4 to 0 5	and	0 20 to 0 24
3rd	0 6 to 0 75	or	0 4 to 0 5	and	0 20 to 0 24
4th	0 6 to 0 75	or	0 4 to 0 5	and	0 20 to 0 24
5th	0 6 to 0 75	or	0 4 to 0 5	and	0 20 to 0 24
6th	0 6 to 0 75	or	0 4 to 0 5	and	0 20 to 0 24
7th	0 6 to 0 75	or	0 4 to 0 5	and	0 20 to 0 24
8th	0 6 to 0 75	or	0 4 to 0 5	and	0 20 to 0 24
9th					0 20 to 0 24
10th					0 20 to 0 24

By insoluble bismuth is here meant compounds of a very slight solubility in water They should therefore be given in suspension, those of extremely slight solubility (the oxychloride, etc.) usually in a watery suspension, those that are more soluble (the subsalicylate, quinine bismuth iodide, the alkaline tartrates, etc.) suspended in a vegetable oil. If a liposoluble compound (e g the camphocarboxylat etc.) is preferred, it is desirable that the injection be given twice weekly in half doses.

The dosage of all bismuth compounds should be calculated according t their content in bismuth metal.

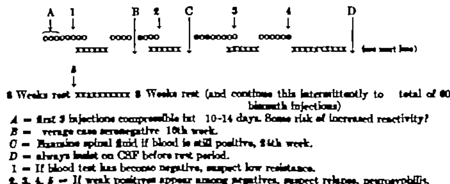
As an alternative t bismuth, course of mercury may be given, either in the form of inunctions (forty days t 3 Gm of unguentum hydrargyri) or of injections (70 mg. of mild mercurous chloride or 120 mg. of mercuric salicylat etc. suspended in suitable base)

League of Nations Investigation and Report on Treatment of Early Syphilis, Committee of Experts on Syphilis and Cognate Subjects, Zurich, November 21–23, 1934. Journal A.M.A., Vol. 104, No. 15, April 13, 1935.

THE AMERICAN CONTINUOUS SYSTEM

The 30–60–03" 'Official Modification (Circular Letter 18, Surgeon General's Office, U S. Army)—The published work of the United States Public Health Service and the Cooperative Clinical Group in the United States has indicated that continuous treatment with an effective arsenical alternating with bismuth on a definitely defined schedule with calendar regularity and without rest periods during the arsenical phase is the optimum conservative technic for the treatment of seronegative and seropositive primary syphilis, secondary syphilis, and early latency (within the first four years of the infection when the duration is known) An essentially similar standard of treatment employing 606 parallel with an acceptable intermittent (British-Scandinavian) system of treatment employing neoarsphenamine, has been recommended by the Commission on Syphilis and Cognate Subjects of the League of Nations as a result of an extended study of an international statistical material. It may therefore, it is believed, be accepted as having the support of authority

For mnemonic convenience the designation, "30–60–03" is suggested, for the standard system for early and early latent syphilis the "30" repre-



senting the number of arsenical injections the 60 representing the number of weeks of bismuth therapy equivalent to 60 injections of bismuth subsalicylate and the "0" and "3 representing respectively no rest periods, and three years of combined treatment observation. By "treatment observation" is meant the total elapsed time from the institution of treatment in accordance with this schedule until the patient is discharged from observation as presumptively cured

Since the sequence of various types of treatment in this system, the prevention of relapse by overlapping of heavy metal and arsenical therapy the serologic controls, the spinal fluid examinations, all are integral parts of the treatment system, the following diagram is offered as presenting these various relationships.

Fig. 439B.

The "30-60-03" for Early Syphilis

Thirty neoarsphenamine or mapharsen injections, sixty weeks of bismuth injections. No rest intervals in the arsenical phase, three years of treatment observation. O = neoarsphenamine or mapharsen; X = bismuth subsalicylate; weekly intervals.

8 Weeks rest xxxxxxxxxx 8 Weeks rest (and continue this intermittently to   total of 60 bismuth injections)

A = first 2 injections compressible int 10–14 days. Some risk of increased reactivity?
B = verage case seronegative 10th week.
C = Examine spinal fluid if blood is still positive, 24th week.
D = always insist on CSF before rest period.
1 = If blood test has become negative, suspect low resistance.
2, 3, 4, 5 = If weak positives appear among negatives, suspect relapse, neurosyphilis.

The "30-60-03" schedule as thus presented can be drawn up in "vertical" as distinguished from the above "horizontal" arrangement, week by   eek, for printing directly on record forms.

The published observations of the USPHS-CCG group on the treatment of early syphilis indicated that the "30-60-03" schedule could be most effectively pplied t seronegative primary syphilis and fully developed secondary syphilis. In the case of seropositive primary syphilis, whose status should be confirmed in the case of seronegative cases by a repetition of the blood test on the *day following the first arsenical injection*, there were definite indications that the seropositive primary phase of the disease lacking the development of a full-fledged immunity reaction on the part of the body was the most resistant to cure and the most prone to relapse of the three groups of cases included under the designation, early syphilis. It has accordingly been proposed that in seropositive primary syphilis and initially negative primary syphilis which becomes seropositive on the blood immediately following the institution of treatment, a 40–80–04 system be employed, meaning thereby an additional 10 arsenical injections and 20 bismuth injections and another year of observation over and above the standards proposed as generally applicable to early and early latent syphilis. This extension of the arsenical phase of treatment can take the form of five courses of the arsenical of eight injections each, in place of the three courses of eight and one course of six injections in the "30–60–03" system. The bismuth therapy may follow the usual two-injection overlap, plus four additional injections in the arsenical intermission that is employed in the "30-60-03"; the remaining bismuth injections to complete the 80-week standard, being continued in 10-injection intermittent courses after the completion of the arsenical phase of treatment.

Fig. 439C.

THE 26-WEEK ARMY SYSTEM

The 26-Week Army System for Early and Latent Cases.—This diagram is adapted from Circular Letter 74 Surgeon General's Office U S. Army

Week	Arsenoxide	Week	Bismuth
1		1	
2		2	
3		3	Bismuth subsalicylate intramuscularly once a week. 5 injections.
4		4	
5	Arsenoxide intravenously twice week. Total 20 injections.	5	
6		6	
7		7

25		25	
26		26	

Dosage 0.05 to 0.07 Gm. arsenoxide based on patient weight. 0.2 Gm. bismuth subsalicylate. (40 injections arsenoxide—16 bismuth subsalicylate.)

Serologic Control of Treatment. In patients with early syphilis serologic test ill be done at the beginning and end of the schedule of treatment outlined in Fig. 439C but treatment may be stopped whether the serologic eaction for syphilis is positive or negative. After the completion of treatment the serologic tests should be repeated three and six months later If the reaction is negative after six months, the case may be classified as result satisfactory and the *Syphilis Register* may be closed. If the reaction is positive after six months, the patient should be referred to a station or general hospital.

In patients with latent syphilis the serologic tests should be repeated at the completion of the treatment outlined, but the *Syphilis Register* may be closed when this treatment is completed, regardless of the result of the serologic test.

Spinal fluid examination should be performed in hospital in patients with early syphilis t the end of the course of treatment outlined in Fig. 439C, or as soon as possible thereafter but in any event before the Syphilis Register is closed. I pparent latent syphilis, spinal puncture should be performed in hospital before treatment or as soon as possible thereafter but in any event before the *Syphilis Register* is closed.

A SYSTEM OF TREATMENT FOR LATENCY

'24-60-100 plus. —Before defining a system by which adequate treatment of latency may be judged, it must be reemphasized (see Chapter X)

that the latency here implied is "monosymptomatic seropositive latency" in which absolutely no clinical evidence of syphilis can be identified on complete physical examination except the positive confirmed and confirmable blood serologic reaction for the disease. An adequate examination of the spinal fluid is necessary to establish the fact that a seeming latency is not complicated by asymptomatic neurosyphilis. A patient who has been adequately treated for an early syphilitic infection but who still remains seropositive on the blood in order to be considered in monosymptomatic seropositive latency (serologically fast) should have had a negative spinal fluid one year after the close of his treatment for early syphilis, and if more than a year has elapsed since the cessation of such treatment, a repetition of the spinal fluid examination is desirable A long series of negative spinal fluids is not necessary to the establishment of the status of monosymptomatic seropositive latency for according to CCG observation, more than one or two repetitions of a negative fluid in the absence of any developing clinical signs is unnecessary

The latency of a syphilitic infection is divided arbitrarily into an early and a late period, partly because of the greater risk of infectious relapse and other types of recurrence in early latency and partly because of the presumed better outlook for complete arrest if not cured in the earlier years of the latent period The dividing line between early and late latency has tended in American practice to be the fourth year of the disease. This is an arbitrary setting which may in the judgment of an expert, be varied one way or the other A young and robust person whose infection is of five or even six years presumed duration, may be advised to accept the standard for an early infection in his treatment. On the other hand, most genuine latency after the fourth year shows relatively little tendency to progression and may be treated by a standard substantially lower than that proposed for the radical cure of early infection.

The treatment of early latency (first four years of the disease) is that of early syphilis—the "30–60–03" system.

The Cooperative Clinical Group's experience (Moore as spokesman) has indicated that for the treatment of late latency (after the fourth year) three courses of eight injections each of an effective arsenical given in continuity and alternation with ten injections of bismuth subsalicylate without overlap and with continuity extending only through the arsenical phase, constitute an adequate beginning The continuous treatment with arsenical and heavy *metal is then followed by an intermittent and* prolonged treatment with bismuth alone which should total, including the three 10-injection bismuth courses given with the arsenical phase, not less than 60 weeks of bismuth therapy Further treatment with bismuth to the extent of 80 weeks, or even 100 weeks, or on the basis of 80 weeks, plus a course a year" for several years, was found to increase appreciably the good results by the criteria employed

It is not necessary however in judging candidates for admission to the services, to insist on prolongation of the heavy metal phase beyond the 60th week. Approximately 70 per cent of monosymptomatic seropositive latency may be expected to reverse to negative on the blood for an indefinite period following a 24–60 course and the failure of the remaining 30 per cent to reverse may be regarded as no bar to eligibility

As a general principle, late latent cases remaining seropositive after a 24–60 course should be observed at intervals of a year or two with physical

examination and appropriate tests for evidence of cardiovascular progression and ultimate neurosyphilitic involvement.

It should be emphasized that late latency is usually much over-treated on the basis of fluctuating positive blood serologic tests alone, or because of conflicts between the results of various laboratories, "serologic discord." The trend of opinion downward, in the form of less and less exacting demands for the treatment of late latency has been largely under the influence of Moore and his associates, whose re-examinations of latent patients (Diseker Clark and Moore) based on 926 patients with latent syphilis followed for five years or longer led to the following statement

1 Latent syphilitics do very well regardless of the type or amount of treatment received.
2 The optimum amount of treatment to reduce progression to a minimum is approximately 20 injections each of an arsenical and a heavy metal.
3 The over-all rate of clinical "cure" with optimum treatment is about 95 per cent.
4 Clinical and serologic cure in latent syphilis have no relationship

MASSIVE DOSE, FORESHORTENED CHEMOTHERAPY OF EARLY SYPHILIS

Description of Procedure, Indications and Contraindications

All methods of intensive therapy are intended for patients with early syphilis (primary secondary relapsing secondary and early latency) who have received little or no previous therapy who are robust young people, especially men, reasonably free from serious visceral disease, particularly hepatitis, myocarditis, severe hypertension, nephritis, excessive alcoholism, blood dyscrasias, active pulmonary tuberculosis, and history of previous serious arsenical reaction. Although it is safe to administer sulfonamides simultaneously with conservative prolonged therapy and even with the twelve-week system it is unsafe to give sulfonamide therapy for gonorrhea or other conditions to patients receiving five to ten day intensive therapy

Addition of Bismuth to Massive Dose Technic—Since July 1941 L. W Shaffer has been using bismuth concurrently with the arsenical. It may be used as follows

Dosage of Bismuth with Intravenous Drip Method.

1 A suspension of bismuth subsalicylate in oil is employed.
2. The patient should receive 0.2 Gm. bismuth subsalicylate (0.13 Gm. bismuth metal) intramuscularly as soon as the diagnosis of early syphilis is confirmed.
3 The second dose of 0.2 Gm. should be given on the third day of treatment, the third dose of 0.2 Gm. on the sixth day and fourth dose of 0 2 Gm. on the ninth day before discharge.

Method of Preparing Mapharsen Solutions. 0.01 Gm. mapharsen (arsenoxide) is dissolved in 100 cc. of 5 per cent dextrose solution. Usual procedure is to prepare 600 cc. of such solution, containing 0 06 Gm. mapharsen—this is enough for three hours of treatment.

When the Vacoliter containing 2000 cc. of 5 per cent dextrose is used, the total daily dose of 0.24 Gm. of mapharsen (arsenoxide) is prepared the first thing in the morning and the solution allowed to run in, in the ten- t twelve-hour treatment period.

This has been the practice in one institution. The preparation of the drug for the ten- to twelve-hour period all at once has simplified the technic to great extent.

Variants in Usual Procedure

1 Primary fever on the first day (Herxheimer)—therapy is stopped if temperature reaches 101 4 or more. This usually happens between the 6th and 8th hour by this time patient may

Fig 440.

PRETREATMENT ROUTINE (ALL METHODS OF INTENSIVE CHEMOTHERAPY)
(After Leder 1940)

1. Urinalysis, including determination of urobilin. Urinalysis repeated daily
2. Determinations of the urea nitrogen content of the blood and the icterus index.
3. Complete blood count, including that of the platelets.
4. Complete physical examination on admission.
5. Serologic examinations made in three different laboratories (these include the Kolmer Kline diagnostic, Kline exclusion, Kahn standard and titered Wassermann tests)
6. Darkfield examination of material from all open sores.
7. Estimation of renal function by determination of the specific gravity of the urine.
8. Special tests of hepatic function by the bilirubin method.
9. Studies of the excretion of arsenic in the urine and in the stool and its concentration in the blood. (Optional for study purposes.)

Fig. 441.

TECHNIC OF 5-DAY INTRAVENOUS DRIP (Hyman, Chargin, Leifer) (After Committee on Massive Drip Intravenous Therapy 1940)

Materials

1. Needle—deep injection type #20, 1½ inch length.
2. Diluent—5 per cent dextrose solution.
3. Drug—mapharsen (arsenoxide) ampules 0.04, 0.06, and 0.6 Gm.
4. Glass gravity cylinder 300 cc. capacity with attached rubber tubing, glass drip chamber adapter for needle. (See Illustration. Vacoliter or similar container may be used instead of apparatus described. (L. W Shaffer))
5. Adhesive or scotch tape (one-half inch width).

Dosage of Mapharsen.

1. Total dosage for the five-day treatment period is determined by the stripped weight of the patient, in patients weighing less than 70 Kg. (155 lbs.) the total dose is 1000 mg (1.0 Gm.) In those weighing 70 kg. (155 lbs.) or more, the total dose of arsenoxide is 1200 mg. (1.2 Gm.)
2. The daily dose is 200 mg. (0.2 Gm.) for patients receiving a total of 1000 mg. (1.0 Gm.).
3. The daily dose is 240 mg. (0.24 Gm.) for patients receiving a total of 1200 mg. (1.2 Gm.)
4. If a patient receives less than the intended daily dose (this will most often occur on the first day of therapy) the deficiency in dosage may then be spread over the remaining days of treatment. Thus, if the patient receives 120 mg (0.12 Gm.) the first day instead of the intended total daily dosage of 240 mg. (0.24 Gm.) he may be given 30 mg. (0.03 Gm.) additional on each of the succeeding four days of treatment.

Procedure: Site of election for insertion of needle (see Fig. 442) After cleansing of forearm and application of a tourniquet above the elbow to distend the veins, the needle is attached to a 2 cc. Luer-type syringe and inserted in a vein on the forearm, usually anterior or outer aspect, between elbow and wrist, to allow movement at these articulations. Needle should be inserted into vein up to the hub, a gauze sponge placed beneath the needle hub, and the needle fixed in place with adhesive (or scotch tape). Alternate arms used on succeeding days.

The adapter of the intravenous set is attached to the needle (after the adapter has been freed of air bubbles) after the removal of the tourniquet, and the solution is allowed to flow rapidly until 10–15 cc. has entered. Should any swelling or infiltration be noted about the needle point, the flow should be stopped; the needle removed, and reintroduced into a different vein in the same or opposite forearm. (Refer to diagram (Fig. 442) and note manner in which tubing is looped on the forearm and taped so that these become a part of the forearm.")

The rate of flow is regulated by the fine adjustment clamp so that solution enters at a speed of about 30–60 drops per minute: thus, the entire quantity of 2000 cc. will require eight to ten hours for introduction.

have received only from 0 12 Gm. t 0 16 Gm. mapharsen. The practice has been t compensate for this insufficient dose in the following manner

First day—0 12 Gm. mapharsen (arsenoxide)
Second day—0.28 Gm. mapharsen (arsenoxide)
Third day—0.28 Gm. mapharsen (arsenoxide)
Fourth day—0.28 Gm. mapharsen (arsenoxide)
Fifth day—0.24 Gm. mapharsen (arsenoxide)

2. Clinical jaundice—when this appears in the course of treatment, the procedure should be interrupted It has only been seen once in all cases studied (Committee report)

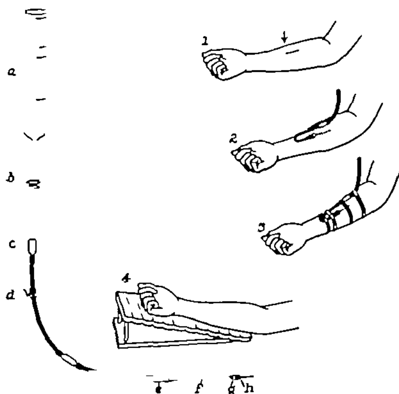

FIG. 442 —SCHEMATIC SET U FOR MASSIVE-DOSE ARSENOTHERAPY (5-DAY DRIP).

( ) 500-cc. graduat cylinder (elevation 2½–3 ft. above level of arm) (b) Murphy clamp (fine adjustment of flow) (c) drip bottle (d) spring clamp (to quickly shut off flow) ( ) glass window (f) finer rubber tubing (g) adapter (h) 20-gauge 1½-inch needle.

1 Site of injection—needle inserted t lnab (bet een elbow and wrist) 2, needle hub, tubing and glass adapter taped firmly ith adhesive so that these become part of forearm (see 3); 3, t show arrangement of drip after insertion of needle 4 arm board—padded for arm rest. (After William Leifer Courtesy of the Committee on Massive Drip Intravenous Therapy)

General Medical Care During 5-Day Intravenous Drip

According t Leifer (1940) description The nursing problems during the period of treatment consists of the preparation of fresh solution for each patient at the end of two or three hours and the refilling of the gravity flask. Meals are served on the ordinary bed tray Patients ca feed themselves. They are also capable of handling the urinal but, naturally must be assisted somewhat in the use of the bedpan. The latter disturbance may be prevented by having the patient evacuate or have an enema during the evening, when treatment has been discontinued.

The patients are given high caloric diet, rich in starches and carbohydrates. The majority of the patient read, listen to the radio or play cards during the day I the evening after discontinuance of therapy they may get out of bed. They suffer little or no discomfort. Many of them register gain in weight of as much as 10 pounds (4.5 kg.). This gain in weight is not d

to any appreciable edema but may be explained by the fact that most of these patients, other wise undernourished are so well treated with regard to food and nursing care.

TECHNIC OF 10-DAY MULTIPLE INJECTION INTENSIVE THERAPY FOR SYPHILIS (Schoch; Thomas)

With this treatment system patients need not be confined to bed but they should be treated in the hospital and observed for at least two days after the last injection of mapharsen (arsenoxide) Routine ward diet may be employed.

T injections of mapharsen (arsenoxide) are given daily for ten day period. The injections are given in the morning and evening of each day ten, or preferably twelve hours apart. Schoch, however has given single injections of 100 t 120 mg daily as an ambulatory procedure. Dosage is governed roughly by eight. Patients weighing 50 to 70 kg (110 to 154 pounds) should receive 0.05 Gm. of mapharsen twice daily for ten days. Patients weighing between 70 and 90 kg (155 t 200 pounds) should receive 0.06 Gm. of mapharsen twice daily for ten days. The dosage may be increased to 0.070 Gm. in each injection for patients weighing over 90 kg. (200 pounds) Each dose of mapharsen (arsenoxide) should be dissolved in from 5 to 10 cc. of distilled water The *solution should be aerated* and *rapidly injected* intravenously promptly after preparation. In cases where solutions are made in bulk, individual doses should be given within at least two-hour period after preparation.

On th first, fourth, eighth and twelfth days, 0.2 Gm. of bismuth subsalicylate in oil should be injected deeply into alternate gluteal muscles.

Thomas and his associates of Bellevue Hospital combine fever therapy with the intensive multiple syringe technic (1941 1943) The risk of serious cerebral accidents with this method increases with the amount of arsenoxide (mapharsen) given. The addition of fever does not prevent cerebral reactions but lessens their frequency by necessitating lower dosage of arsenical.

REACTIONS FROM 5-10 DAY INTENSIVE THERAPY AND THEIR MANAGEMENT

Minor Reactions

1 *Pain in the arm* Cold wet dressings, ice-bag aspirin codein only if pain is severe.

2 *Mild headache* Aspirin or codeine usually gives prompt relief If headache is severe, increasing and persistent, consider this as possible prodrome of toxic encephalopathy

3 *Nausea and vomiting* Give only fluids by mouth, and sedation if necessary If persistent, discontinue treatment temporarily May give 5 per cent or 10 per cent dextrose solution alone intravenously

4 *Primary Fever* Sharp rise in temperature occurs on the first day of treat ment especially with intravenous drip It is usually almost normal by evening and normal by the next day If the temperature goes above 101.4 F discontinue drip for the day Next day drip may be reinstituted, practically always without recurrence of fever This early fever need not cause omission of the second dose when multiple syringe method is used. Primary fever is usually accompanied by a flare-up of the syphilitic lesions (Herxheimer reaction or therapeutic shock) Symptomatic treatment may be used if necessary

5 *Secondary fever* Secondary rises of temperature in excess of 101 F at any time after the first day of treatment are an indication for inter rupting therapy because secondary fever is sometimes associated with a mild toxicoderma. Most often in the five-day treatment the fever occurs on the last evening of therapy Mapharsen should not be given again until the temperature is normal. If fever recurs when treatment

is reinstituted, efforts at intensive therapy should be abandoned entirely

If the patient has received at least a total of 800 mg (0.8 gm) of mapharsen (arsenoxide) before the appearance of fever intensive arsenotherapy by any system should not be reinstituted. In this case all further arsenical therapy may be omitted but the patient should receive a total of at least 12 weekly intramuscular injections of bismuth subsalicylate before all treatment is stopped

Symptomatic treatment for this reaction may be used if necessary

6 *Toxicoderma* Usually appears in the post treatment period on the seventh day and is often preceded by and accompanied with fever The type is most commonly morbilliform, scarlatiniform or urticarial, and there is no exfoliation. This is not arsenical exfoliative dermatitis, and is not a serious sensitizing reaction. The rash usually fades in one and one-half to four days without therapy Symptomatic treatment may be used, when indicated

Since this reaction does not usually occur with the intravenous drip method until all treatment has been completed, it has no bearing on interruption of such treatment. When the ten-day multiple injection system is used, the occurrence of this "ninth-day erythema" is an indication for interrupting treatment. This reaction may be associated (rarely) with toxic encephalopathy and continued treatment may increase the risk.

7 *Renal damage* Usually insignificant, consisting of minor traces of albumin, occasional red and white blood cells. No treatment is needed. Marked albuminuria or hematuria is a signal for discontinuing treatment.

8 *Peripheral neuritis* Rarely encountered, and only in the post-treatment period. Usually manifested only by subjective symptoms, most often paraesthesias. Objective changes are rare and only sensory in type, never motor The process disappears spontaneously This reaction was common in the cases treated early in the five-day method, probably because of immobility of the arm and the use of a drug too toxic (neoarsphenamine) for such a method.

9 *Nitritoid reaction* Rarely observed with multiple injections or with the intravenous drip procedure, unless the rate of flow of the latter is inordinately fast (mapharsen is well known to produce this reaction only rarely)

10 *Precordial oppression.* (Falk and Rattner 1942 Prats, Varas, and Harasti, 1942) This occurs occasionally with five-day treatment. Disconcerting but not frequent or serious.

Major Reactions

1 *Severe headache* Especially towards the fourth or fifth day of treatment, the occurrence of severe, persistent and increasing headache not readily relieved by aspirin or codeine, should be viewed as of possible serious import (prodrome of toxic encephalopathy) It is best to discontinue intensive therapy and after a rest interval from all arsenical therapy of at least four weeks (this rest period to be occupied with weekly bismuth injections) to place the patient on the standard or twenty-six week treatment schedule the duration of which may be shortened to the ex

tent of the mapharsen dosage before the reaction occurred (e g., if the patient received a total of 400 mg. mapharsen before the reaction 1200 mg additional should be given by injections twice weekly with bismuth added as in the standard schedule)

2 *Jaundice* This is an uncommon complication and calls for discontinuance of intensive therapy No instance of acute yellow atrophy has occurred although Rattner and Falk (1942) observed a case of severe hepatitis with other visceral damage (see below)

For the treatment of the reaction, the patient may be given intravenous 10 per cent dextrose solution high carbohydrate-low fat diet, and injections of liver extract therapeutically Intestinal elimination should be encouraged with saline catharsis.

3 *Blood dyscrasias (especially purpura or bleeding from any part of the body)* Rarely encountered, but necessitating permanent discontinuance of all arsenotherapy Treatment usually consists of blood transfusions.

4 *Exfoliative dermatitis* Rarely if ever encountered. Requires permanent discontinuance of all arsenotherapy Symptomatic treatment, dextrose intravenously and liver extract.

5 *Encephalopathy* Women are especially susceptible. This reaction may be manifested by severe headache, vertigo, tremor fever unusually severe nausea and vomiting, mental confusion, disorientation, and apathy· by single or repeated convulsive seizures, and by prolonged chorea. In serious instances hyperthermia usually supervenes and *death* may result. May occur on the third to fifth day of treatment, or not until the sixth or seventh day rarely thereafter Often preceded by headache of increasing severity (see above) There is no means of anticipating this reaction (Thomas, Wexler and Dattner 1942)

In mild cases, the suspicion of toxic encephalopathy should be checked by examination of the spinal fluid for cells, globulin or increased protein If such tests are positive, further treatment with arsenical drugs should be abandoned. If the spinal fluid is normal, treatment may be resumed if the symptoms have completely disappeared and the temperature is normal.

Treatment of this serious reaction is of uncertain value but the prognosis is not as bad as is usually assumed (Chargin 1940) Suggested procedures include (1) repeated drainage of spinal fluid (20 to 40 cc.) in repeated taps daily (2) dehydration by use of intravenous 50 per cent sucrose solution 50 to 200 cc. (3) sedation is of value in all cases. Where symptoms are mild, any of the barbiturates may be used by mouth. If convulsions occur sodium amytal 0.24 Gm. (3¾ grains) may be given intravenously or intramuscularly (this dose may be repeated every two to three hours for several doses if convulsions occur or the patient is restless for use of adrenalin see p 435 Oxygen inhalations should also be given. Sodium thiosulphate is of no value (Chargin, 1940)

6 *Severe renal injury* (rare) Thomas and his colleagues (1943) have reported acute nephrosis in patients receiving short arsenical and prolonged fever treatment but no particular renal damage occurs in their patients treated with the multiple injection method (ten or six days) Rattner and Falk (1942) reported a severe case with acute glomerulonephritis, anuria, uremia, hepatitis ileus and pericarditis in a patient treated by the five-day method.

Post Treatment Routine after 8–10 Day Intensive Therapy (to be carried out before discharge from hospital).

1 Complete physical examination.
2. Laboratory studies:
   (a) Titered blood serologic test for syphilis.
   (b) Complet urine analysis.
   (c) Complet blood count (hemoglobin, red blood cell and whit blood cell count and differential)
   (d) Other laboratory procedures (icteric index, serum bilirubin, urobilinogen, non-protein nitrogen) where indicated.

OUTLINE OF PROPOSED 12 WEEK SCHEDULE OF MODIFIED INTENSIVE TREATMENT (Eagle, 1943)

Patients are to be treated with mapharsen (arsenoxide) three times weekly (Monday Wednesday and Friday or Tuesday Thursday and Saturday) at the following dosage scale —

Less than 120 lbs. (55 kg.)	50 mg.
120–155 lbs. (55–70 kg)	60 mg
Greater than 155 lbs.	70 mg

Treatment is to continue for twelve weeks or a total of 36 injections. Hospitalization is not necessary and patients are to be treated on "duty status."

Patients are to receive intramuscular injections of bismuth subsalicylate (0.2 Gm., equivalent to 0 13 Gm. of metallic bismuth) once weekly throughout the course of mapharsen (arsenoxide) treatment, to a total of 12 injections

Fig 445.

FOLLOW-UP OBSERVATION AFTER ALL METHODS OF INTENSIVE CHEMOTHERAPY

1 Patient should be reexamined t monthly intervals for six months.
2. This reexamination should include a complete physical examination with special attention to the mucous membranes of the mouth and throat, the genitals and the perianal region for early overlooked evidences of infectious elapse
3. A quantitative blood serologic test for syphilis should be performed monthly for six months, and then t the 9th and 12th month. (The blood serologic reactions usually become negative t the 12th–16th week after the start of treatment)
4. Examination of the spinal fluid should be done if feasible, sometime between the 6th and 12th month.
5. The patient should not receive any further antisyphilitic therapy except as specifically set forth under management of the unsatisfactory case

MANAGEMENT OF THE UNSATISFACTORY CASE

A patient who has become clinically "cured" and serologically negative and remained so until the twelfth month of observation, and in whom the spinal fluid is negative, may be discharged from observation as a "*satisfactory* result." Should such a person return at a later date with a new darkfield positive lesion, this may be considered as a new infection and the patient may be retreated in the original manner (Schoch, 1945, Moore, 1945 L. W Shaffer 1945) See discussion of Reinfection p. 185

A case must be considered as unsatisfactory or a treatment failure, if

1 There is definite objective evidence of infectious relapse, corroborated by positive blood serologic reaction for syphilis, and if possible by positive darkfield examination.
2. There is incontrovertible evidence of serologic relapse without clinical relapse, i.e., the patient blood serologic test has dropped to negative or near negative and then to persistently strongly positive (this is best interpreted by a quantitative procedure)
3. Reagin fastness, i.e., where the blood serologic reaction for syphilis has never reverted to negative but remains persistently positive (preferably determined by constant titer of quantitative tests) for six months period after treatment.

The unsatisfactory case (infectious relapse, serologic relapse, seroresistance) and the new infection may be retreated by intensive therapy except in the event of serious reaction from the original treatment.

The results of intensive retreatment of the unsatisfactory case have not been fully evaluated, but appear to be less satisfactory than original treatment.

ADDITIONAL SPECIAL CONSIDERATIONS CONCERNING EARLY SYPHILIS TREATMENT

Criteria of Adequacy of Treatment for Syphilis.—The answer to this question depends fundamentally upon the definition of "adequacy" If by adequacy is meant the securing of a condition of noninfectiousness in an infectious case, one kind of answer will be appropriate if adequacy is to be interpreted in terms of clinical or of radical cure, another answer will be appropriate if adequacy means the placing of an infected individual at one or another type or stage of involvement in syphilis on a symptomatic status that will permit of full or limited service in the armed forces, still another answer is necessary The subject is dealt with under each of these three heads briefly as follows

Treatment to Noninfectiousness.—The immediate infectiousness of surface lesions of syphilis is controlled in all but the rare treatment resistant or arsenic-fast case, it will be recalled, by the first one, or at most, two, injections of an effective trivalent arsenical provided the dose is adequate (0.3 to 0.5 Gm arsphenamine 606 0 4 to 0 6 Gm. neoarsphenamine 40 to 60 milligrams mapharsen. The duration of this effect of one or two injections is not precisely known, but is estimated roughly as approximately thirty to ninety days. Failure to continue treatment does not necessarily but may in a percentage of cases ranging from 0 to 64 per cent, lead to infectious relapse. A useful tabulation from Cooperative Clinical Group and University of Pennsylvania material is herewith presented

Fig 444

Arsenical treatment alone, number of injections.	Infectious relapse, per cent.	Additional heavy metal injections.	Infectious relapse, per cent.
1 4	64	20†	45
5– 9	14	20	9
10–19		20	4
20–29		20	3 6
26 5*		29.2 or more	0
30–40 ..		"appropriate	1.2

* University of Pennsylvania figures; all others are C.C.G.
† One week of mercurial inunctions equals one injection.

From this tabulation it will be apparent that the critical point at which sharp reduction in the probability of recurrent infectiousness takes place is between the fifth and ninth injections of the arsenical (14 per cent relapse without and 9 per cent with heavy metal) and that the so-called 20–20 standard often quoted as adequate for treatment to noninfectiousness, reduces the risk of infectious relapse to 4 per cent, beyond which a slow reduction to 0 to 1.2 per cent is secured by prolonging treatment beyond 30 arsenical injections with 30 or more injections of heavy metal.

Heavy metal in the statistical table presented above, is taken to represent 0.2 Gm of an insoluble bismuth salt of not less than 57 per cent metallic content, or one week of mercurial inunctions, or its intramuscular equivalent in a water soluble or insoluble mercurial salt.

It will presently be apparent, therefore, that the best treatment to secure noninfectiousness is practically identical with the optimum treatment for the securing of "satisfactory results" or "cure"

The Influence of th Development of Secondaries on Relapse.—A very interesting and seemingly paradoxical situation was revealed in the comparison of serological with clinical relapse under treatment—a relation of particular importance because it might well form the basis for polemic discussion. The stage of syphilis at which treatment is begun influences the incidence of mucocutaneous relapse in different way from that in which it affects all other forms of relapse. The first Cooperative Clinical Group survey of mucocutaneous relapse as such (presented t the Copenhagen Congress) indicated that it occurs in 10 per cent of patients beginning treatment in the seronegative primary stage· 8.6 per cent of those beginning treatment in the seropositive primary stage and only 4.2 per cent in those who began treatment after their secondaries had fully developed. Relapse incidence of the mucocutaneous type was therefore markedly less if the patient was allowed to develop his full cutaneous secondary reaction to the disease, the difference amounting to as much as 58 per cent reduction in probability as the patient passed from seronegative primary to the florid secondary phase. On the other hand, the existence of distinct relapsing type was foreshadowed by the fact that patients who began treatment with late or recurrent secondaries relapsed in 24.3 per cent of cases. Serological relapse, on the other hand, occurred in 12 per cent of patients whose treatment was begun in seronegative primary syphilis· 10.2 per cent if the treatment as begun in seropositive primary syphilis; 18.1 per cent under the same circumstances in early secondary syphilis (first year) and 20 per cent if treatment was not begun until delayed secondaries after the first year It ppears, therefore that t begin the treatment of patient in the seronegative stage of primary syphilis, while it has already been shown definitely t increase the prospect of complet cure, none the less subjects him to definite slight risk of mucocutaneous recurrence and therefore of more prolonged infectiousness. The probable explanation, of course, is that the skin and mucous membranes have never been given the opportunity to develop what might be thought of as local tissue immunity by full reaction t the disease

It must of course be appreciated that the reduced incidence of relapse and progression in patients who have had secondaries arises simply from the fact that in reaching that stage they have automatically so to speak, set behind them that much of the life history of the disease It must, too, remain for further study to decide whether the increased risk of infectious recurrence after early treatment justifies postponement until the patient has developed secondaries. At the present time the higher proportion of curative results seems to justify immediate treatment rather than postponement. The increased risk of infectiousness through recurrence can hardly be greater than the risk of infectiousness represented by a patient allowed to live at large in the com

[1] The percentages estimated on the basis of 3244 cases observed and treated for six months or over were seronegative primary 16.4 per cent seropositive primary 20.8 per cent; secondary (first year) 9.3 per cent secondary delayed 9.2 per cent. The principle illustrated is the same in both.

munity without benefit of the arsphenamines until his secondary eruption has fully developed. In any event, the application of such a principle demands universal hospitalization for the patient between the primary stage and the full development of secondaries, an obvious impracticability at this time. Until the proponents of postponement (as for example, Bernard) can advance indubitable evidence that there is other than merely mucocutaneous protective value in permitting a patient to go on to secondaries, the postponement of treatment until secondaries develop is not only against the interests of the public health but against that of the individual patient, who above all things desires the greatest possibility of personal cure.

Jadassohn, from an international questionnaire, has reported that the effect of arsphenamine in controlling the infectiousness of syphilis has led to an estimated reduction in incidence of new cases of the disease of 75 to 80 per cent in Belgium, Sweden, and Holland; 60 per cent in Finland 50 per cent in Denmark; 40 to 50 per cent in Switzerland 20 to 60 per cent in Italy and Czechoslovakia; and 25 per cent in Norway

Rules for Preventing Infectious Relapse.—The prevention of infectious recurrence and the reduction of relapse to the lowest possible terms requires of the practitioner then, an unhesitating acceptance of the following rules (1) The concept of abortive cure by short courses should be abandoned, no matter how early the patient may come under treatment. (2) Not less than 20 injections of an arsphenamine, and more if possible, preferably in one or two courses, and an equivalent amount of heavy metal without rest intervals should be given in an early case to control infectiousness. (3) Treatment should be continuous rather than intermittent or intensive, there being no time, at least within the first year or more, that the patient is not under the influence of one or another effective mode of treatment for syphilis with an arsphenamine or heavy metal. (4) Treatment should be massed well to the fore—that is, within the first three months, for this is the period in which mass as distinguished from prolongation reaches its greatest effectiveness in preventing relapse. (*cf* massive dose arsenotherapy)

Stokes, Miller and Beerman in their study of bismuth arsphenamine sulphonat observed similar phenomenon. The proportion of relapse in continuously treated cases was 8 1 per cent and in those allowed rest intervals 14.3 per cent. Of the continuously treated patients, 60 per cent had comparatively little treatment (20 injections or less) while 66 per cent of the intermittently treated patients who had the higher incidence of relapse, had had comparatively heavy courses of 21 injections or more (40 per cent had over 40 injections) It appeared that smaller amount of treatment continuously applied yielded fewer relapses of all kinds than larger amount with rest periods or lapses.

With so much emphasis placed on the seriousness of lapse in the promotion of infectious recurrence, it is proper to emphasize as the fifth rule for the physician, (5) his responsibility in educating his patient and in holding him to a sufficiently prolonged course and in utilizing follow-up assistance if and when it is available. He should understand, too, that (6) infectious relapse is detected by actual physical examination with special emphasis on the mouth, anus, and genitalia rather than by serological tests. One should examine especially the lips, penis, scrotum and vulva. (7) Positive serological tests may warn of infectious relapse and confirm the diagnosis, but since they cannot be frequently applied, physical examination and instruction of the patient himself in the recognition of infectious lesions are the more important approaches. (8) Serological tests and stripped physical examinations,

to be of value in detecting relapse should, if anything be more frequently made after treatment is completed and the patient is put on observation than during treatment itself The opposite is common practice and this applies especially to the first two or three years of the disease. (9) Negative serological tests, as has been repeatedly emphasized are not proof of noninfectiousness, immediate or future. A negative Wassermann or Kahn reaction should not deceive the physician or patient into relaxing precautions (10) Treatment and time are the chief preventives of infectiousness. Since potentially infectious relapses occur overwhelmingly in the first two years of early syphilis, (11) sexual relations and intimate contact without absolute protection should be allowed only while the patient is under actual arsenical treatment. The duration of noninfectiousness when treatment is stopped before the twelfth injection of arsphenamine may not, apparently exceed one month.

Adequacy with Respect to 'Cure or 'Satisfactory Results."—Information on this subject is based on case material observed for not less than two, and upward to twenty years since the onset of the infection or the institution of treatment. Material of less than two years of observational control is fundamentally weak in its demonstration of the possibility of relapse since the first two years of infection are overwhelmingly those of relapse predisposition. On adequacy in the sense of satisfactory results," five groups of data will be quoted (a) Cooperative Clinical Group results in the treatment of early syphilis by a continuous alternating use of arsenical and heavy metal without rest periods, through sixty-five weeks of treatment observation (b) Johns Hopkins Hospital Syphilis Clinic (Padget spokesman) reporting on 551 patients completely re-examined five years or more after the termination of their original treatment for early syphilis (c) optimal treatment for early syphilis, one to twenty years observation Cannon reporting (d) a shortened twenty week system, Hood reporting on Johns Hopkins Hospital material (e) the five-day intensive intravenous drip arsenotherapy of syphilis (without the use of heavy metal) Leifer Chargin and Hyman, 1941 and Elliott, Baehr Shaffer Usher and Lough 1941 reporting

It is not possible at this time to offer more than speculative estimates on ten-day multiple syringe and ten to twelve-week intensive mapharsen-bismuth (Eagle-Hogan) systems which are under study

The Cooperative Clinical Group' standard treatment system experience indicates that for satisfactory results, treatment must be continuous and not intermittent or irregular and must combine the alternate use of an effective arsenical (mapharsen is not represented in this material) and bismuth. Striking reductions in effectiveness with occurrence of infection relapse progression of syphilitic manifestations, serologic relapse and seroresistance occur in all phases of early syphilis in which intermittence or irregularity is allowed to occur Disregarding the precise system of administration, the highest proportion of satisfactory result in seronegative primary syphilis was obtained with 10 to 19 injections of arsphenamine with accompanying heavy metal in seropositive primary syphilis, with 25 to 35 injections; in early secondary syphilis (seen in the first year) 20 to 29 injections. Higher rather than lower dosage of the arsphenamine is recommended. Failure to secure satisfactory result by 20 injections or less may be met by 10 additional injections, plus heavy metal, which may double the proportion of unsatisfactory outcomes reclaimed. The irreducible margin of failure in the treatment of early syphilis by older standards ranges from 4 per cent to 27 per cent, depending on method, stage at which treatment begins, adequacy of treatment during the first two years of the infection.

Johns Hopkins Syphilis Clinic, Padget reporting on a particularly valuable material because of the length of observation (over ten years in half the patients) showed clearly the importance to adequacy of treatment result, of the stage at which treatment is begun (82 per cent cure in seronegative primary syphilis, 68.8 per cent in secondary syphilis 58.7 per cent in early latent

syphilis). The poorest results, as in the Cooperative Clinical Group series, were observed among patients whose treatment was begun in the seropositive primary stage. Cure was obtained by 83.4 per cent of the patients whose treatment during the first six months was by a continuous system, and was increased to 90.4 per cent if treatment during the next six months was likewise continuous. It was shown that the final or "adequate" outcome depended in a directly quantitative fashion not only on the number of doses of the arsphenamine received, but also inversely upon the time span during which it was given. In other words, the more injections in the shorter time, the better the results. The development of early or intermediate relapse was found to be of grave prognostic significance.

Cannon found in a group of about six hundred patients treated with three standard arsphenamines, that arsphenamine 606 was incontestably superior to neoarsphenamine or silver arsphenamine, and that one year of regular and continuous treatment with the arsenical injections closely spaced (two- to three-day intervals in the first three to five weeks and at intervals of not less than one week thereafter) gave the highest proportion of satisfactory results. The difference between seronegative primary, seropositive primary and secondary syphilis was not more than 6 per cent.

The 20-20 Arsenical-Bismuth Simultaneous Injection Course. Hood Reporting.—This shortened system, not comparable because of longer intervals (weekly) with the twenty-six-week system of Circular Letter No. 74, utilizes weekly injections of mapharsen and simultaneous weekly intramuscular injections of an oil-suspended bismuth salt. The maximum period of observation (thirty-three months) was only sufficient to indicate that the proportion of unsatisfactory results in the form of seroresistance, serorelapse, clinical relapse and involvement of the central nervous system, amounting to 12.6 per cent of the observed series, was approximately that of unsatisfactory results obtained in early syphilis treated with other arsenical drugs and treatment systems. If confirmed by longer observation, such a treatment system should show how little rather than how much treatment is necessary to produce the average or so-called "standard" results which are so strikingly uniform throughout the entire range from five-day intravenous drip to sixty-five-week continuous combined therapy.

Massive Dose Arsenotherapy "Five-day Drip."—The two series, Leifer *et al.*, and Elliott *et al.*, the former with of course the longer series of observed cases, illustrate the following principles regarding adequacy:

(a) Curative results can be obtained with a trivalent arsenical alone (neoarsphenamine, mapharsen).

(b) Of the two, mapharsen because of its low reactivity is the drug of choice, and 1200 mg. administered in five days, the optimum dose.

(c) In seronegative primary syphilis, 90 per cent to 100 per cent pursue a satisfactory and uneventful course; without reference to type of drug or stage of disease, an aggregate of 81 per cent secured a satisfactory result in one five-day course and one retreatment in 15 cases raised the result to approximately 88 per cent for the entire series (Leifer *et al.*). Elliott and coworkers estimated their curative results as at least 85 per cent of all cases with early syphilis.

Adequacy of Treatment from the Standpoint of Service in the Armed Forces.—A tentative basis for evaluation proposed for admission of registrants with syphilis to the United States Army is as follows:

Registrants with (1) confirmed positive serologic tests for syphilis and no clinical manifestations of the disease or (2) with convincing histories of a trustworthy diagnosis of syphilis; or (3) of treatment for the disease on serologic or clinical grounds even though such evidence may possibly have been inadequate, may be considered for unlimited military service:

(a) Provided that a negative spinal fluid since infection and treatment has been reported from a trustworthy source; and

(b) Provided that in infections estimated to be of less than four years' duration, at least 30 to 40 arsenical and 40 to 60 insoluble bismuth or its equivalent injections with a minimum total of 75 injections have been given, with approximate continuity (no rest periods or lapses) during the first thirty weeks of treatment; and

(c) Provided that except as further qualified below in infections estimated to be of over four years' duration, at least 20 arsenical injections and 40 to 60 insoluble bismuth injections or its equivalent with a minimum total of 60 injections have been given in alternating courses, rest periods between consecutive courses not exceeding eight weeks, being allowable.

Evidence of duration of the infection shall be weighed by the examiner with due regard for the age, general venereal history and medical guidance of the registrant.

In infections of unknown duration it shall be presumed for classification purposes that those of registrants under twenty-six years of age are of less than four years duration, and over twenty-six years, of more than four years duration.

In congenital infections and in acquired infections of more than ten years' known duration, in which no clinical progression occurred since treatment was begun; and in which normal spinal fluid and negative physical examination is recorded not less than two years after treatment was terminated, the infection shall be regarded as quiescent, and the registrant eligible for unlimited military service provided the treatment in question shall have included 20 arsenical and 20 heavy metal injections.

For the determination of treatment, the signed statements of acceptable treatment sources administering it with total number of doses of each drug and approximate calendar dates of administration and available laboratory and clinical data shall be required as evidence.

The Prognostic Significance of Secondary and Serologic Relapse.—The following principles, based in the main upon the groups of material cited in connection with the *criteria of adequacy of treatment for syphilis*, are widely accepted. Early evidence of potentially unfavorable or relapsing course in an early syphilitic infection can be found in (*a*) failure of the primary or secondary lesions to heal under an arsenical therapy (*b*) continued presence of *Spirochaeta pallida* in the lesions after the employment of a known effective trivalent arsenical (these two groups constitute treatment resistant syphilis) (*c*) prematurely early reversal of a positive serologic reaction on the blood to negative (fourth to seventh week in seropositive primary or secondary syphilis) (*d*) failure of a positive serologic reaction on the blood to reverse to negative after the sixteenth week (in the intensive or five-day drip system reversal is ordinarily expected by quantitative tests between the tenth and eighteenth weeks after the institution of treatment but late secondaries may not reverse for many months even though "cured")

Cooperative Clinical Group results (Stokes and coworkers) (observation period too short) showed a relapse expectancy of 19 7 per cent including all forms, of which, when observed for more than six months, 12.1 per cent was mucocutaneous, 3 4 per cent asymptomatic neurosyphilis, 4 1 per cent symptomatic neurosyphilis, and 0.9 per cent cardiovascular syphilis.

The unfavorable prognostic significance of early and intermediate relapse was well brought out in Padget s series in which "cure was achieved in 73.2 per cent of 456 patients in whom no relapse was observed, whereas only 28.2 per cent of those sustaining an intermediate relapse achieved cure. Persistent seropositive reactions on the blood however occurred in 16 per cent of those who sustained no relapse, and in 10 3 per cent of those who underwent intermediate relapse. Late benign syphilis developed 8 times as frequently in relapsers as in nonrelapsers, cardiovascular syphilis 3.5 times as frequently neurosyphilis 6 times as frequently multiple late manifestations 7.5 times as frequently in relapsers as in nonrelapsers. The occurrence of weak positive serologic reactions on the blood appearing in the course of a series of negatives in treated early syphilis has been emphasized as of relapse significance by certain authors.

Significance of Seropositivity after Treatment Which Was Begun during Early Syphilis.—Certain aspects of relapsing and persistent seropositiveness after treatment begun in early syphilis have been indicated above *Broadly* speaking Padget s experience indicated that a residue of 14.0 per cent persistent serologic positiveness would appear in a series of early syphilitics on whom the otherwise satisfactory results he described had been secured In these cases there would be no manifestations such as abnormal spinal fluid cardiovascular disease visceral disease and so forth to accompany the per

sistent seropositiveness. The inclination would be, therefore, to rate it in these cases as without significance. Broadly speaking, persistence of a positive serologic reaction on the blood of early syphilitics under treatment by the older standard continuous systems was an indication of presence of asymptomatic neurosyphilis, and called for an examination of the spinal fluid immediately The more intensive foreshortened treatment systems seem so materially to have reduced the likelihood of the occurrence of asymptomatic neurosyphilis that the neurosyphilitic significance of persistent seropositivity will probably be greatly reduced by their use. In addition to asymptomatic neurosyphilis, syphilis of the cardiovascular system often coming to recognition five or more years after the cessation of treatment may be included in the prognostic significance of seropositiveness of a persistent type in early syphilis.

Moore and Padget in their nalysis of seroresistant syphilis (early) emphasize the seriousness of seroresistance in early syphilis and its relatively lesser significance in late syphilis. Twenty-three per cent of their seroresistant group sustained infectious relapse as against 5 per cent who secured prompt serologic reversal. Neurosyphilis occurs in 31 per cent of the seroresistant cases, but in only 16 per cent of those who sustain prompt reversal.

The Prevention of Cardiovascular Syphilis.—This is still the *terra incognita* of modern syphilology and the studies thus far summarized have thrown relatively little light upon it. Langer and others have attributed the increase in the incidence of aortitis since 1918 t the use of arsphenamine in the treatment of syphilis but our material on early syphilis, so far as it goes, fails to substantiate this belief, the incidence of recognizable aortic lesions not increasing materially in the period studied. It is, of course true that our study does not extend forward into the period of maximum recognition of this form of syphilis. Moore Danglade and Reisinger in considering Langer contention, believed that the apparent increase coincident with the use of arsphenamine in treatment is due rather to more accurat pathologic study with increasing knowledge of microscopical appearance of aortic syphilis. Progression of cardiovascular syphilis in spi of various methods of treatment occurred in 0.8 to 1.8 per cent of our patients. Warthin observation, which placed the incidence of aortic syphilis in syphilitic adults between 1909 and 1919 t 27.6 per cent, and between 1919 and 1929 at 26.8 per cent, further supports the view that raphenamine is not responsible for the apparently increasing incidence observed by Langer

THE PREVENTIVE TREATMENT OF EARLY NEUROSYPHILIS

The treatment of neurosyphilis is considered as a unit under Chapter XX. It must never be forgotten, however that the effective treatment of neurosyphilis rests on its early detection, and on the vigorous, determined and systematic application to early systemic syphilis of the methods described in this chapter Inadequate treatment is worse than no treatment since the incubation period of clinical neurosyphilis in the inadequately treated individual (11.6 years) is six years shorter than in those who receive no treatment (17 6 years) prior to the time their neurosyphilis became clinically recognizable (Kemp 1940) Where definite symptomatic neurosyphilis especially involving the cranial nerves is apparent when the patient comes under treatment, the necessity for bismuth preparation has been repeatedly emphasized and quarantine should be enforced, so to speak, if the patient is infectious, while this preparation is being carried out. The Cooperative Clinical Group studies indicated that a certain proportion of early neurosyphilis is inevitable in spite of either much or little treatment, this proportion amounting to from 6 to 7 per cent of patients. It is none the less true that by far the larger part of early asymptomatic neurosyphilis responds in the course of standard effective treatment. In 1747 spinal fluid examinations in the Cooperative Group series it will be recalled that 32.7 per cent were abnormal in the Wassermann test or cell count or both, and 67.3 per cent were negative It was found that regard

less of the system of treatment appraisal a great deal of effect in reversing slightly abnormal spinal fluids was produced even by a small amount of treatment. On the other hand this effect was much less striking with respect to the more markedly abnormal fluids, including those with positive serologic reactions and especially those with paretic or Type III formulae.

The difference between slight abnormality and marked abnormality is especially apparent in the paretic formulae. Under both systems of appraisal it is at least twice as difficult to reverse a paretic as any other markedly abnormal fluid under little or much treatment (little treatment, 30.8 per cent reversed *vs* 69.2 per cent which failed to reverse and much treatment 38 5 reversed *vs* 61.5 failed to reverse) This is true even when tryparsamide and malarial therapy results are included

Fig 445

THE DECALOGUE OF PREVENTION OF EARLY NEUROSYPHILIS

1 Never give single arsenical injections, short courses (3 t 4 injections) or mercury by mouth. Give 8 to 10 arsphenamine injections in the first course
2. N rest intervals. Have the patient on one or another effective form of treatment continuously the first year
3. Examine the spinal fluid before the end of the first year and in any case before rest period. Have the puncture correctly done, so that there will be no confusion about the cell count (no blood contamination)
4 Take slight rises in cell count (above 7) seriously especially if found after the patient has had some treatment.
5 Th appearance of paretic formula is serious. If it does not respond within eight weeks to intensification of treatment, the fluid examination being repeated, it calls for tryparsamide or fever therapy The later in the course of systematic, energetic treatment that this formula occurs, the more serious it is.
6 A esistant positiv blood serological test must be thought of as suggestive of early neurosyphilis, examine the spinal fluid.
7 A negative blood serological test does not make spinal fluid examination unnecessary
8. When possible hav the fundus of the eye examined early for signs of nerve involvement.
9 Signs in the fluid usually precede symptoms from the nervous system. Do not expect t detect early neurosyphilis by relying on reflex changes, abnormal pupils, etc. These are late neurosyphilis.
10 Remember that headach is significant but not conclusive and that spinal fluid may be normal, but the patient have or later develop, neurosyphilis.

Treatment-fast spinal fluids resisting all efforts to reverse them appeared in 1.3 per cent of the total number of patients seen and 5 8 per cent of the 730 abnormal spinal fluids. This is almost identical with the incidence of paresis from the clinical side in Bruusgaard s postmortem series of spontaneously evolving, untreated syphilitic patients.

It appeared finally that more irreversible spinal fluids developed among seropositive primary early secondary and delayed secondary cases than among seronegative primary cases, the per cent being 0 0 seronegative primary 1 0 seropositive primary 1.3 early secondary and 6 2 delayed secondary Thus it appears again that the institution of treatment in the seronegative primary stage has the most significant advantage of reducing the probability that the nervous system will be irremediably involved.

In Fig 445 are summarized the preventive principles applicable in early neurosyphilis. Details as to procedure are included in the chapter on Neurosyphilis.

CHAPTER XV

THE LANDMARKS OF LATE SYPHILIS ON SKIN AND MUCOUS MEMBRANES

Familiarity with the cutaneous lesions and scars of late syphilis is of great value to the diagnostician in that it serves in the first place to provide "suspicion arousers" in the case of patients whose general medical condition does not suggest syphilis, and, in the second place not infrequently provides sufficient evidence to clinch the diagnosis in the absence of that almost universal criterion of reference the positive blood serologic reaction. This latter function will, of course, vary in importance with the serological technic employed It is only fair to say that the proportion of negative blood serologic reactions observed in the ensuing case presentations is probably higher than we would now obtain with the Kolmer technic or other sensitive procedure. But the fact remains that the first, the chief or the only clue to a latent syphilitic infection or rather a relatively quiescent one, may lie in some lesion of skin or mucosae to which the patient has given little or no attention, and that a cutaneous or mucosal lesion, correctly interpreted may identify a syphilitic infection which would otherwise be missed because of anomalous signs or a negative serology

In the period of latency following the florid secondary eruptive period, the syphilitic infection following its natural course, or failing arrest by treatment, is quite prone to develop cutaneous lesions. At first these present the disseminate distribution and relatively nondestructive character of the secondary eruption. These we have spoken of as "recurrences" rather than as typical late lesions. As time elapses the recurrences become more solitary and more destructive, taking on the characteristics of gummatous infiltration with a combination of paucity of organisms and excessive reaction, which may be part allergy part vascular change, but which none the less has a very distinct clinical identity In the pathology of these lesions one sees the granuloma *of syphilis most typically portrayed—the giant cells, the lymphocytic infiltration*, some epithelioid and fibroblastic proliferation, peripheral obliterative endarteritis of the finer capillaries and arterioles, and central softening and necrosis. In the earlier stages of the infiltration the picture of profuse round-cell infiltration may suggest, apparently round-cell sarcoma. In the later fully developed granuloma the picture may to the inexperienced, strongly suggest tuberculosis until all the clinical evidence is at hand.

Atrophic and Pigmentary Syphilids.—The general rule that secondary syphilids involute without trace of their presence has definite exceptions in the atrophic and pigmentary residua, which are among the most distinctive lesions of the latent period of the disease, and the most helpful landmarks in the identification of infections which might never otherwise attract attention. The chief source of residual changes is the loss of pigment-producing power in certain cases of macular and maculopapular syphilids, sometimes accompanied in certain predisposed individuals, on involution, by a faint depression or macular atrophy at the site of the preceding lesion. The atrophy or the

less of the system of treatment appraisal a great deal of effect in reversing slightly abnormal spinal fluids was produced even by a small amount of treatment. On the other hand, this effect was much less striking with respect to the more markedly abnormal fluids, including those with positive serologic reactions and especially those with paretic or Type III formulae

The difference between slight abnormality and marked abnormality is especially apparent in the paretic formulae Under both systems of appraisal it is at least twice as difficult to reverse a paretic as any other markedly abnormal fluid under little or much treatment (little treatment, 30.8 per cent reversed *vs* 69.2 per cent which failed to reverse and much treatment 38.5 reversed *vs* 61.5 failed to reverse) This is true even when tryparsamide and malarial therapy results are included

CHAPTER XV

THE LANDMARKS OF LATE SYPHILIS ON SKIN AND MUCOUS MEMBRANES

Familiarity with the cutaneous lesions and scars of late syphilis is of great value to the diagnostician in that it serves in the first place to provide "suspicion arousers" in the case of patients whose general medical condition does not suggest syphilis, and in the second place not infrequently provides sufficient evidence to clinch the diagnosis in the absence of that almost universal criterion of reference the positive blood serologic reaction. This latter function will of course vary in importance with the serological technic employed it is only fair to say that the proportion of negative blood serologic reactions observed in the ensuing case presentations is probably higher than we would now obtain with the Kolmer technic or other sensitive procedure. But the fact remains that the first, the chief or the only clue to a latent syphilitic infection or rather a relatively quiescent one, may be in some lesion of skin or mucosae to which the patient has given little or no attention, and that a cutaneous or mucosal lesion, correctly interpreted, may identify a syphilitic infection which would otherwise be missed because of anomalous signs or a negative serology

In the period of latency following the florid secondary eruptive period, the syphilitic infection following its natural course, or failing arrest by treatment, is quite prone to develop cutaneous lesions. At first these present the disseminate distribution and relatively nondestructive character of the secondary eruption. These we have spoken of as "recurrences" rather than as typical late lesions. As time elapses the recurrences become more solitary and more destructive, taking on the characteristics of gummatous infiltration, with a combination of paucity of organisms and excessive reaction, which may be part allergy part vascular change, but which none the less has a very distinct clinical identity In the pathology of these lesions one sees the granuloma of syphilis most typically portrayed—the giant cells, the lymphocytic infiltration, some epithelioid and fibroblastic proliferation, peripheral obliterative endarteritis of the finer capillaries and arterioles, and central softening and necrosis. In the earlier stages of the infiltration the picture of profuse round cell infiltration may suggest, apparently round-cell sarcoma. In the later fully developed granuloma the picture may to the inexperienced strongly suggest tuberculosis until all the clinical evidence is at hand.

Atrophic and Pigmentary Syphilids.—The general rule that secondary syphilids involute without trace of their presence has definite exceptions in the atrophic and pigmentary residua, which are among the most distinctive lesions of the latent period of the disease, and the most helpful landmarks in the identification of infections which might never otherwise attract attention. The chief source of residual changes is the loss of pigment-producing power in certain cases of macular and maculopapular syphilids, sometimes accompanied in certain predisposed individuals, on involution, by a faint depression or macular atrophy at the site of the preceding lesion The atrophy or the

depigmentation may appear separately and without the necessary intervention of a previous visible syphilid The favorite site for the macular depigmen

FIG. 446 —SUSPECT PIEBALD NECK.

The history of this patient, who presents typical leukoderma colli, illustrates number of interesting diagnostic points. He entered the clinic in a state of stupor and disorientation bordering on coma. According to his escort he came for failing vision, of sudden onset, with diplopia. An xtreme grade of ataxia had developed in two days time. A genital scar was present, but no history of infection was obtainable. A year before entry h had had "smallpox. A superficial trophic scarring, shown in Fig. 402, bore testimony t the fact that his secondary syphilid had been diagnosed variola.

On examination it was found that the patient had left homonymous hemianopsia, an acut recent paralysis of the left internal rectus, positive blood Wassermann reaction, and neurological signs of a rapidly progressive meningeal and vascular process in the nervous system hich "looks like CNS lues. The positive Wassermann reaction sent him to the syphilologist, who then identified the pathognomonic sign of leukoderma colli, and identified the supposed variola scarring as the atrophic macula syphiloderm. The macular atrophy is not true scar of the varioliform type It is rather thinning of the skin without marked change in the appendages, and show itself quit as often by bulging t the site of the atrophic macula as by depression. It cannot be denied, however that the scarring of variola and the macular atrophy of syphilis may t times closely resemble each other I this case the slow course of the smallpox, the purely macular and papular character of the lesions, and the absence of the distinctive variola prodromes and sequelae of a constitutional type might have suggested the correct diagnosis in patient with so profuse an eruption.

Neurologically speaking, this patient presents the encephalomyelitis of early syphilis of the nervous system The process is apparently primary and not neurorecurrence due to inadequate treatment. While the response of the patient to treatment was good, he never entirely recovered normal mentality the so-called psychic scar of Collins persisting (see Chapter XX). The spinal fluid t entrance showed the following findings

WR /// 0.5 and 0.4 cc., Nonne positive 80 lymphocytes.

The earlier recognition of the pigmentary syphiloderm or the papular secondaries might have forestalled so serious process in the nervous system.

tation is the side of the neck the macular atrophy occurring on the back and flanks

Syphilitic Leukoderma.—"Syphilitic leukoderma" as the pigmentary disturbance is called or "leukoderma colli" when the changes occur as they

most frequently do upon the neck and shoulders, is a highly characteristic lesion, with almost pathognomonic value in diagnosis. The best imitation of it is said to be produced by the pigmentation accompanying the *involution* of an extensive psoriasis under arsenical medication. This is, in our experience, rarely confusing. Chloasma, the patchy hyperpigmentation of the forehead, face, and neck about the ears, in women with asthenia and uterine disturbances, does not show the definite macular character or "spotting" of true

FIG. 417.—SYPHILITIC LEUKODERMA FOLLOWING INVOLUTION OF A SYPHILID UNDER TREATMENT.

This is an example of syphilitic leukoderma considerably more extensive than mere leukoderma colli. It developed during the involution under treatment of maculopapular syphilid, associated with mucous patches and condylomata. The macular depigmentation on more or less general hyperpigmentation extends to the shoulders, back, and arms. Over the lower thorax and lumbar regions the macular depigmentation passes over into the atrophic macular syphiloderm. In extensive syphilitic leukoderma one should bear in mind the differentiation from vitiligo, patchy depigmentation with slight marginal hyperpigmentation involving large areas, having more or less of geographic contour rather than the appearance of smaller scattered macules upon darker background.

The history of this case presents several points of interest from the standpoint of diagnosis.

The patient was married, thirty-three years of age, her husband salesman. Two months before entry into the clinic she had had an "ulceration" involving the labia, which was painful, not associated with lymph node inflammation, and cleared up in two weeks. She did not see physician at this time. As the labial lesions cleared up, an eruption began t appear on the neck, which extended to the entire body with the exception of the scalp, palms, and soles.

When the eruption first appeared she stated that she visited physician who told her it would soon pass off. No further inquiries were made, apparently.

One week before coming to the clinic she visited physician in neighboring large city who took blood test, told her the result was negative, and gave her white lotion.

The patient was positive that neither physician had inquired about the genital lesion, nor had either examined her mouth, or in fact, given the condition more than casual inspection.

A darkfield examination of mucous patches about the labia when she entered the clinic showed *Spirochaeta pallida*. The Wassermann reaction was also positive.

syphilitic leukoderma, but is a vague, irregular patchy semigeographic affair of fawns and browns, a discoloration rather than a white spotting with definite oval depigmented macules. Vitiligo, the depigmentation in large geographic areas, whose cause is entirely unknown, need not be a source of confusion. The geographic contours and large individual depigmented areas are entirely different from the close-set but discrete macular depigmentation of syphilitic leukoderma. The question as to whether vitiligo or better leukoderma m

general can be regarded as frequently of syphilitic origin has been considered by a number of authors, whose opinions, with observations of his own, are *summarized by John Lane. Unless the term "leukoderma" is used in the* French sense, to include syphilitic pigmentary changes, the instrumentality of syphilis seems to be small The use of the term vitiligo for the general condition will assist in preventing confusion. The erythema from hot or cold applications produces a type of retiform coarsely meshed pigmentation (Fig. 448) whose history will usually distinguish it, and which lacks the definite macular lesions that may usually be found in a true syphilitic leukoderma. The Juliusberg type of parapsoriasis sometimes produces a pigmentary change (Fig 295) quite suggestive of syphilitic leukoderma, which we have known to deceive careful observers momentarily but which rarely confuses on further study of the eruption as a whole.

Ehrmann and Wertheim have proposed the most recent theory of the origin of syphilitic leukoderma in the form of functional inhibition of the pig

Fig. 448 —Retiform pigmentation of the neck caused by the application of heat t swollen glands. The history of repeated or protracted hot or cold applications usually eliminates this condition from differential diagnosis Note the coarseness of the mottling which is entirely different from the macular depigmentation of syphilitic leukoderma.

ment cells of the basal layer of the epidermis within the macular or papular lesion produced by the presence of *Spirochaeta pallida* They find that leukoderma is present in abortive form in most patients with macular and papular syphilids, but that the leukoderma of the syphilitic lesion is only brought out by the exposure of the rest of the skin to light with resultant contrasting hyperpigmentation The functional disability disappears after a time permitting the restoration of the skin to normal The occurrence of a leukoderma during involution under treatment without special exposure to light, however seems to argue that there are other factors besides light, including a possible hyperpigmentation due to arsenic in some cases The combination of hyperpigmentation, depigmented macules, and macular atrophy is well shown in Fig 447

Recurrent and Late Syphilids of the Skin.—Didactic teaching of the morphology and diagnosis of late syphilids by laying too much emphasis upon mere names and upon disparateness rather than fundamental unity has, we

Fig. 449.

THE TEN BASIC PHYSICAL CHARACTERISTICS OF LATE SYPHILIDS

1. Solitary character; or at least the presence of few lesions.
2. Asymmetry; though by no means invariable.
3. Induration: deep palpable infiltration.
4. Indolence; relatively low-grade inflammatory process.
5. Arciform configuration; borders polycyclic or forming segments of circles, both in the individual lesion and in the configuration of a group of lesions.
6. Sharp margination of lesions; in ulcers, "punched out" appearance.
7. Tissue destruction and replacement with or without ulceration.
8. Tendency to central or one-sided healing with peripheral extension.
9. Scar formation; superficial *atrophic* (thin and wrinkled) *non-contractile*. The scar retains the arciform configuration of the original lesion.
10. Peripheral hyperpigmentation of a rather persistent type.

FIG. 450.—THE "SHOWER" OF NODULAR LATE RECURRENCES.

This lesion might be designated figuratively as a "shower" of recurrences. The scar produced by such a lesion is shown in Fig. 468. All the essential characteristics of a late syphilid are present except the arciform configuration. After the involution of such a lesion and, in fact, during its activity differentiation from a papulonecrotic tuberculid and from the scars of acne necrotica might be necessary. The zigzag lines of pigmentation, which show that some of the individual lesions have "traveled," eliminate the two possibilities mentioned.

This infection was of four years' duration and began with a chancre in the vagina. At the time of examination the lesion pictured was of one year's duration, and the chest, upper arms, and chin were involved. This lesion partakes to some extent then of the wide distribution of a secondary lesion with the physical characteristics of a late syphilid.

believe, befogged the relatively simple essentials of diagnosis in a cloud of nomenclature. We shall accordingly not discuss the nomenclature of various

Fig 451 —This is typical annular papular recurrence during the course of an otherwise practically quiescent syphilitic infection. Note the arciform and polycyclic grouping of papules in the upper lesion and the scalloped contour of the lower The faint pigmentation of the center is also pparent. The border is faint brownish-pink color and definitely though not deeply indurated Lesions of this type may be much more profuse and widely scattered.

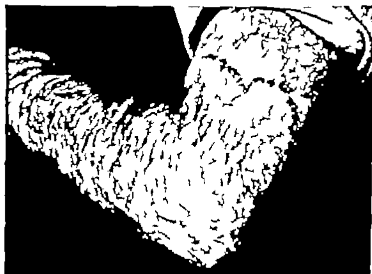

Fig. 452 —This is typical psoriasiform circinate papular recurrent syphilid in patient with syphilitic aortitis and positive blood Wassermann reaction. Note the faint pigmentation toward the convex side of the lesion which indicates the direction of extension as being up the arm. The extensor surface of the forearm, which presents lesions somewhat resembling tubercalid in appearance is show in Fig. 543 The arciform configuration is the main clinching point in the morphological diagnosis of the syphilid.

types of late syphilids beyond the division into nodular nonulcerative forms, nodulo-ulcerative types, and simple gumma. The nodular types are gummatous infiltrations which do not break down. Involution, while it may occur without leaving a trace, is usually accompanied by some degree of atrophy and pigmentation. There may or may not be slight scaling and what appears to be scale may at times be found on closer examination to be crusting over

FIG. 453.—THE PSORIASIFORM LATE SYPHILID.

Late syphilids may be of extreme superficiality and atypical configuration and leave so little in the way of scarring and atrophy that the objective diagnosis from the lesion may be momentarily in doubt, or have to depend on collateral evidence. This is especially the case in what might be called the psoriasiform late syphilid, of which Fig. 453 is an example. A vital element in the differentiation is the search for the slightest sign of erosion or ulceration, and in the careful distinguishing of *crust* from *scale*. At several points in the large irregular patches the dark brownish points of crusting are visible, and removal of these crusts discloses superficial but definite erosions, not the smooth shiny bright red surface of the scaling psoriatic papule. Compare the scale and structure of the psoriatic lesions in Fig. 455. The syphilid was so superficial that it had produced almost no atrophy, but the residual pigmentation in the areas over which the infiltration has wandered is very apparent. Residual pigmentation may occur in psoriasis, but it is usually the result of treatment, especially with chrysarobin, arsenic, or the *roentgen-ray, and is not so sharply defined.*

In history and diagnosis this case presented no distinctive features. The Wassermann reaction was positive, the infection of perhaps thirteen years' duration. The psoriasiform lesions were unusually extensive, involving most of the trunk and legs. The differential diagnosis of psoriasis and syphilis is further discussed in Figs. 454, 456, 457.

a superficial ulcer. Nodulo-ulcerative types may present both nodular lesions and ulcerative breakdown in varying proportions. The infiltrative phase may be shortlived and inconspicuous, and the ulcerative lesions multiple and relatively deep. The configuration both of this type and the preceding is extremely important, and as much attention should be paid by the examiner to the gross appearance and "picture" of the lesion as to its individual units.

Fig 431 —This is typical annular papular recurrence during the course of an otherwise practically quiescent syphilitic infection. Not the arciform and polycyclic grouping of papules in the upper lesion and the scalloped contour of the lower The f int pigmentation of the center is also pparent. The border is faint brownish-pink color and definitely though not deeply indurated. Lesions of this type may be much more profuse and widely scattered.

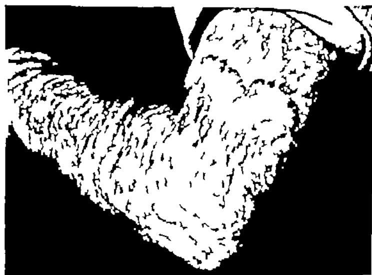

Fig 432 —This i typical psoriasiform circinat papular recurrent syphilid in patient with syphilitic aortitis and positive blood W ssermann reaction. Not the faint pigmentation toward the convex side of the lesion which indicates the direction of extension as being up the arm. The extensor surface of the forearm hich presents lesions somewhat resembling tuberculid in ppearance is show in Fig 543 The arciform configuration is the main clinching point in the morphological diagnosis of the syphilid

Fig 435.—Psoriasis of the back for comparison with Figs. 433 and 437

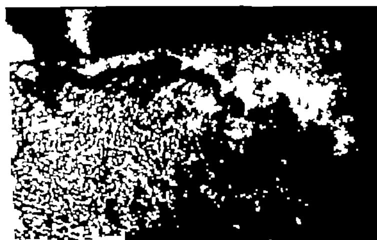

Fig. 436.—This figure is introduced at this point for contrast with Fig. 437 Note the difference between the two types of border While both are arciform, that of the syphilid (Fig 437) is the more pronounced and the more coarsely nodular The border of the above lesion is composed of miliary nodules. Note too the persistence of activity in the center The lesion shown above is tuberculous, and the miliary nodules are individual tubercles. The persistence of the process in the scar is more distinctive of tuberculosis. The differential diagnosis of tuberculosis and late syphilis of the skin is discussed further in Figs. 473, 480.

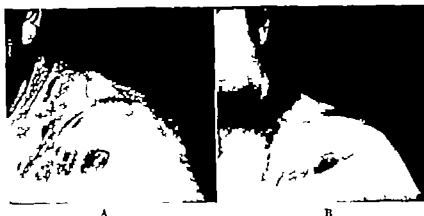
the actual arciform lesion. He reasoned by analogy that the allergic, or *Umstimmung* type of tissue reaction in late syphilis would make it possible for relatively small number of organisms to produce particularly choice and well delineated examples of this immunobiologic reaction resulting in circinate and arciform configuration.

In fact, it is precisely because he fails to see the shape and arrangement of the parts of a late syphilid that the average observer makes mistakes. He pays too much attention to the fact of nodulation or crusting or ulceration, and does not notice the pathognomonic geography of the process. Scar formation, always highly significant and always demanding explanation, often escapes undetected in the interest aroused by the active part of the process. The solitary "gumma," a relatively less important lesion of late syphilis, has

FIG. 457.—A TYPICAL CIRCINATE NODULAR LATE SYPHILID.

The bearer of this gaboard was wholly unaware that anything ailed his back. He came for intermittent stomach trouble of five years' duration, which on the completion of his medical examination proved to be due to a duodenal ulcer.

This eruption occurs upon the seborrheic area of the back, and should be compared with Fig. 480 (seborrhea petaloides) to assist in differentiation, and also with Fig. 455 (psoriasis). The essential lesion was a pink *indurated* papule with a marked tendency to brownish pigmentation. Some of the circinate groupings were slightly scaling, but there was no suggestion of the abundant imbricated silvery scale of psoriasis. The lesions left scars, superficial, atrophic, and preserving a record of the configuration of the involuted lesions.



Compare the coarsely papular or nodular border with that in Fig. 456.

Any one of these indurated, arciform, nodular, scar-producing lesions would have made a 90 per cent diagnosis of syphilis, regardless of the Wassermann reaction. The patient had had gonorrhea seventeen years before but could give no history of syphilis. He was seen before organized work in the Section of Dermatology was begun and further records are incomplete. The response to treatment was prompt.

The indurated arc with scars does not need ulceration to arouse the strongest suspicions of syphilis.

received most of the emphasis in teaching in the past, and is the average practitioner's conception of a late syphilid. It develops as a cutaneous or subcutaneous tumor, at first pinkish, then becoming rapidly a darker red to bluish tinge. General softening occurs or a minute punctum may form at the highest point, whose rapidly extending margin permits a discharge of grumous pus, or more often discloses a yellowish tough rubbery slough which on final separation leaves a granulating ulcer. The gumma may occasionally involute

without breaking down. These three types, then the papular or nodular the nodulo-ulcerative, and the simple gumma, are the distinctive groups of late cutaneous syphilids.

A B

Fig 438.—A classical syphilid of the nodulo-ulcerative type. The lesion was of years' duration and had been treated locally Note how much more apparent the base morphological features are hen the lesion begins to clean up and heal. The lack of definition in the earlier photograph is due to eczematous changes from local treatment.

This patient had had 12 pregnancies, one miscarriage, nd three stillbirths without the fact arousing suspicion enough t lead to Wassermann test at the time she sustained an operation in 1913.

Fig. 439.—A typical ery superficial nodulo-ulcerative syphilid of the neck. The patient could give no history of syphilis, but had had gonorrhea nine years before. The tongue showed sclerosing glossitis (see Fig. 524) The Wassermann reaction as positive. This patient came to the clinic for duodenal ulcer syndrome and had no notion that he had syphilis.

The Basic Physical Characteristics of Late Cutaneous Syphilids.—Figure 440 summarizes the physical characteristics of the late syphilid. No one of the ten individual items can be accepted alone, but the combinations often achieve pathognomonic value and quite outrank the blood serologic test in their diagnostic worth All granulomatous processes in the skin share some of these

characteristics in varying degree. In the diagnosis of syphilids the combination of induration with arciform or polycyclic configuration is perhaps the most

Fig 460 —The solitary gumma is the classical late or tertiary syphilid of the older medical texts and teaching, and the only one which arouses the suspicions of many physicians. It is a comparatively uncommon lesion, which begins as a small nodule, often at site of trauma, especially over the bones of the skull, the presternal, the supraclavicular and the pretibial regions. This nodule grows t tumor of variable size, which has rubbery elastic feel and often dusky color In this condition it is often taken for a malignant neoplasm or tuberculosis (see Figs. 434, 478) nd cut into for diagnosis, or excised outright. This clinical diagnosis of malignant neoplasm is at times apparently confirmed by a report of round-cell sarcoma from the pathologic laboratory Especially is such diagnosis apt to be made if the lesion is young Older gummata show such marked inflammatory changes and fibrosis that they are recognized as granulomata. The danger is that if they contain giant cells, as they well may the inexperienced will regard them as tuberculous.

Both the appearance of this ulcer and its location over the claviculo-acromial articulation at once suggest syphilis. The findings and history in this case presented the following outstanding points in diagnosis.

1 The patient s shoulder lesion was not her chief complaint. She came for soreness at the base of the tongue and in the throat following extraction of tooth year before. The patient and her physician had both recognized that these lesions were ulcers, but she had received only gargles and mouth-washes, and teaspoonful of some liquid medicine of unknown type three times daily for three months.

2. She had had one miscarriage 2 children had died in infancy and she had 2 living healthy children. She recalled that her husband had taken rubbing treatment before marriage, thirteen years ago.

3. Her first Wassermann reaction in the clinic was egative

4. Three subsequent tests ere positive

5. The spinal fluid was negative.

6. The living children showed no evidence of the disease. The father would not report for examination.

7 The patient disappeared from observation and t eatment after her third arsphenamine injection.

8. Th shoulder lesion in this patient was regarded carbuncle.

"Small round-cell sarcoma, tuberculosis, and bscess" or carbuncle" are the masquerades in diagnosis of more than one gumma.

important, and the trained palpating finger is repeatedly called into use by the expert in differentiating such lesions. An indurated arc or circle or an arci-

form or scalloped chain of fleshy papules should arouse the most insistent suspicion. Similarly the arciform grouping of ulcers and scallops or arcs in

FIG. 461 —THE TYPICAL NODULO-ULCERATIVE SYPHILID—WASSERMANN NEGATIVE.

This lesion is the ideal nodulo-ulcerative late syphilid. It presents every single one of the ten fundamental characteristics. It is the only lesion on the body (speaking of the group of ulcers as the "lesion") It is unilateral, indurated, indolent. Note that the surrounding skin in the direction of extension is practically normal. There is no suggestion of metastatic nodule formation beyond the periphery as in lupus vulgaris, no diffuse inflammatory areola, as in ecthymatous processes. The arc is perfect, the margin sharply defined, the lesion obviously destructive. Healing has been central, the lesion spreading fan-shaped toward the periphery The non-contractile character of the scar is evidenced by the absolute lack of distortion of face over which an ulcerative lesion of such area and depth has passed. Even the crows feet at the outer canthus of the eye are absolutely unaltered by tension. The hyperpigmentation of the periphery of the scar is less apparent than in some syphilids, but can be recognized along the healed margin. The lesion had begun as nodule ten months before the patient came to the clinic.

When the lesion was three months old the patient had consulted physician, but had been lost track of He had had his suspicions aroused and had had Wassermann reaction taken, which was negative. The patient then disappeared from observation, and when seen again the lesion had reached its present size and configuration. A diagnosis of *lupus vulgaris* had been made, and she had received one roentgen-ray treatment, without any effect on the lesion.

It is evident that the negative Wassermann reaction had eliminated syphilis in the mind of the physician who first saw this case and who subsequently made diagnosis of lupus vulgaris (tuberculosis cutis) The correctness of the negative Wassermann result was confirmed by our own findings. This patient has never had positiv Wassermann reaction on th blood in more than two years' observation. Her spinal fluid is negative. There is no evidence of syphilis in any of the viscera or special sense organs, and the neurologic examination is negative. The only point in her history suggestive of syphilis is the occurrence of four miscarriages following the birth of four living healthy children.

A positive Wassermann reaction is in no way necessary to the diagnosis of syphilis from lesion such as this, although it would be valuable confirmation. Aside from the fact that it is perfect syphilid, the diagnosis of lupus vulgaris is eliminated by the absence of tubercles (" apple-jelly" nodules) by the rapid course, the non-contractile scar and the immediate and complete response to arsphenamine and inunctions.

the margin of thin atrophic scars should receive the most careful consideration and checking. The noncontractile scar of the superficial late syphilid while imitated at times by such processes as the dry erythematous type of tuber

culous and the scars of the tuberculous lesion known as erythema induratum (Fig 556) is none the less an important and distinctive feature. It is remark

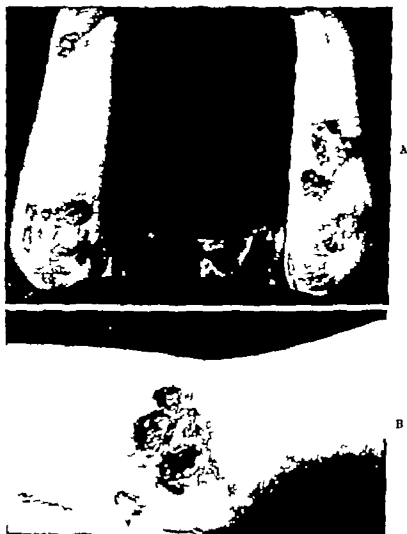


FIG. 462.—ACCORDING TO THE PATIENT'S STATEMENT PHYSICIANS LOOKED AT THE CONDITION SHOWN IN A AND CURED WITH VACCINE, APPARENTLY UNDER THE IMPRESSION THAT IT WAS EITHER FURUNCULOSIS OR ECTHYMA. HAD HE SEARCHED FOR THE YOUNGEST LESION SHOWN IN B, HE WOULD HAVE ENCOUNTERED A TYPICAL PICTURE OF THE ULCERATIVE LATE SYPHILID WITH ALL THE ESSENTIAL CHARACTERISTICS FOR A DIAGNOSIS.

The clover-leaf configuration produces the polycyclic border; the process extends peripherally as it heals centrally; there is distinct pigmentation along the involuted edge; the scar is not sufficiently large as yet to show all the orthodox characteristics. The ulcers have a typical punched-out appearance. *The characteristics of the scar are better seen in the ulceration on the extensor surface shown in A.*

The Wassermann reaction was strongly positive. It had apparently never been taken prior to her entry into the clinic.

able how even a deeply ulcerative syphilid may wander about the face (Figs. 500, 501) invading even the eyelid without producing ectropion, while a more

remote tuberculous ulcerative process (Fig. 494 B) may evert the lid and even distort the mouth and lips. The scar of blastomycosis presents a similar and diagnostically important tendency to contracture (Fig 505) The periph

FIG. 483.—THESE TWO PHOTOGRAPHS ARE SHOWN TOGETHER TO ILLUSTRATE THE MEANING OF THE TERM "CONFIGURATION" AS APPLIED TO THE MARGIN OF ULCERS RATHER THAN TO GROUP OF LESIONS.

The upper ulcer has the arciform or polycyclic configuration characteristic of syphilitic gummatous ulcer. The lower is irregular with jagged margin, undermined at certain points, crusted and ecthymatous at others, and with gangrenous remnants of tissue about the base. Ulcers of this type may result from local bacterial invasion (as in diabetes) or hematogenous dissemination of pyogenic organisms. The process may at times be tuberculous in character (approaching the type of erythema induratum) It is important t remember that ulcerative processes about the long bones may produce local osteoperiostitis or be the sequels of involvement of the bone, so that the mere finding of periostitis by roentgen-ray in conjunction with an ulcer over bone is not proof that the process is syphilitic.

The history of the patient with the gummatous ulcer illustrates the way in which modern treatment methods, improperly carried out, are altering the clinical landmarks of syphilis. (See Chapters I and XIV)

eral hyperpigmentation of the late syphilid may be simulated at times by the effect of vascular stasis in chronic ulcers of the lower extremity but the pigmentation of vascular stasis tends to be diffuse and extensive, the typical pigmentation of the syphilid to be limited to the margin of the scar forming

a narrow band. Tuberculids of the leg (erythema induratum) may show this marginal pigmentation of their scars, but the scars of other granulomatous

FIG. 464.—THE SITUATION OF ULCERS ON THE LOWER EXTREMITIES HAS OCCASIONALLY CONSIDERABLE SUGGESTIVE VALUE IN DIAGNOSIS.

No invariable rule exists, but the following rules of thumb are helpful

1 Ulcers over the upper two-thirds, especially of the anterior and outer aspects of the tibia, are more apt to be syphilitic than ulcers of the inner lower third.

2. Ulcers of the lower third of the leg, especially of the inner aspect, usually involve a circulatory stasis factor and are more apt to be varicose than syphilitic, or to have the one process imposed on the other

3. Ulcers of the calf region, especially in women, are more suggestive of tuberculosis (erythema induratum) than syphilis, though both may be present.

A sharp or punched-out margin and circular outline do not prove a leg ulcer to be syphilitic, especially in the presence of evidence of vascular stasis.

The typical stasis or anemic ulcer is usually of long standing and surrounded by a dense ring or considerable area of scar tissue and inelastic hide-bound and thickened or glazed skin. The border is sharply defined, rounded, not much elevated, and the base is flat and covered with small pale granulations. The fibrous proliferation about the ulcer often binds it tight to the deeper connective tissue over the bone. There may be associated periosteal changes. Look for varicose veins, old eczematous changes, and elephantiasic thickening of the skin with hyperpigmentation around the ankle as a guide to a stasis factor in ulcers of the leg

The ulcer shown in this illustration is an anemic ulcer occurring in a patient with syphilis, complicated by a compound fracture with secondary infection, periostitis of the fibula, and arthritis of the metatarsal articulations. The situation of the ulcer, its flat anemic base and hide-bound border surrounded by a general fibrosis and hyperpigmentation, are characteristic of a traumatic-stasis ulcer. While the osteoperiostitis responded to a considerable extent to antisyphilitic treatment, the ulcer as such began to heal only when measures to combat the vascular stasis (gelatin stocking) were undertaken.

Kilbourne has advised bismuth and iodide therapeutic test in leg ulcers suggestive of syphilis in seronegative patients, in preference to the arsphenamines.

lesions are singularly free from it. The peripheral pigmentation of a syphilid has a remarkable persistence, and may remain unchanged for months or fade slowly over several years

Fig. 403.—This is a late syphilid in a location more in keeping with inguinal granuloma and phagedenic chancroid. The epithelioma-like border of the larger ulcer might be confusing were it not for the evidence of extensive healing, the multiplicity of the lesions, and the type of scar. A similar type of lesion on the face is shown in Fig. 800. The blood Wassermann reaction must often be the differentiating factor between this lesion and the chronic phagedenic chancroid, which latter, however, is much more destructive.

Fig. 404.—The typical atrophic scar of an arciform nodular or infiltrative syphilid. Note the patulous follicle mouths and the faint atrophic crinkling. This patient had an asymptomatic neurosyphilis with a negative blood Wassermann reaction. There were other scars on the body which attracted attention to the underlying syphilis. His chief complaint was nervousness.

Fig 467 —These t scars were the result pparently of syphilitic lesions in man approaching sixty years of age which had been healed with axle grease. Note the lobulation and the marked peripheral hyperpigmentation in A (tattoo?) Note also the trophic wrinkling. The scar in B shows the punching or stencilling that suggests syphilitic origin.

The Wassermann reaction was strongly positive. This finding the cutaneous scars, and penile scar were so far as could be ascertained from the most searching examination of every accessible structure of the body bsolutely th only bjective manifestations of syphilis which was apparently contracted in 1886, t hich time he had a chancroid that was treated locally *H had never received any treatment for syphilis.*

Fig. 468.—The cluster of small round trophic scars on the front of this patient thorax are those of typical shower of recurrences such as show in act ve form in Fig. 450. This patient had other scars on the back and thighs hich ere typical of the arciform nodulo-ulcerative syphilid.

The blood Wassermann reaction and th spinal fluid were gative epeatedly The patient had definit history of syphilitic infection contracted t enty-t years before.

Fig 460 —This patient illustrates the importance of the combination of active lesion and scar in the diagnosis of cutaneous syphilids. The patient, aged forty married, had complained of stiff shoulder. The trouble had come on following fall in hich he had fractured his clavicle on the affected side. Good union had occurred, but stiffness of the shoulder followed.

In the course of his examination doubtful history of syphilis was elicited. His knee-jerks are reduced. The patient's blood was seronegative. Roentgenograms of shoulder and teeth were negative. The patient had had stiff spine for sixteen years. The right testicle contained firm nodule. Manipulation of the shoulder under ether was ordered and performed, ith temporary benefit.

At the time of this examination the lesions shown above were described as "areas of chronic irritation on both forearms, and the patient stated later that he had been told they were cuff chafes. Dermatologic consultation was not called.

Six months later patient was re-examined on complaint of pain in the side. At this time prostatitis was recognized. The Wassermann reaction was again negative, but dermatologic consultation as called. The lesions were of about year standing t the time of the photograph.

What is there about these lesions that should arouse suspicion?

1. They are destructive. Actual ulcers exist below the crusts.

2. They produce scars, whose configuration is circinate, which are trophic and noncontractile, and peripherally hyperpigmented.

3. The active lesions are indurated.

The provocative Wassermann reaction yielded two strong positives and two weak positives in seven tests. There was also an immediate flare-up (Herxheimer) and subsidence of the lesions

The aches and pains disappeared promptly under treatment, but there was no resolution of the old process in the spine. The shoulders, however which were still causing some trouble, cleared up entirely Certain paresthesias about the thorax and waist were attributed by the neurologists as much t the spondylitis as to the possibility of neurosyphilis. There were definite lightning pains in the legs, however

A high index of suspicion demands satisfactory explanation and an elimination of syphilis in scar-producing lesions of th skin.

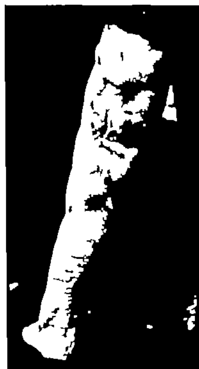

Fig 470—An exception t the relatively superficial and non-contractile character of the scars of the cutaneous syphilids. This is the scar of the deep gumma, which entails usually an enormous destruction of tissue and leaves correspondingly large and deforming scar not unlike that of solitary gumma of the liver

Thirty-seven years ago this woman, now sixty-one years of age, developed ulcers over the left tibia which healed spontaneously Seventeen years later contracture developed hich it appears by examination t this time was due to peripheral nerve injury Six years ago abscesses began to develop about the knee and in the flesh of the left thigh posteriorly The lesions ere lanced repeatedly and refused to heal, forming sinuses which drained for months t time. On one occasion curetment of one of the sinuses was performed She also sustained tendon transplant for the shortening that occurred in conjunction with the paralysis. At this time she had ulcers on the front of the knee. The family history was not in the least suggestive of syphilis and her personal history on this score was negative.

This type of deep destructive scarring with chronic sinus formation may of course, be tuberculous and even pyogenic the sequel of chronic suppurative osteomyelitis. But the significant fact in this case is that no ttempt was apparently made through period of six years to reach satisfactory diagnosis When the patient entered the clinic she had never had Wassermann test or roentgenographic study of the bony structures involved

The Wassermann reaction was strongly positive

The radiogram of the left knee and leg showed periosteal changes suggestive of syphilis.

This patient had evidence of syphilis that should have identified her case without the positive Wassermann reaction. Her pupils were of th Argyll R bertson type, her Romberg was positive; there were slight reflex changes.

It is interesting t note that one inexperienced examiner called the leg lesions "trophic.

GENERAL DIFFERENTIATION OF LATE CUTANEOUS SYPHILIS FROM OTHER GRANULOMAS OF THE SKIN

The differentiation of late syphilids from tuberculosis, lepra, sporotrichosis, blastomycosis, and vegetative granuloma must be a routine part of the business of every physician who deals with syphilis. The differentiation should not be made on the basis of the blood serologic reaction alone nor is it always

possible to invoke other systemic signs of syphilis or tuberculosis to assist in a differentiation of these two diseases. The decision must, therefore be made at times on morphological considerations and direct laboratory investigation of the lesion alone, or in such a study must be found the crucial evidence to clinch a diagnosis suggested but not confirmed by other signs. The aspect of this differential problem changes with every case. It is impossible to draw up a tabular statement which applies equally to lesions situated upon the face and upon the leg The constitutional accompaniments, instead of shedding light, may increase confusion. Even the therapeutic test has serious pitfalls,

Fig. 471.—An illustration of the importance of location as well as configuration in determining the character of scar This patient had been treated for several months on diagnosis of "varicose ulcer though there were no apparent varicosities, and the lesion is high and oddly situated for an ulcer with stasis factor T be typically varicose there should be varicosities, deep or superficial; edema; and the ulcer would be more likely to appear on the inner aspect *of the leg near the ankle*, upon a skin showing t least some evidence of chronic vascular change, inflammation, and thickening, instead of the entire normality apparent in the figure. Note the sharp circumscription of the pigment. This patient also had an asymptomatic neurosyphilis.

and may give false positive results. It is impossible in studying the various cutaneous granulomata to escape the belief that there are certain fundamentals of bodily reaction to all the granuloma-producing agents which are present alike in syphilis, lepra, tuberculosis, sporothrix, and blastomycotic infections. The choicest picture of plasma-cell infiltration in our possession occurs not in a syphilid, where orthodoxy demands, but in a pyogenic granuloma developing upon a syringo-adenomatous nevus. It is essential to realize, therefore, that holes will be found in any scheme of differentiation of the granulomas that diagnosis must be made by preponderance of evidence and that absolutely pathognomonic signs will be few if indeed they exist at all. This caution

should be applied by the clinician who emphasizes configuration and apple-jelly nodules, by the pathologist who leans on giant cells, plasma cells, and lymphocytes and by the practitioner who depends upon the blood serologic reaction

Differentiation of Cutaneous Tuberculosis and Syphilis.—The differentiation of tuberculosis and late syphilis of the skin and mucous membranes is easily the most difficult of the series from the purely morphological standpoint. No table of differential points can completely cover the individual case or

Fig 472.—This is the typical scar of large nodulo-ulcerative syphilid of the pretibial region below the knee Not the atrophic wrinkling, the peculiar pigmentary mottling, the hyperpigmented border and the "kidney-shaped" outline There is bsolutely no distortion in spit of the large area covered by the destructive process. W have seen dozen such scars in patient whose herniotomy ound refused t heal, hich had been completely overlooked in his pre-operative examination. When after forty days in bed it became apparent that the wound was not going to heal, W ssermann reaction was taken and found strongly positive The ound promptly healed after treatment as begun.

provide infallible criteria but the following (Fig 473) will serve to summarize those particulars in which a preponderance of evidence for or against the diagnosis of tuberculosis or syphilis may be accumulated

Omitting from consideration for the moment the forms of tuberculosis previously spoken of as tuberculids, Fig. 480 p 701 presents the points which may fail to differentiate the two diseases if they are too implicitly relied upon.

The technic of recognizing the apple-jelly nodule is illustrated in Fig 4 4 This elementary lesion upon whose identification the diagnosis will often depend, is a tubercle in the deeper layers of the corium or the fat, which is

Fig. 473.

DIFFERENTIATION OF CUTANEOUS AND MUCOSAL TUBERCULOSIS AND SYPHILIS

Syphilis	*Tuberculosis.*
Polymorphism Gre ter variety of lesions in the course of the infection.	Tendency t single type of lesion throughout the course of the disease.
Tends t shorter duration and more rapid evolution of lesions (eeks or months)	Extreme chronicity of lesion (years) suggest tuberculosis.
Arciform configurations the rule.	Arciform configurations unusual.
Lesions markedly indurated (dry or nodular type)	Induration less striking
Ulceration peripheral.	Ulceration tends t be central.
Spontaneous healing not unusual	Spontaneous healing rare.
Scars usually thin, trophic non-contractile	Scars may be either trophic or tough and contractile.
Scars usually clea completely healed.	Scars pt t contain tubercles.
Peripheral pigmentation pronounced.	Peripheral pigmentation rare.
Pathologic picture of granuloma ith giant cells often not distinctive. Coat-sleeve perivascular plasma cell infiltration and obliterative endarteritis of capillaries most important. *Spirocheta pallida* present if staining technic is adequat and valiable.	Typical tubercles should be present for diagnosis. Finding of bacilli in tissue desirable in doubtful cases but usually difficult. May be present in pus from deeper lesions
Guinea-pig inoculation of tissue negativ for tuberculosis.	Guinea-pig inoculation may be positive for tuberculosis, but not invariably
Tuberculin subcutaneously 0.25 to 1 mg. produces no local reaction in lesion.	Tuberculin subcutaneously 0.25 mg., may produce definite focal and general reaction.
Wassermann reaction usually positive, but may be negative repeatedly	Wassermann reaction usually negative, but may be weakly positive.
Arsphenamin usually produces marked Herxheimer reaction.	Arsphenamin may produce slight flare-up, but not usually
Arsphenamin treatment gives complete specific response.	Arsphenamin treatment produces improvement but rarely cure.
Mercury gives the nearest to specific therapeutic test (succinimid or inunctions)	Mercury may produce slight but temporary improvement in all but mixed lesions. Bismuth action unsettled
Collateral indubitable evidence of systemic syphilis may be present.	Collateral indubitable evidence of systemic tuberculosis may be present.
Repeated absence of tubercle bacilli in sputum or secretions from mucosal lesion favors syphilis.	T bercle bacilli often present in sputum and smears from mucosal lesions.
Pseudot bercles (rare) when present are coarse (5 t 10 mm. in diameter)	Elementary and characteristic lesion is the apple-jelly nodule or subcutaneous tubercle, 2 t 5 mm. in diameter

ordinarily invisible in the pink or red of the inflammatory base, but can be detected by expressing the blood from the tissue with a glass spatula, "dia scope," or even the lip of a tumbler or a heavy microscopical slide When thus viewed under glass pressure, the brownish, translucent miliary tubercle, 1 or 2 mm. in diameter stands out clearly against the pale background. The term "apple-jelly" is suggested by its color The apple-jelly nodule is not always present in tuberculous processes in the skin. In certain cases of dry erythema tous tuberculosis, especially of the skin of the face, it may be impossible to identify them. Likewise in certain violently ulcerative tuberculodermas, no signs of tubercle formation can be detected in the gross. On the mucous mem branes the tubercle can be identified as a minute pale granule on the mucosal surface the lesions often being present at a considerable distance from the active ulceration. The hypertrophic nodose tuberculosis of the nose and vegetative tuberculomas (Fig. 569) do not present typical apple-jelly tubercles,

but rather translucent ridges and agminate masses that may be closely imitated by syphilids. The verrucous type of tuberculosis, usually a reaction to

Fig. 474.—Method of demonstrating pple-jelly nodules (tubercles) in cutaneous tuberculosis. This is the sit of primary inoculation with tuberculosis, and practically nothing was visible in the reddish inflammatory scar until glass pressure was pplied (B) with diascope. The ring of miliary tubercles is then easily seen through the glass.

Fig. 475.—The persistence of tubercles in the scar of lesion is one of the important aids in differentiating tuberculous from syphilitic lesions. This is depressed atrophic noncontractile scar studded with miliary tubercles. A lesion, hose border more closely suggests syphilid, is shown in Fig. 456.

direct cutaneous inoculation, may present no tubercles even on histologic examination. Fortunately although its configuration (Figs. 503 504) may

Fig. 477

A SIX YEAR MASQUERADE OF SYPHILIS AS SURGICAL TUBERCULOSIS

A woman, aged thirty married (see Fig. 476)

Family History: 3 children, one miscarriage. Later questioning disclosed one premature birth, child dying in three weeks.
Complaint: "Boils, Stiff Neck, Scrofula. Pain in the hip six years go, especially nocturnal, worse when at rest.
Treated by Doctor Four Months for Rheumatism. Got worse. Consultation called.
"Boil" on Hip Opened by Doctors. Bone scraped. Told it was tuberculous.
Opened Lesion Refused to Heal. Two more operations, bone removed at each. Worse for time, finally healed.
N Ankylosis or Stiffness of Joint.
Developed "Boil" on Left Shoulder Last Winter Lanced, but did not heal properly Still having trouble.
Boils Appeared on Neck Four Years Ago. Opened by physicians and kept open. Patient told she had scrofula. Painful lumps, stiffness now
Three Operations on Neck.
Coughs Good Deal th Past Six Years especially past nine months. No night-sweats or hemoptysis. Weight loss 9 pounds.
First Examiner Reports "Left shoulder posterior, number of indurated lumps, scars from incision of old boils.
Otolaryngologist Advises Removal of Tonsils and -ray to glands and induration in neck.
Medical Advice, after negative chest ray the same.
Blood Wassermann Report Returns Strongly Positive. Is Repeated, Same Result.

Four Suspicion-arousers Miscarriage, bone sequestrum, refusal to heal, infiltration of scar
"Boil" and carbuncle, together with sarcoma and tuberculosis, are common misinterpretations of the gumma. The oldest child has heredosyphilis.
When Nodule or Tumor in or Beneath the Skin, on Incision, "Cartwheels" Out Into Ring of Nodules About an Infiltrated Scar or Unhealed Wound, Suspect Gumma.

suggest a syphilid the structure of the papillomatous, warty lesion is more that of blastomycosis than syphilis.

Fig. 478.—An infiltrative syphilid of the subcutaneous tissue, suggesting so-called nodal tuberculosis of the fascia, associated with lesion of the larynx and vocal cords, thought t be tuberculous. Serological reactions positive, prompt response t treatment for syphilis. Surgical exploration for biopsy before the serological test was taken.

Fig. 479.—An exceedingly superficial type of tuberculosis on the buttock. Note the resemblance of the superficial trophic scar to that of syphilis. Even the border is distinctly suggestive. Not however the miliary reddish-brow point in the active part of the lesion. These are too small and too numerous for gummatou foci. The lesion is of fourteen years duration and began in childhood. While t time syphilid may have duration of years, th longer cutaneous lesion lasts, th more probable is it that it is tuberculous. This is especially true if the lesion begins *in childhood or early adult lif*

I our experience the most difficult differential problems involving cutaneous tuberculosis and syphilis have occurred in lesions on the face and the buccal mucosa. These are illustrated in connection with the regional topography of late syphilids of the face. In spit of the use of every diagnostic resort, one is occasionally left with an uncertainty as t whether the lesion with which he ha been dealing is tuberculosis or syphilis (see Figs. 460, 502) In some cases biopsy animal inoculation, and prolonged mercurial therapeutic tests are needed t establish the diagnosis.

Differentiation of Late Syphilids and Certain "Tuberculids. —This problem has been touched upon to some extent in discussing the differential problems of secondary syphilids. The tuberculoma which is most likely t be confused with late syphilid, is the indurative tuber culous plaque known as erythema induratum. This lesion usually develops upon the inner posterior surface of the leg above the ankle in young omen ho are inclined to overweight, anemia, and amenorrhea (Fig. 516) The background is that of an occult tuberculosis, and the lesion itself is tuberculous as shown by animal inoculations, though the histologic architecture is rarely typical. Clinically the pink to purplish, brawny infiltrations are quite typical to the experienced. The central portion of the plaque tends to soften and break down, but ulceration is rarely ex tensive at any given time, and the typical configuration of late syphilids is usually lacking. The plaque of erythema induratum is often composed of group of coalescent papulonecrotic lesions

Fig 480.

DIAGNOSTIC POINTS COMMON TO BOTH CUTANEOUS TUBERCULOSIS AND SYPHILIS

1 Apple-jelly nodules may occur in both conditions, but are much rarer in syphilis.
2. Localization upon face and nose occurs in both and furnishes some of the most difficult problems.
3. Thin trophic scars occur in both diseases.
4 Weak or biologic false positive Wassermann reactions may occur in tuberculosis by older technics and highly cholesterinized antigens.
5. A Herxheimer reaction t arsphenamin may occur in both processes.
6. Frambesiform, nodular and hypertrophic lesions may occur in both diseases.
7 Adjacent lymphatic glands may be involved in both diseases.
8. Constitutional symptoms may closely simulate each other:
   Pulmonary symptoms.
   Lymphadenitis.
   Bone involvement.
   Loss of weight, fever night-sweats, gastric disturbances.
9 The Von Pirquet reaction does not differentiate them.
10. Improvement and even symptomatic cure (?) may occur under arsphenamin treat ment, and even improvement under mercury (slight) and iodids.
11. The histologic pictures may sufficiently resemble each other occasionally to confuse the pathologist.

with their central plugs replaced by softened and broken-down mass. The lesions are often markedly tender in contrast to syphilids. The finding of the essential lesion of the tuberculid—the necrotic centered papule shown in Figs. 553 596 and 548—is sometimes essential to diagnosis.

A vigorous warning should be given gainst dependence on arsphenamine for the therapeutic differentiation of the tuberculids. The non-specific effects of this drug have been discussed in Chapter V but need reiteration in this connection. If in the absence of expert consultation therapeutic test must be resorted to, it should always be with mercury alone.

The scars of erythema induratum often furnish the closest imitations of those of syphilids with which we are familiar Their localization (Fig. 557) on the posterior surface of the leg, and their usual lack of characteristic configuration (exception in Fig. 557 A) may be the chief dif ferential points. In peripheral hyperpigmentation and in character of scarring they may be remarkably deceptive. The finding of the scars of tuberculid (folliclis) on the hands (Fig. 548) is occasionally an important aid.

Scrofuloderma, the bluish-red soggy inflammatory skin which surrounds the openings of tuberculous sinuses, is often thought to be distinctive of tuberculosis. It seems not to be generally known that deep syphilitic process may drain through sinus after gummatous softening, especially in the case of bone and joint involvement, and confusion of syphilis and tuberculosis

occasionally results (Figs. 607 611) While a species of syphilitic "scrofuloderma occasionally develops, there is more of tendency of the syphilitic process to take on the configurations of lat syphilid in the process of extending into the skin.

"Tuberculosis colliquativa, recently reviewed by Michelson, may at times reproduce the indurated plaque type of late syphilid with multiple points of ulcerative breakdown. In the nodular stage, Michelson states, differentiation may be almost impossible without serological nd bacteriological findings. Tuberculosis is of a cyanotic blue color syphilis more a rusty red. The tuberculous scar is thick and keloidal, that of the syphilid thin and atrophic. The syphilitic ulcer border is punched out and indurated, the tuberculous border is thin, irregular and undermined. The differentiation of "nodal tuberculosis of the fascia (Figs. 478, 480), tuberculous gumma (Fig 539) and the tuberculoid "sarcoids (Fig. 515) is presented in connection with

A B

Fig. 481 —Typical lesions observed in patient ith maculo-anesthetic lepra. I A note the peering gaze and infiltrated brows the enlarged nipples the pudgy hands. This patient knees are shown in B. The ulcers are due t burns resulting from contact with hot radiator pipe adjacent t the patient bunk in lumber camp. The ulcers had been diagnosed syphilitic, but the blood Wassermann reaction was negative. Traumatized knees of which the patient makes no complaint should arouse a suspicion of lepra. The ulnar nerve was three times normal size, nodular and insensitive The nasal smear teemed with intracellular acid-fast Hansen bacilli. There were of course, extensive nerve changes.

the case histories and figures (see also Chapter V) All these lesions have the disconcerting peculiarity of responding t systematic arsenical therapy so that they furnish fertile field for error in the practice of those ho re unfamiliar with the nonspecific peculiarities of these drugs

Combinations of Syphilis and Tuberculosis in the Skin.—These are less uncommon than one would imagine, and especially in young people may be highly confusing One of us (J.H.S.) has seen combined syphilis and lupus vulgaris of the nose involut partially under mercury the remainder of the cure being accomplished by tuberculin. In view of the curious combination of nonspecific effects secured from the arsphenamine treatment of tuberculosis and tuberculids and the tuberculin nonspecific treatment of syphilis, it must be conceded that many cases will be impossible of differentiation into their component parts. Examples of such problems are presented in Figs. 538 and 539 I those cases which have studied the distribution and characteristics of the

combined process seemed to point to the tuberculosis as primary and the syphilid as superposed. Fusion types combining syphilis and tuberculosis have received increasing attention in the recent literature, including articles by Fernet, LeBaron, and Bloch-Michel (1933), Gougerot, Lons, and Dreyfus (1936), Gougerot and Boulle (1936) (tuberculous pseudochancre) Tomé Bona (1930) (Vignolo-Lutati lymphatic syndrome) Salbene (1930) (lupo-syphilitic hybridism of nose and jaw in heredosyphilis) Sergent and Longjumas (1930) (syphiloscrofula)

The Differentiation of Cutaneous Late Syphilis and Leprosy—Leprosy and syphilis, especially in temperate climates, where the former disease is not indigenous and therefore unfamiliar are so commonly confused that it is unusual to see leper who has not been diagnosed syphilitic and usually treated for the disease There can be no doubt that the differentiation is at times exceedingly difficult and that the occurrence of positive blood Wassermann reaction

Fig 462.

THE DIFFERENTIATION OF CUTANEOUS LATE SYPHILIS AND LEPRA

Late Syphilis.	*Lepra (mixed and nodular)*
Evolution more rapid than that of lepra.	Evolution usually extremely slow
Seldom diffusely infiltrates face, brow and ears.	Distinct tendency to infiltrate face, brows, and ears.
Lat alopecia of eyebrows and scalp rare or unknown.	Alopecia of eyebrows and scalp common.
Tendency to ulcerative breakdown more marked.	Tendency to ulceration of lesions slight (ulcers usually trophic or traumatic)
Ulcers have typical configuration.	Ulcers lack configuration.
Coincident laryngeal changes possible, but unusual.	Coincident laryngeal changes common.
No nodular enlargement of ulnar nerve.	Ulnar nerve enlargement and insensitiveness quite distinctive.
Atrophy of interossei rare, but possible (motor neuron disease).	Atrophy of interossei common.
N claw-hand (main en griff)	Contracture (main en griffe) common.
No blue, pudgy "Morvan" hands.	Morvan or syringomyelic or peripheral neuritic hands.
N depigmentation associated with nerve changes.	Depigmented areas associated with nerve changes.
Dissociation of pain and temperature or complete anesthesia rare. Hence no burns.	Complete regional anesthesia and loss of pain-temperature sense common, hence severe burns (knees, hands, etc)
N characteristic association of nerve changes and skin lesions.	Annular infiltrates with central depigmentation and anesthesia common.
Changes in the nervous system of central origin chiefly	Nerve changes preponderantly those of peripheral neuritis.
N sal smear negative for Hansen bacilli.	Nasal smear may show Hansen bacilli (or may not)
Smear from papule or nodule negative for bacilli.	Smear from papule may (or may not) show bacilli.
No hypertrophy of male nipple.	Hypertrophy of male nipple not uncommon.

in some 80 per cent of lepers by the older technics has not helped to clarify the picture. As with tuberculosis, the differentiation of each case is an individual problem, fitted with difficulty into any summary scheme. It is possible to find exceptions to almost any dogmatic differentiation. None the less the following points are of material assistance in distinguishing the commoner chronic mixed and nodular types from late syphilis.

The differential problems are most difficult in the earlier stages of the disease, when, as in Figs. 349, 481 the hoarseness, alopecia of the eyebrows, papules and nodules in the face, macular eruption on the trunk, and perhaps circinate or gyrate infiltrate or two, are remarkably suggestive of syphilis. The arousing of suspicion begins with the facies and the bluish hands (Fig 462), for one rarely sees pure anesthetic type without skin lesions. Burned or traumatized knees (Fig. 481) structures of which the average person is extremely careful, should always arouse suspicion of lepra. In one of Stokes patients the first clue (anesthesia) was his story that he had

been vexed by toe that would not heal, and placing the foot on box, had shot the offending member off ith revolver It is alw ys well t go over the extremities of patients with infiltrated

Fig 483.—The bluish pudgy hands of the leper whose back is shown in Fig 484. Not the glossy "trophic" skin of peripheral neuritis.

Fig. 484 —Typical lesion of maculo-anesthetic lepra. Thi patient in nine years had been seen by seven physicians, most of whom had evidentl made diagnosis of syphilis, t judge from the treatment he had received. The large nnular lesion on the inner spect of the left forearm is a typical annula infiltration ith central anesthesia nd depigment tion The diagnosis confirmed bacteriologically

facies, using pin t detect areas of complet anesthesia, no matter hat the appearance of the eruption or the blood serologic findings may be A smear should then be made from the nasal mucosa or from nodule and stained (Ziehl Neelsen) for acid-fast intracellular organisms The

finding of an enlarged nodular and insensitive ulnar nerve is of the greatest assistance. The unusual possibilities of confusion of cutaneous lepra with syphilis are well illustrated by a case seen before a dermatologic society in which able observers believed the infiltration of the face and ears to be syphilis, and the squamous leprous eruption on arms and legs to be an arsenical dermatitis following arsphenamine treatment. Late lepra, with leonine facies and neurotrophic changes, is usually only a problem to the inexperienced. It must be recalled that syphilis and leprosy cannot be differentiated from each other by blood serologic tests for syphilis which are biologically falsely positive for syphilis in so high a proportion of cases of leprosy that they are best wholly distrusted until such time as biologic false positives can be distinguished from true syphilitic positives. The existing verification tests to date do not provide such a differentiation. The diagnosis of leprosy must therefore be positively made by the finding of the organism or other means. For those who require the latest information on the immunobiologic diagnosis of leprosy reference should be had to the article by Pardo-Castello and Tiant (1943).

The Differentiation of Syphilis and Sporotrichosis.—The response of sporotrichosis to iodides, and the existence of a deep gummatous type is responsible probably for a not infrequent confusion of this disease with syphilis. The various types of sporotrichosis and their differential diagnostic characteristics have been recently admirably reviewed by H. Foerster. The sporotrichotic gumma, probably representing a hematogenous infection, is rare in this country and

Fig 424.

DIFFERENTIATION OF CUTANEOUS LATE SYPHILIS AND SPOROTRICHOSIS

Syphilis.	*Sporotrichosis.*
Inoculation focus not present.	Site of inoculation often recognizable, but not invariably.
Nodules tend to be in the skin at the outset.	Nodules under the skin (lymphatic) at the outset.
Arciform and polycyclic configuration the rule.	Linear distribution the rule.
No chain formation of satellites along the lymphatics.	Marked tendency to chain formation along the lymphatics.
Little tendency to adjacent lymph-node involvement, comparatively.	Marked tendency to lymph-node involvement.
Culture negative for sporothrix.	Culture usually positive for sporothrix.
Collateral evidence of syphilis.	Wassermann shows no tendency to false positives.

usually will require cultural differentiation. The lymphangitic types seen in this country and shown in Figs. 504–505 have the following differential points.

The very great importance of culture (4 per cent maltose agar at room temperature) should be stressed for doubtful cases. There is nothing characteristic in the histologic picture of sporotrichosis upon which diagnostic reliance may be placed. The lesions of sporotrichosis seem to show a tendency to earlier breakdown than those even of a gummatous syphilid, and aspiration of the earliest nodules will often yield pus with a pure culture of the organism. Therapeutic tests are very unreliable indeed. In a case clinically diagnosed a syphilid on our service and treated exclusively with arsphenamine and mercury (no iodide or roentgen-ray) after healing had taken place, the laboratory presented us with a beautiful culture of sporothrix, fortunately obtained from the lesion in the routine procedure of differentiation before treatment was begun.

Differentiation of Late Syphilis and Blastomycosis.—The lesions of blastomycosis are the least likely of the granulomas to be confused with late syphilids, yet confusion can and does occur (Figs. 504, 567). The lesion produced by the blastomycete is clinically a papilloma, containing numerous epidermal abscesses, from which exude on pressure minute droplets of pus containing the organisms. The cutis is involved in the inflammatory process, and with the peripheral extension of the infection a thin but often tough and deforming scar may develop. The configuration of the lesions is perhaps the most suggestive feature of a syphilid, yet the arciform tendency is not marked and lacks the frequently exquisite definition and striking character of the late syphilitic contours. The pathologic picture of blastomycosis, the epithelial abscesses containing the organism in tissue sections from untreated cases, the papilloma, and the finding

Phagedena Geometrica (Broca); Pyoderma Gangrenosum; Microaerophilic Streptococcal Infection and so forth.—This title includes large group of ulcerations of chronic type with undermined policyclic borders and tendency to persist, recur and grow in spurts, in spite of vigorous attempts at local therapy. They may be primary or secondary to such conditions as local trauma (post-operative), chancroid, chancre, pyoderma, syphilid, colitis, or empyema. The borders of the ulcers are typically boggy bluish, soft, undermined, serpiginous and ragged. The base is moist and covered with mucopurulent exudat The tissue has a "melted out" appearance with little or no tendency to granulation. When healed, the scars are parchment-like, slightly pigmented and indistinguishable from those of syphilids. I the type described by Meleney especially (1924 1930) various types of organisms, particularly hemolytic and nonhemolytic streptococci, the hemolytic types growing t low oxygen tension ("microaerophilic"), with

A B

Fig 487—Differentiation of psoriasis, seborrheic dermatitis, and lat syphilis of the scalp nd forehead

The trophy which distinguished A and B is easily seen in the fine wrinkling of the skin of the entire forehead hen the brow are contracted. Definite scarring is visible. Not that while the process involves the inner canthus of the eye there is no sign of cicatricial contraction. The process in the psoriatic is much more superficial and ther is no sign of permanent damage to the skin.

The syphilid in the patient here show as considerably more extensive than ppears in the photograph. There was large patch over the left shoulder another over the sacrum. Serious bone involvement had occurred, with necrosis of the skull show in the photograph and destructive arthritis of the elbows nd knees. It is worth remembering that arthritis may accompany psoriasis and momentarily confuse the picture with syphilis. This patient blood Wassermann reaction was positive her spinal fluid negative. She had lost 40 pounds in weight. The recovery under treatment as phenomenal.

The necrosis of the skull in A would clinch the case for syphilis if all other signs failed. Yet in Fig. 501 is shown the case of woman ith very similar lesion of the skin of the forehead and face and necrosis of the frontal bone who was treated for five years by various physicians for eczema thout having her syphilis recognized.

hemolytic staphylococci and other types of organisms occur in symbiosis. The lesions may appear on any part of the cutaneous surface, ncluding the center of the face most frequently on the extremities and genitalia and occurring in the axilla complication of hydradenitis suppurativa. They are differentiated from syphilitic ulcers by their acut ppearance, rapidity of development, bogginess in place of induration, undermined borders, and lack of spontaneous tendency t heal (Brunsting, Goeckerman and O'Leary 1930, Greenbaum, 1911)

Epithelioma of the Skin.—This important diagnostic problem differs from some heretofore considered in that it is occasionally wiser to err in the direction of a too ready diagnosis of epithelioma than of a neglect of epithelioma in favor of syphilis The essence of differentiation in the majority of cases lies in a study of the border of the lesion (Figs. 40 507 316 615 see also Chapter

XI) The elementary lesion of epithelioma of whatever type is the pearly nodule with faint superficial telangiectases over the surface. Occasionally the border of an epithelioma may fail to show distinct "pearling," and suspicion as to its character be aroused only by the hardness and resistance of the tissue. A rolled border on any lesion, regardless of configuration or other features, at once draws epithelioma into the differential diagnosis. While squamous-cell epithelioma the more malignant type rarely shows any tendency to a healing reaction, basal-cell epithelioma may show marked evidence of healing and in the mildest types give rise to a smooth, depressed noncontractile scar with an active margin not a little suggestive of a syphilid. Squamous-cell epithelioma gives rise to ragged excavations which are not suggestive of syphilis basal-cell epithelioma, on the other hand may produce a superficial ulceration quite suggestive of an ulcerative late syphilid. In the so-called "Paget-like" forms of epithelioma originating often in the hair follicles and sweat glands ("tubular" type) the process may wander about the skin of the face and neck for a period of years, producing scarring quite suggestive of a syphilid, or extensive partially denuded areas whose outline may seem suggestive, and whose slightly raised border may have a distinct induration albeit likewise usually a suggestion of a pearly sheen. Epithelioma of the skin does not in general rise from cutaneous gumma, differing in this respect quite sharply from the notorious tendency of gumma of the mucous membrane to become epitheliomatous. In large doubtful lesions an examination of tissue from the margin may be made. Small doubtful lesions may be excised entire, and biopsies should be taken from suspected lesions about the lip or on the buccal mucosa, though there is difference of opinion as to the risk of producing metastasis in this way It is certain that manual and instrumental manipulation of doubtful lesions is undesirable from this standpoint, so that squeezing and pinching lesions as a test for induration and hardness should be reduced to a minimum. (Class demonstrations especially) The presence of preepitheliomatous lesions such as the senile keratosis always swings the diagnosis of an ulcerative lesion in favor of epithelioma.

In the differentiation of epithelioma from syphilids of the mucous membranes the presence of preepitheliomatous lesions and of sources of irritation is likewise important. Leukoplakia of the mucous membranes and lip (Figs. 417-481) at once throws the burden of proof upon the contender for syphilis, for the high malignancy of mucosal epithelioma makes an erroneous diagnosis of syphilis, to the exclusion of epithelioma, almost inexcusable It is, in general, safer t regard suspicious lesion on the mucous membrane, and especially the tongue as an epithelioma until it is proved otherwise. Malignant lesions in these situations show tendency to cauliflower growth, rolled margin and hardness to touch which can usually be readily recognized. All ulcerative lesions on the mucosa should be checked by the blood serologic test, and if positive, one or tw arsphenamine injections may be given in two or three days as therapeutic test. *This must not, however be regarded as sufficient*, and examination of tissue from suspicious parts of the lesion should be made at the same time (cautery excision if possible) to rule out the possibility of malignant degeneration in gumma. Arsenicals have no significant effect on uncomplicated epithelioma, so that no nonspecific effects need be guarded against, and mercury because of its slowness should not be used. Pain or lack of it is an untrustworthy criterion in distinguishing malignancy from syphilis of the mouth and throat, for an epithelioma may progress to hopeless state before many patients begin to make complaint.

The patient bo has developed epithelioma as complication of gumma in the mouth or throat should be vigorously treated for syphilis after operation and radiotherapy have been begun. Stokes has seen patient ith syphilis who had sustained hemiglossectomy for car cinoma of the tongue develop second carcinoma upon gumma ppearing in the remaining half of the tongue. The positive blood serologic reaction, identified before his previous operation, had been ignored.

Endothelioma Capitis, Angiosarcoma (Endothelioma) and Fibrosarcoma.—The endothelioma of the scalp (Kaposi) is multiple nodular tumor of the scalp which may occasionally be *momentarily mistaken for gumma by those unacquainted with the existence of the neoplasm.* The condition is essentially multiple basal-cell epithelioma. Angiosarcoma or endothelioma of the skin (Fig 571) may be confused with syphilis and may show temporary response to arsphenamine therapy The necrosis of bone and the often circinate margins of the ulcerative lesions add color to the deception. The elementary lesion of the angiosarcoma is nodule in the skin which rapidly undergoes necrosis, forming a punched-out ulcer not unlike a small broken-down gumma. The pathologic diagnosis must usually be made from these earliest lesions, for the margin of the larger ulcers assumes a granulomatous structure from secondary infection. Two of the three cases under our observation had been diagnosed and treated as syphilitic for considerable periods, and one

A B

FIG. 456.—WHEN LATE SYPHILID SIMULATING PSORIASIS APPEARS UPON THE ELBOW WHAT DIFFERENTIAL CRITERIA SHALL W INVOKE?

These two photographs tell the story of the gross morphologic differentiation in the majority of cases.

Psoriasis (A)

- Note that though the lesion is annular there is no induration. It is flat and superficial.
- Note the abundant dense imbricated silvery scale which is characteristic of psoriasis. The black spots are the intense red surface of the underlying papular lesion.
- Note that there is no atrophy and there are no scars.
- A typical capillary hemorrhage occurred from the abraded areas.

Late Syphilid (B)

- Note the fleshy look, the appearance of induration.
- Note the arciform grouping of the major lesions. Not the scantier scale and its thinner more friable quality
- Note the trophy where lesions have involuted. Note the scars.
- N capillary hemorrhage could be obtained from the abraded lesion.

of them had almost healed under such management. The fibrosarcoma occasionally produces lesion which suggests momentarily nodular syphilid The so-called "Kaposi hemorrhagic sarcoma of the leg relatively rare tumor seen oftenest in person of Jewish race, is nodular infiltrative and plaquelike lesion of the lower leg, associated with quite distinctive hemorrhagic changes in the skin, leading t characteristic pigmentation and color changes.

The Lymphomata of th Skin and Mycosis Fungoides.—Leukemic and Hodgkin infiltrations of the skin may occasionally produce lesions quite resembling late syphilids in color feel, and configuration (Figs. 531 532) They are rarely ulcerative Under roentgen-ray treatment, nd at times spontaneously they may involut leaving slight trophic remains or no traces whatever The lymphatic leukemias give rise occasionally t extensive papular eruptions that may suggest

Fig. 489.—This presents a circinate type of seborrheic dermatitis which has been described as seborrhea petaloides. Less marked examples of the same variety of this dermatosis have been described by Toyama. Note that the location of the lesion is at one of the sites of predilection for seborrheic dermatitis (scalp, face, presternal, and interscapular region). The lesions form on a seborrheic base, the skin being oily and the follicles patulous and plugged with sebaceous material. The circinate lesion is pinkish-yellow in color; there is no induration, and the scale is greasy and yellowish. On curetting it off no papule or induration remains. There are no signs of scarring or atrophy. (From the collection of the late Frederick G. Harris.)

Fig. 490.—A form of lichen planus which, when identified, may assist in differentiation of lesions which imitate syphilids. This is the hypertrophic type with dense adherent keratotic scale and may be confused with the keratodermic syphilid. Typical lesions of lichen planus may be identified, usually about the knees, wrist, genitalia, or mucous membranes. This woman had every known lesion of lichen planus at one and the same time except the bullous type. She had twice been told she had syphilis.

syphilids. They involve the face, trunk, and extremities; the papular lesions are firm and indurated; they do not scale, and they are usually intensely pruritic (often suggesting prurigo). The

blood picture usually identifies the process. The loss of hair from involvement of the follicles, affecting the eyebrows especially is often seen in the massive nodular infiltration of the face, which is especially common in splenomyelogenous leukemias. They often suggest late syphilids and lepromas. The removal or grinding down of hair in such region as the eyebrow as a result of rubbing and scratching, must not be confused with true alopecia.

Mycosis fungoides, lymphogranuloma of unknown cause presents two distinct types—the chronic and the "type d'emblée. In the former a prodromal period of months or years may be marked by furiously pruritic dermatitis, often involving the entire body or confined to patches. The surface involved in the dermatitis presently becomes infiltrated, and brawny plaques and circinate gyrat nd annular indurations appea (Fig 485). This tendency to lymphogranu-

F g 491 —This patient, grocer forty-three years of age came t the clinic complaining of an eruption on his forehead. On examination group of lesions, similar t those shown in the photograph but with the arciform character more pronounced and some ulceration in addition, of whose existence the patient was unaware as found over the left scapula. H had, however had patch that he knew of on the buttock very similar in character to the forehead lesion Eighteen years before the patient had had penile lesion with bubo, but no secondary eruption. There was no record of any treatment.

Th blood Wassermann reaction was negative. None the less diagnosis of syphilis was made and treatment begun.

The spinal fluid showed WR negativ 0.3 cc., Nonne positive 92 lymphocytes.

The bone conduction was reduced, right, —7 seconds; left, —9 seconds.

Th fundus of th eye showed mild neuroretinitis.

The lesion involuted rapidly following th institution of treatment.

Not that in spite of the bnormal spinal fluid the neurologic examination as negative (except for slight nystagmus) The patient was an uncontrollable morphine addict and left before treatment was completed.

If patient presents susp.cious but rather anomalous lesion, as in this case, careful search of the entire skin surface and the mucous membranes may as here disclose lesion more typical in ppearance but of hose existence the patient is una are.

The collateral findings here given illustrat defects in th complete work-up of th case. The spinal fluid Wassermann as done on only 0.3 and 0.4 cc though it might have been positive on 1 cc. A provocative test might have been done but as overlooked. The record is inadequate in that no history of previous treatment or statement that none had been given as included

Never accept patient's statement that ther is nothing to be seen. Se for yourself.

lomatous change becomes more marked, nd t mors develop, often undergoing rapid breakdown and ulceration, nd again growing t enormou size before degeneration occurs. Many of these ulcerative lesion have the configuration of syphilids. I the "type d'emblée there is no prodromal or premycotic dermatitic stage the first lesion to ppear being tumor which rapidly breaks down, often strikingly resembling an ulcerating gumma on the leg. The histology of these lesions is quit characteristically that of lymphogranuloma, and the course of authentic cases of both types is practically invariably fatal. Striking responses to combination of arsphenamine and roentgen-ray have been reported. Itching nd history of dermatitis, or evidence of its presence, with the characteristic histopathologic picture in the infiltration may mak the diagnosis early The condition is, fortunately rather rare

NODULAR AND HYPERTROPHIC SYPHILIDS OF THE NOSE

Late syphilids of the nose may bear a striking resemblance to hypertrophic tuberculous lesions of this part of the face, and to acne rosacea and rhinophyma. The underlying inflammatory background tends to conceal the char-

Fig. 482.—Typical superficial syphilids of the nose. A is the nodular syphilid often erroneously diagnosed acne rosacea or lupus vulgaris. Note the coarseness of the nodules and the individual nodular ulceration. Case B is almost duplicate of A, yet B is lupus vulgaris (tuberculosis) and A is syphilid. The typical miliary apple-jelly nodule could be identified in the skin in Case B. C represents the lesion in Case A (syphilid) after treatment with mercury and arsphenamine. Note the completeness of the involution, the small amount of residual damage, and the cat-scratch scarring. D represents syphilid beginning at the bridge of the nose and wandering downward toward cheek and lip. Note the configuration and border and the entire lack of deformity from scarring, hich greatly simplify the diagnosis.

cateristics of the process. The principles outlined in Figs. 410 473 474, 496 may differentiate a late syphilid from lupus vulgaris, but there is no form of *the diseases involved in which the therapeutic test with mercury or a biopsy* must be resorted to more often for a decision. Arsenicals are not to be trusted for these therapeutic tests and mercury may even yield momentarily perplex

ing results (Fig 499) The status of bismuth in such tests is still uncertain. If biopsy is done, a shaving from the skin over the ala if it is involved will usually leave almost no scar provided the cartilage is not nicked

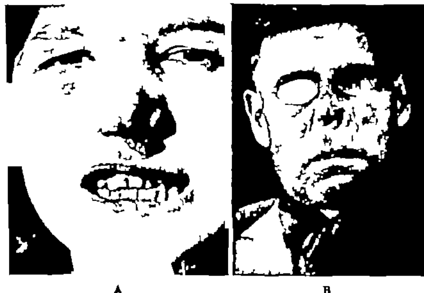
The scarring produced by a syphilid of the nodular type in this region is quite characteristic (Fig 492 C) The individual nodules heal, leaving "cat scratch marks, the process between them simply fading out with some transient pigmentation. The tuberculous process leaves a more pronounced diffuse atrophy and scarring and is rarely so superficial as the syphilid. It is much more likely to leave the nose pinched and shrunken, with loss of tissue in the alae, producing a "bitten out" appearance (Fig. 494 C) This may however occur in syphilis (Fig 498) The residua of a severe acnitis (tuberculid) should be noted in Fig 362, as a possible source of confusion.

Fig 493.—A nodular syphilid of the upper lip and nose The active parts of the lesion were of livid color but at no time had there been any ulceration. The scarring is none the less apparent over the ala. We have seen this lesion almost duplicated by verruca vulgaris of the upper lip.

Rhinophyma and acne rosacea develop on a seborrheic base, with vascular dilatation over the so-called "rosacea oval," including the nose the adjacent infra-orbital region, the skin between the eyebrows, and over the chin. The seborrheic base with oiliness, follicular dilatation and above all comedone formation, is an essential part of the process. The elephantiasic hypertrophy of the "rum blossom" (rhinophyma—Fig 495) does not present the elementary nodular and ulcerative lesions or the crusting of the late syphilid though there may be pustules. In some rosaceas there is simply a nodular hypertrophy without definite comedone or sebaceous cyst formation. When a syphilid develops upon a rosacea the differential diagnosis may become still more difficult, and must depend largely upon the finding of characteristic scars and atrophy at some point where the process has undergone involution The extension of a syphilid downward on to the face (Fig 492, D) assists greatly in diagnosis. If the blood serologic reactions are negative other signs of the disease may be developed by a full investigation.

Fig. 404.—A is the tuberculous lesion known as "lupus vulgaris erythematoides, dry non-ulcerative form of tuberculosis whose configurations may suggest those of syphilid. Both border and scar are studded with apple-jelly tubercles. Note the absence of cicatricial contraction in which this case suggests syphilid. (Collection of F G Harris) B is typical ulcerative lupus vulgaris ith the resultant ectropion. *The bridge of the nose presents* scar containing numerous t bercles. The nasopharynx is involved. Note the pinching and shrinkage of the tip of the nose more suggestive of tuberculosis than syphilis. C is the condition kno as tuberculosis orificialis faciei, form of tuberculosis developing by extension from mucous membranes. The larynx, pharynx, nasopharynx, and lips are all involved, condition decidedly against the diagnosis of syphilis, hich rarely involves skin and adjacent mucous membrane unless occasionally at the commissures. The deep involvement of the cartilage and the destruction of the ala, less common in syphilids which involve the skin of this part of the face, was apparent in C.

Fig 495.—Rhinophyma, condition t be differentiated from hypertrophic syphilids of the nose. (Collection of Dr John A. Fordyce.)



DIFFERENTIAL DIAGNOSIS OF DESTRUCTIVE LATE SYPHILIDS OF THE NOSE

The destructive types shown in Figs 497 and 498 differ decidedly from the nodular and tuberous late syphilids of the skin of the nasal region. In these lesions again the confusion of tuberculosis, syphilis, epithelioma, and of rhinophyma and rhinoscleroma at the outset is easily possible. Some important differential clues are summarized in Fig 496

The differentiation of syphilis from rhinoscleroma depends upon the intrinsic rarity of the latter in this country the *hardness* and keloidal sheen of the hypertrophic tissue (usually the ala nasi) the late occurrence, or more usually absence of ulceration the hypertrophic cicatricial changes in the pharynx, and the finding of the bacillus of rhinoscleroma in excised tissue

DIFFERENTIAL DIAGNOSIS OF DESTRUCTIVE LATE SYPHILIDS OF THE NOSE

1 A destructive lesion beginning on the septum is more apt t be syphilid than tuberculosis or epithelioma. *Syphilids perforat septum and palat in preference to other cartilages of the nose*
2. The more radically and rapidly destructive of the deeper tissues, the more the diagnosis tends toward epithelioma.
3. A destructive lesion of the nose which is slow t respond t treatment for syphilis should have an early pathologic examination of tissue taken from the extranasal nd intranasal borders to detect the presence of epithelioma. Some of the reported malignant lat syphilis of the nose is, in reality epithelioma. Bacteriologic study (microaerophilic strep., lepra bacilli, et) desirable.
4 Other conditions requiring differentiation include (a) *septal lesions* including *traumatic perforation* (low down, clean edge), *chrome ulcer* (similar location in chrome workers, other chrome lesions of the skin present), *lepra* (ulcer higher up, intracellular Hansen bacilli in smear); (b) *gangosa* (ya)—extensive destruction of soft tissue and bone strikingly resembling late syphilis; (c) Meleney *microaerophilic hemolytic streptococcal ulcer*—burrowing, undermining, acute, with boggy ragged and bluish borders and a tendency to sinus formation; (d) *diabetic gangrene* of center face—presence of diabetes, exclusion of syphilis; ( ) *rhinoscleroma*—hard hypertrophic lesions bulging into nose and nasopharynx; organisms found in smear and characteristic histology (f) *Hodgkin disease* and other types of lymphoblastoma and leukemia—edema, inflammation, swelling, necrosis, identified by biopsy and blood studies (rare); and (g) *sarcoma*—identified by biopsy
5. Never forget the possibility of factitial lesion produced by escharotics in examining suspected destructive syphilids about the nose (Figs. 497 B and 499)
6. Nasal syphilis involving the bones may be very slow to respond to treatment, which increases the difficulty of diagnosis.
7 The diagnosis of late destructive syphilids of the nose may t times depend entirely upon collateral evidence, no single objective feature or group of signs in the lesion itself sufficing for diagnosis.

A B

Fig. 497.—That the rule of presumptive tuberculosis or epithelioma in the presence of marked destruction of cartilage is not invariable is illustrated by this series of photographs. A is gumma of the septum, causing collapse of the nasal bridge, with extension of the gummatous infiltration on to the upper lip. An exactly similar picture produced in one of our patients, proved after months of treatment for syphilis (Fig. 615) t be epithelioma, originating intranasally nd recognized only when it was too late by biopsy of the edge appearing t the lip. B is a destructive syphilid of the nose with gumma of the septum, treated for some months with radium as tuberculosis ithout Wassermann test. When this was finally taken it proved t be strongly positive and the patient made slow but finally good response to arsphenamine and a prolonged course of inunctions. *Epithelioma must be watched for in such lesions.*

Fig 498 —The active lesion in this case was of exactly the same type as that on the nose of Fig 494, C, yet the former is lupus vulgaris, while the latter was syphilid. The syphilid was identified in the following w y:

1 A scar on the penis with history of lesion in 1900.
2. Secondaries in the scalp. Recurrent mucous lesions at the time
3. Rapid progress of the present lesion. Three months had removed most of the tip of the ala.
4 N detectable tubercles (pple-jelly nodules)
5 N signs of tuberculosis of lungs, throat, larynx, or nose
6. Beginning involvement of the septum. Syphilis select the septum.
7 Leukoplakia.
8. A positive Wassermann series. Th first Wassermann reaction was negative. The series showed *HI HI* neg., *IH IH*
9 An immediate response t treatment for syphilis.

The lesion was then hypertrophic syphilid of the nose These lesions have no characteristic configuration in many cases hich will distinguish them. They must be identified entirely by collateral evidence by elimination of the possibilities of tuberculosis, rhinophyma, rhinoscleroma, microaerophilic streptococcus infection and other forms of gangrene ith ulceration and epithelioma, nd by the effect of therapeutic test for syphilis.

Fig 499 —Note the improvement produced in B as compared with A as result of mercurial therapeutic test. The change took place ith ten daily injections of mercury succinimide—yet the lesion is tuberculous of the skin, w th factitial destruction of the nose by the use of an escharotic past The correct diagnosis was established, after an erroneous diagnosis of syphilis has been made by the failure of the patient t improve beyond the point shown, and the results of biopsy which showed typical tubercles in the periphery of the lesion. Non-specific effects in treatment for syphilis extend even to the use of mercury t some slight degree although experience soon convinces one that mercury is the most trust orthy drug in differentiating syphilis from tuberculosis by therapeutic test.

A B

Fig. 300.

These Two Faces Present a Type of Syphilitic Lesion Often Associated with Involvement of the Bones, which is evidently quite unfamiliar to the medical profession at large to judge by the history of diagnostic errors which such patients usually present.

Case A.—With lesions of the clavicle and sternum as well as of the skin of the neck and face, twenty-three years elapsed from the first appearance of the lesion in this case to the making of the correct diagnosis. The original medical diagnosis was cancer which was subsequently changed by various physicians to scrofula and tuberculosis of the skin. Cautery and local applications of arsenic pastes had been used. **Her First Wassermann Test Was Taken When She Entered the Clinic, June 25, 1918,** at least ten years after the test had become part of medical practice.

The picture is, of course, grossly distorted by local interference with the lesions, but **the Distinction from Tuberculosis** can be based in part at least upon the sharp margination of the lesions with complete absence of the extension of the periphery in the form of apple-jelly tubercles, which is the rule in tuberculous processes. The scars are perfectly clean, and considering the extent and depth of the process the amount of contracture is very slight.

The Distinction from Epithelioma is More Difficult to Make. Although the border is not distinctly pearled, and there are entirely too many lesions for the average epithelioma, it is sometimes necessary to remove tissue for pathologic examination before a diagnosis of benign lesion can be made. This had apparently never been done in this case although destructive treatment had been freely employed. At the present time it would be quite inexcusable to proceed to destructive measures until the identity of the lesion had been established.

A Duration of Twenty-six Years is Not too Long for a Syphilid. It is, of course, also possible in tuberculosis, but hardly in keeping with epithelioma.

Case B.—The first physician to examine this patient in the clinic left the statement in the record, "No skin lesion of lues." The configuration of the lesion and scar below the right malar region is, however, distinctly suggestive of syphilis.

The trouble began with a nodule behind the right ramus of the jaw two years before. An attempt at surgical excision resulted in an extension of the process. There was evidently associated involvement of the articulation, which swelled and the jaw became locked, but later released. No Wassermann test had been taken nor had the patient been treated for syphilis. There was apparently no history of infection. The Wassermann reaction taken after entering the clinic was positive. The response to treatment was prompt.

Fig. 401.

Note the depression in the right frontal region (scarred) indicating loss of bone. The skin lesion is destructive and leaves a superficial thin atrophic scar. Several large but no miliary nodules are detectable in the margin of the active patches. Note, too, that the scar is non-contractile—that the lips meet normally and without distortion.

Twelve years ago at the age of twenty-four this patient was hit on the forehead by a closet door. A small nodule developed, which was excised a year later and with it a piece of dead bone was removed. The lesion would not heal, and two years later more bone was removed and a pedicle graft from the forearm attempted, but without result. The lesion then persisted five more years and healed spontaneously. Then the face became involved, a small nodule appearing near the eye and a moist ulcerative process gradually extending about the face. For five years she had been treated for eczema by various doctors.

From her childhood and adolescent history the following facts stand out. She had had a general eruption at the age of thirteen of an extensive ulcerative type. As an infant she had been ailing and had been constantly under medical care. Following the appearance of the general eruption one elbow had stiffened and partially ankylosed. At the time the lesion on the forehead appeared the tibias had also become tender to touch and had begun to enlarge.

What are the outstanding facts thus far in this case?

1. An extensive ulcerative eruption associated with a bone lesion (stiffened elbow) at thirteen years, before the usual age of sexual experience.
2. A nodule appearing after trauma, which means a local lowering of resistance.
3. Dead bone.
4. A graft that failed.
5. An ulcer that would not heal and more dead bone.
6. Coincident involvement of the tibias.
7. An "eczema" that destroys tissue and leaves a scar.
8. A superficial atrophic non-contractile scarring of the entire face.
9. No apple-jelly nodules in the scar.

Trauma, Nodule or Tumor Incision, Dead Bone Failure to Heal, More Surgery, More Dead Bone, Slow Course, and Final Healing is a Typical Sequence in Clinical Syphilis. The Wassermann reaction was not in general use when this sequence began, but it might well have been invoked later.

Why Not "Eczema"? Eczema is a dermatitis—an inflammatory non-destructive process, producing thickening, not thinning of the skin, and almost never leaving scars. This was, on sight, a Granuloma. The clean non-contractile scar and absence of miliary tubercles (apple-jelly nodules) makes lupus vulgaris improbable and this is the only other granuloma which the picture suggests.

An Examination of the Elbow and the Tibias Should Have Aroused Suspicion.

When after twelve years this patient was finally examined completely it was found that she had a strongly positive Wassermann reaction, a dacryocystitis, and the x-ray picture of syphilitic periostitis involving tibias and left elbow. Neither of these findings was really essential, and the diagnosis could have been made with confidence on the gross examination and history.

Fig. 402.—A coarsely nodular dry lesion of the face strongly suggestive of late syphilid, and subjected to the therapeutic test, with negative results. The condition is an erythemato-squamous and nodular tuberculosis, the nodules being agglomerated masses of tubercles. The response to ultraviolet light was excellent.

Fig. 403.—The configuration, peripheral extension, and central atrophic scarring suggest syphilid. The lesion has, however verrucous, papillomatous scaling border, the scale being densely adherent (not crust). This is tuberculosis verrucosa cutis, beginning at the healed mouths of sinuses from broken down tuberculous lymph nodes. Late superficial syphilids may in the same way occasionally begin at the site of a broken-down gumma, especially following incision or other trauma.

Fig 504

Fig. 505

Fig. 504.—A typical example of blastomycosis on the face The circinate contour papillomatous border and central atrophic scar are apparent. The papillomatous margin is the most important differential point. Tuberculosis verrucosa cutis, blastomycosis, certain basal-cell epitheliomas, and bromoderma are four conditions likely to be confused ith each other but less likely t be mistaken for syphilids if the papilloma be kept in mind (see Fig. 505) Excision of biopsy tissue from suspected blastomycosis, trauma, and surgical curettage of the lesion of blastomycosis may cause generalization of the infection, so that care must be used in diagnostic manipulation. Iodides and arsphenamine may give false therapeutic test for syphilis in these lesions if used.

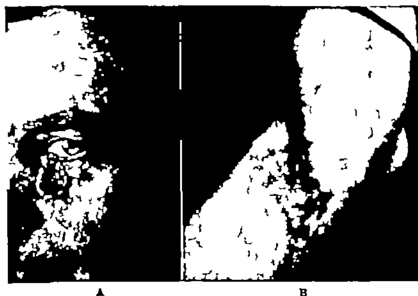


Fig. 505 —Blastomycosis of the pubic region. In its early stages this condition could have been readily confused with inguinal granuloma or syphilis were it not for the papillomatous border (Collection of Dr F G Harris.)

Fig. 506.—Sporotrichosis of the forehead The site of inoculation is above the inner canthus. The preauricular node is enlarged, and pus can be obtained on aspiration, yielding pure culture of the organism. Sporotrichosis is diagnostic problem mainly in the Middle West, and in these regions it is saf rule t take cultures from doubtful lesions on maltose agar especially if there are adjacent softened lymph nodes. The cultures grow at room temperature Iodide cannot be used in therapeutic tests because of its effect on sporotrichosis.

Fig. 507.—The rolled pearly border of epithelioma in man of thirty years. The youth of the patient or coincident syphilis does not infallibly exclude epithelioma from the diagnosis.

A B

Fig. 508.—Gumma of the eyelid resembling epithelioma. The lesion resisted two radium treatments, and later healed under arsphenamine following the finding of a positive Wassermann. At the time, however, the patient presented the late syphilid at the knee which was overlooked. Biopsy reported "granuloma."

Fig. 509.—A factitial lesion on the trunk suggesting syphilid. It consisted of multiple eschars, closely grouped about the umbilicus. The fact that the lesion is in bizarre position, shows no central involution, and presents multiple dry gangrenous eschars at once arouses the suspicion that it is *self-inflicted affair.* The facies of the young girl was typical of the malingering mentality. She cauterized herself with lye to avoid work and arouse sympathy.

Fig. 510.—Indolence, Induration, Arc.

Without warning or apparent reason this man (aged forty-five) suddenly developed swelling on the chin, which broke down and discharged. At first the lesion, which was brawny and indurated, was regarded as carbuncle. It was incised, but did not clear up. Instead others began to appear only to be incised or opened in their turn. After matter of three months or so, in which diagnosis of sycosis satisfied the patient and physician, dermatologist was called.

Unfortunately the photograph cannot exhibit in its full perfection the indolence combined with an almost brawny induration which characterized the whole process. It does, however, show the arc extending under the chin. The beard was intact—not pustule to be found at the time of examination even in the indurated area, which seemed entirely free from the canalization with pus sinuses that characterizes trichophytic sycosis. On sight the lesion carries 75 per cent diagnosis of syphilis. The other possibilities after three months are of course trichophytic sycosis, lupoid sycosis, sporotrichosis, actinomycosis.

The Wassermann reaction was strongly positive the therapeutic response immediate.

This patient could give no history of infection. He had at one time had "tuberculous symptoms, but no Wassermann test was available at that time.

DERMATOPHYTOSES (RINGWORMS) IN THE DIFFERENTIAL DIAGNOSIS OF LATE SYPHILIS

The annular configuration of many syphilids and especially of recurrent and late syphilids seems to have had a fatal effect on their diagnosis in the hands of the dermatologically untrained practitioner and the layman. The term "ringworm" perpetuates the idea that a circular or circinate lesion is of local parasitic origin, and has reduced the threshold of suspicion for syphilis. It is

Fig. 511.—A typical ringworm of the back of the neck. There are miliary vesicles in the margin and scaling with occasional minute pustules in the center. The border is palpable, but not indurated.

a better plan to regard ringed lesions as suspicious of syphilis and eliminate the graver possibility than to form a habit of dismissing arcs and circles as insignificant, or worthy only of local treatment and no observation.

Confusion with syphilis should seldom arise except in those forms of dermatophytic infection which involve the palms and soles and which produce circinate lesions on the face or body. The

Fig. 512.—A dermatophytosis of the trunk, showing the typical superficiality, the border, the scaling center, and the presence of satellite lesions in the surrounding normal skin producing the anomalous configuration. The organism was demonstrable in the scales.

Note the complete absence of atrophy and scarring even in a lesion of this extent. The progress of the process was much too rapid for a syphilid.

more severe forms of trichophytic infection, giving rise to fungous hypertrophic lesions, such as kerion, or to deep involvement of the bearded region with marked thickening and crusting with pus, abscesses and loss of hair from follicular pustulation do not in the least resemble syphilids as they have been here described. Dermatophytic processes in the skin are in general more acutely inflammatory and more rapidly progressive than syphilis.

Circinate dermatophytic lesions of the skin present a sharply defined border which is always less indurated than its width and height would lead one to expect of a corresponding syphilid.

The lesion is essentially above the surface of the skin and not below it, and this fact can be detected by the palpating finger

Fig 513.—Scarring produced by the infiltrative type of erythematous lupus, approaching sarcoid. The atrophic remains may suggest the scars of syphilid. Note the "chapping" of the lips. Follicular plugs, lesions about the ears, and bald scarred patches in the scalp help to clinch the diagnosis of erythematous lupus.

Fig 514.—The infiltrative or edematous border and arciform configuration with atrophic center occasionally seen in erythematous lupus. The blackish horny puncta near the lower eyelid and inner canthus are the epithelial plugs of this disease, though they need not be dark in color A hand lens is essential to the diagnosis of many cases of erythematous lupus.

The border of the dermatophytic lesion is scaling With the aid of low-power lens minut vesicles or vesicopustules can be detected, especially if the scale be lightly rubbed off That of the syphilid presents diff se translucence or nodular character but no vesicles or pustules.

Satellit lesions in the surrounding skin not continuous with the original lesion, and con-

Fig. 515.—Sarcoidosis of which the above is cutaneous lesion is clinical syndrome of tuberculoid character and is in fact believed by many observers to be an anergic nonconsenting type of tuberculosis with lesions in the lungs, bones, viscera, spleen, liver and so forth. The cutaneous lesions are characterized by lymphocytic infiltration of the corium with epithelioid cell proliferation and often giant-cell formation, whose histology may at times suggest either tuberculosis or gumma. Clinically they are bluish or brownish-red, slightly translucent, or at times almost colorless deep plaques, and intumescences, firm, fleshy and sometimes lobulated, occurring most often about the face. They may however appear as papules, nodules, or plaques on other parts of the body Transitions from erythematous lupus to sarcoid exist. In this case, observed over period of several years, and thoroughly studied from every angle, the transition from erythematous lupus through erythema elevatum diutinum to Boeck sarcoid could be watched. The sarcoid responds to the administration of arsenic, and hence to the prolonged administration of arsphenamine as in this case. This is sometimes the basis of error in diagnosis. Sarcoids rarely ulcerate, but the resemblance to nodular syphilid as here is sometimes very striking

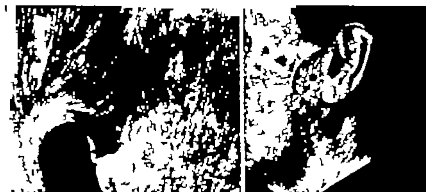

Fig. 516.—Basal-cell epitheliomas of superficial type with central healing and peripheral extension, somewhat suggestive of syphilids. The pearly border may not be recognizable, there may be cordlike induration and decision may be dependent on biopsy or on collateral evidence either for epithelioma (keratoses, etc.) or for syphilis. In doubtful cases with large or extending lesions it is safer to lean toward malignancy than toward syphilis in treatment, though investigation of the possibilities should be complete.

sequently anomalous configurations, are much commoner in dermatophytoses than syphilids. The center of a dermatophytic lesion is scaling and usually presents the lichenified appearance of dermatitis (Fig. 511) that of syphilid is wrinkled and atrophic, but there is little or no scale. The center of the dermatophytic lesion may present vesicles and vesicopustules which are absent in the syphilid.

Many dermatophytic lesions center around the hair follicles, and this fact may be detected both by the lens and by the ease with which hairs can be pulled out. In many cases the pustule is seen to have developed in the follicle mouth, its top pierced by hair. Dermatophytosis of hairy region shows a much more pronounced tendency t produce alopecia than do syphilids of hairy region, although an indurated syphilid may occasionally produce secondary alopecia, not so much from specific follicular localization of the lesion as from the general destructive effect of the diffuse infiltration.

Dermatophytic infections, with the exception of favus, d not tend to leave scars. It is remarkable how pyogenic and dermatophytic granuloma such as kerion can subside completely leaving the skin practically normal and the hair often intact or capable of complet restoration.

Whenever dermatophytic infection is suspected because of the superficiality the scaling, or the character of the border of lesion, an examination of scales and hairs for the causative organism must be made. The scraping should be thorough, but seldom deep enough to draw blood or lymph. The border is usually the richest in organisms. Scales and hairs, especially those which come out without effort, or which show deformity or softening of the shaft and papilla, should be soaked in 20 per cent potassium hydroxide solution for fifteen minutes to an hour until the keratin has softened, and then examined under high power for the mycelium and spores of the fungus.

LATE SYPHILIDS OF THE LIP AND MUCOUS MEMBRANES

The following types of late syphilids of the lip deserve special mention

1 Diffuse gummatous nonulcerative syphilid.

2. Ulcerative gummatous infiltration.

3 Solitary *gumma of the lip*

4 Nodular and nodulo-ulcerative late syphilids involving the lip and adjacent skin.

All of these types are here illustrated

Late syphilids of the mucous membranes occur in the following forms

1 Late recurrences presenting the arciform configuration and the nodular and ulcerative character of the nodulo-ulcerative syphilid of the skin.

2 Interstitial or sclerosing glossitis.

3 Fissure.

4 Solitary gumma.

5 Perforating gumma of the soft palate.

As late syphilis approaches the mucocutaneous junctions and invades the mucous membranes, a new risk, that of malignant degeneration makes its appearance. This malignant degeneration does not necessarily wait until the involution of the syphilid and the formation of a scar but may begin while the syphilid is still active and of comparatively recent development, and progress side by side with the syphilitic lesion, its presence unsuspected until glandular metastasis has occurred. For that reason it is highly important to inspect syphilids, especially ulcerative lesions on or near the mucous membranes, for the rolled or pearly border which suggests early epithelioma to search for lymphnodes at first examination to make microscopic examinations of tissue from suspicious lesions and to regard as suspicious and investigate microscopically all supposedly syphilitic lesions of the mucous membranes which do not make an immediate and complete response to the arsenicals and heavy metal. If for any reason such as the need for eliminating tuberculosis, slower methods of treatment than that with an arsenical must be employed it is better to take a specimen for examination first and treat afterward if

only inflammatory changes are found than to discover that a lesion is malignant after it fails to involute under several weeks of treatment. The metastasis of malignant lesions on the mucous membranes and mucocutaneous junctions is very rapid, and delay is exceedingly dangerous. The coexistence of a positive serologic reaction on the blood and a lesion on the lip or mucous membrane does not *ipso facto* prove the lesion to be a syphilid.

Because of their location, which often interferes with mastication and deglutition, late syphilids of the mucous membranes, especially of the tongue

Fig. 517

A SUMMARY OF THE CHARACTERISTICS OF LEUKOPLAKIA

A Grayish or Silvery Sharply Defined, Imbricated, Roughened, and Thickened Patch on mucous or mucocutaneous surface. A diffuse silvering of the mucosa, or stippling of silvery points, such is produced by lichen planus, is not the type of leukoplakia contemplated in this description.

On Finding Leukoplakia Look Backward Toward Syphilis, Forward Toward Cancer. Leukoplakia is not always of syphilitic origin, but it should always arouse strong suspicion of syphilis.

Irritation Alone Especially from T bacco and Bad Teeth, May Produce Leukoplakia, but irritation plus syphilis is even more effective. Syphilitics who use tobacco are especially subject to leukoplakia.

Leukoplakia also Occurs on the Penis and About the Mucous Surfaces of the Labia.

Syphilitic Leukoplakia is Scar—the scar of the mucous patch. It is not an active process, and it is useless to search it with the darkfield for *Spirochaeta pallida*.

Syphilitic Leukoplakia M y However Coexist with Fresh Mucous Patches, and with later gummatous manifestations on the mucous membranes. The surface of leukoplakia is drier tougher more leathery than mucous patch. It is not an easily removable pellicle or exudate.

In Conformity with the Sites of Predilection for Mucous Lesions, leukoplakia of the commissures of the mouth and the lip is most suggestive of syphilis. Next comes leukoplakia of the dorsum of the tongue, then of the anterior faucial pillars. Leukoplakia of the buccal and gingival mucosa is least suggestive of syphilis, and line of thickening along the junction of the teeth or slight buccal silvering is not suggestive at all.

A Wassermann Test is Not Sufficient to Eliminate th Possibility of Syphilis from patient presenting clinically suspicious type of leukoplakia. Look further even to the spinal fluid.

The Risk of Malignant Degeneration in All Forms of Leukoplakia is Serious. Destroy each patch with radium, cautery or excision as indicated.

A Leukoplakial Patch Which is Raised, has raised border or which is ulcerative or eroded may be already malignant. Excise such lesions and examine microscopically if possible in serial section before completing treatment or discharging the patient. Feel for glands.

Treatment for Syphilis Has N Effect on a Fully Developed Leukoplakia. Destructive measures are necessary part of its management whenever found.

Syphilitic Patients Should Give Up Smoking and practice rigid mouth hygiene if they show any tendency to relapse on the mucous surfaces, in order t reduce the tendency t develop leukoplakia.

and pharynx, may be associated with a grade of constitutional disturbance emaciation, and cachexia which is out of all proportion to their physical importance as lesions. Stokes has seen a starvation acidosis of a serious grade in a patient brought in as an ambulance case whose entire trouble was traceable to a crateriform ulcer of the posterior pharyngeal wall that was so painful that *swallowing had* become impossible.

Because of their location, and the associated constitutional condition, gummatous lesions of the posterior portion of the tongue, of the pharynx and nasopharynx and of the epiglottis are especially apt to be regarded as tuber

culous. This error is less likely to occur if the lesion is a typical solitary gummatous ulcer whose yellow base and raised or crateriform indolently inflammatory margin are comparatively easy to recognize. The arciform configuration of several confluent lesions may suggest their syphilitic character. Tuberculous ulcers are more ragged, usually more acutely inflammatory and

Fig. 418.

TYPICAL APPEARANCE AND LOCALIZATION FOR SYPHILITIC LEUKOPLAKIA

Male, aged forty-one, married.

A, Commissural leukoplakia. Note the imbricated leathery appearance and the sharp contrast with the mucous membranes. The mucous patch shown in Fig. 412, A, is the commonest source of leukoplakial lesions of this type.

B, Labial leukoplakia the result of mucous lesions such as that in Fig. 412, B. This is typical smoker patch.

DISCUSSION

This patient came to the Section of Dermatology for "eczema of the hands" of fifteen years duration. He had not the slightest suspicion that he had syphilis, and could give no history of early manifestations, although he admitted two attacks of gonorrhea.

Immediately upon examining his mouth he was told that there was an 80 to 90 per cent probability that he had syphilis. The Wassermann reaction taken next day was strongly positive.

The eczema of the hands was at first supposed to be a palmar syphilid, but responded too slowly to treatment, and relapsed with typical fissuring in six months.

There was no definite history of mucous lesions obtainable. The patient did not seek relief for his leukoplakia. He was a moderate smoker of pipe and cigars.

There is no evidence of beginning malignant degeneration about these lesions. None the less they were treated with radium with completely satisfactory results.

It is not contended that all leukoplakia is syphilitic, but leukoplakia of the lips and commissures should invariably arouse suspicion and lead to a full investigation for syphilis. This patient could not be followed long enough to secure a spinal fluid examination, though there were clinical reasons for suspecting the need for it (early paresis (?))

painful, though not necessarily so, and are apt to present a characteristic of all tuberculous processes in that the margins are less sharply defined than those of syphilids, and minute reddish yellow translucent points beyond the edge of the ulcer indicate the sites of tubercles in the subjacent tissue which has not yet broken down. It is frequently possible to demonstrate tubercle

bacilli in smears from the floors of tuberculous lesions of the pharynx and tongue, and tuberculosis of these regions is seldom primary so that a focus can be found in the chest on physical examination.

Fig. 510

LEUKOPLAKIA OF THE DORSUM OF THE TONGUE IN A SYPHILITIC WHO COMPLAINED ONLY OF PSORIASIS

Male, aged forty-three, married.

This patient came to the clinic to seek relief for psoriasis and for a sore tongue. He had no idea that he had syphilis and seemed dazed when told before the blood Wassermann test was taken that the condition on the tongue was almost certainly syphilitic. Subsequently he showed in both speech and manner signs suggestive of early paresis. The neurologic examination, however, yielded nothing.

The Wassermann reaction on the blood was strongly positive. Spinal fluid Wassermann +++ with 0.4 and 1 c.c., Nonne positive, 60 small lymphocytes and 3 large lymphocytes, gold sol 4555543210.

The small ulcerative lesion and nodule did not respond to treatment for syphilis and were regarded as probably early epithelioma. Radium was used.

Note the destruction of the papillæ by the process which produced the leukoplakia. This destruction of the papillæ with an equal amount of scarring but without leukoplakia can be produced by syphilitic sclerosing glossitis which produces a smooth red shiny tongue (see Fig. 384).

This patient had had psoriasis for fourteen years. The leukoplakia of the tongue had first attracted his attention eighteen months before coming to the clinic. There was also some involvement of the angles of the mouth. On questioning, the patient recalled having had canker sores in this region for some years.

The canker sore (aphthous ulcer) is a familiar misinterpretation of the mucous patch.

In psoriasis occurring in conjunction with leukoplakia of the tongue leukoplakia is sometimes regarded as psoriasis of the tongue. The consensus of authoritative opinion is that true psoriasis of the mucous membranes is disputable.

Note the negative neurologic examination with so high a grade of cerebrospinal involvement.

The pathologic demonstration of malignant changes in a syphilid of the mucous membranes may call for more than one examination of tissue, inasmuch as the beginnings of a malignant degeneration may be missed in a single biopsy from an extensive lesion. In general, for tissue examination the piece

should be taken from the border which is *hardest* to the palpating finger To avoid the slightest risk of inducing traumatic metastasis, the biopsy should be taken on the operating table under conditions which permit immediate execution of any operative procedure which may be called for if a malignant degeneration is found

Fig 510

NON-SYPHILITIC LEUKOPLAKIA WITH COINCIDENT SECONDARY SYPHILIS

Male, aged twenty single, farm hand.

This leukoplakia was limited to the buccal mucosa of the left side of the mouth, and was the result of the chronic irritation of chewing tobacco. Nothing could be a better demonstration of the fact that syphilis even when present is not invariably the cause of leukoplakia.

This patient had a coincident florid secondary syphilis, too early to have been instrumental in the development of the leukoplakia.

It is interesting that no signs of a primary lesion could be found, but there was history of a bubo *below the right ramus of the jaw* which had been incised a year before A chronic inflammatory process in the skin about the scar suggested the possibility of actinomycosis, but the pathologic diagnosis of the excised gland was tuberculosis, and nothing could be obtained from the pus.

The patient according to his statement had been assured by a physician that the corymbose follicular and papular secondary syphilid was a drug eruption. The Wassermann reaction was strongly positive

The differentiation of gumma and tuberculosis by the examination of excised tissue from lesions in the mouth and throat involves a considerable factor of possible error Both lesions are histologically granulomata and the picture presented by the tissue in the absence of typical tubercles may make a reliable diagnosis of tuberculosis impossible. *In all such examinations, especially when carried out by a laboratory not in close touch with the clinician who excised the tissue the typical tubercle in sufficient numbers to place the diagnosis beyond question, or the finding of the bacilli is the only sound basis for a diagnosis*

of tuberculoma. In all other cases in which tuberculosis is suggested, but not established, a report of "Granuloma, uncertain etiology but probably tuberculous" is the conservative diagnosis. If plasma cells are present we believe it

Fig. 341

EARLY CARCINOMATOUS DEGENERATION LEUKOPLAKIA OF THE TONGUE. NO SYPHILIS DEMONSTRABLE

Female, aged forty-one, widow

Note the superficial ulcers.

The only significant physical findings were hypo-acidity and small fibroid uterus. Syphilis is, however, sometimes difficult to demonstrate by single examination in women.

A pathologic examination for malignancy should be secured on every leukoplakia which shows any *signs* of ulcerative or proliferative change.

Fig. 342.—Gummatous nonulcerative infiltration of the lower lip. Note the entire absence of ulceration. Lesions of this type may attain an almost wooden hardness. (Collection of Dr F. G. Harris.)

to be entirely within the province of the pathologist to suggest the possibility of a syphiloma, and entirely proper on the basis of such a report for a clinician to institute a therapeutic test for syphilis rather than an immediate operative intervention. *Ten to fifteen daily injections of mercury succinimide* (½ *grain*) *or*

should be taken from the border which is *hardest* to the palpating finger To avoid the slightest risk of inducing traumatic metastasis, the biopsy should be taken on the operating table under conditions which permit immediate execution of any operative procedure which may be called for if a malignant degeneration is found

Fig. 520

NON-SYPHILITIC LEUKOPLAKIA WITH COINCIDENT SECONDARY SYPHILIS

Male aged twenty single, farm hand.

This leukoplakia limited t the buccal mucosa of the left side of the mouth, and was the result of the chronic irrit tion of chewing tobacco. Nothing could be better demonstration of the fact that syphilis even when present is not invariably the cause of leukoplakia.

This patient had coincident florid secondary syphilis, too early to have been instrumental in the development of the leukoplakia.

It is interesting that no signs of primary lesion could be found, but there was a history of bubo below the right ramus of the jaw hich had been incised year before A chronic inflammatory process in the skin bout the scar suggested the possibility of actinomycosis, but the pathologic diagnosis of the excised gland was tuberculosis, and nothing could be obtained from the pus.

The patient according t his statement had been assured by physicia that the corymbose follicular nd papula secondary syphilid as a drug eruption. The Wassermann reaction w strongly positive

The differentiation of gumma and tuberculosis by the examination of excised tissue from lesions in the mouth and throat involves a considerable factor of possible error Both lesions are histologically granulomata and the picture presented by the tissue in the absence of typical tubercles may make a reliable diagnosis of tuberculosis impossible. *In all such examinations especially when carried out by a laboratory not in close touch with the clinician who excised the tissue the typical tubercle in sufficient numbers to place the diagnosis beyond question, or the finding of the bacilli, is the only sound basis for a diagnosis*

Fig. 381.

SUPERFICIAL SCLEROSING SYPHILITIC GLOSSITIS ("GLATTZUNGE")

Male, aged fifty-two, farmer

A Tongue Over Considerable Portion of Whose Surface the Papillæ Have Disappeared, or Whose Outlines or Surface are Distorted or Lobulated by Smooth Cicatricial Contractile Bands Should Arouse Strong Suspicion of Syphilis.

Note the smooth shiny atrophy of the left side of the tongue as compared with the normal "furry" surface on the right. The same smooth atrophy may involve the whole surface, or may be confined entirely to the portion of the tongue posterior to the circumvallate papillæ, where it can be felt rather than seen. The smoothness is the sequel of superficial gummatous infiltration which on involution leaves the atrophy. The active process often does not attract the patient's attention, or may be accompanied only by slight redness, or burning sensation on eating acid foods. This latter is a nondescript symptom that may occur with any form of glossitis and is not at all distinctive of syphilis.

Symmetric cross-striation of the tongue, which also occurs in this picture, is not evidence of the presence of syphilis unless produced by actual scar tissue. The congenital anomaly of "scrotal tongue" is sometimes confused with the scarred tongue of interstitial glossitis through failure to appreciate that there must be actual *scarring*, not merely furrow.

It was Suggested on Examination of This Patient, That All the Pathologic Change Might Be Ascribed to His Rather Heavy Use of Tobacco. None the less, an investigation for syphilis was made. The following was the result:

1. A penile lesion at nineteen years (thirty-three years ago).
2. Married twenty-four years, wife well, 4 children well, no miscarriages (married after the infectious period).
3. A negative blood Wassermann reaction, negative on one repetition, **But Once Positive and With One "Clears Slowly" in 6 Tests Following Provocative Injection.**
4. A negative spinal fluid, but definitely irregular pupils and marked reduction of bone fork sensation.

Whether Tobacco is a Factor or Not, It Is Worth While to Investigate Syphilis in Patients with Tongues Like This. This Patient had Syphilis Albeit the Infection was a Mild One.

FIG 525 —SCLEROSING GLOSSITIS OF THE DEEP OR INTERSTITIAL TYPE

This type of lesion produces lobulation of the margin of the tongue after the process subsides. Deep gummas likewise produce cicatricial contracture (Collection of Dr F G Harris)

A B

FIG. 526 —SYPHILITIC SCLEROSING GLOSSITIS LIMITED BY LICHEN PLANUS OF THE TONGUE.

In B is shown the reticulation and stippling of the buccal mucosa of the same patient which is characteristic of lichen planus. It seems trit t suggest it, but no lesion on the tongue should be diagnosed without an examination of the mouth and of the skin.

FIG 527

FACTITIAL GLOSSITIS IN BENIGN PLAQUE OF THE TONGUE

A Patch of Smooth Atrophy of the Tongue is Not Pathognomonic of Syphilis.

T the right of the midline on the dorsum of the tongue is patch the size of penny exhibiting not only loss of papillæ but tual superficial scarring with leukoplakia.

On the left-hand margin of the tongue i thick bit plaque one of t lesions originally present constituting the condition known benign plaques of the tongue

On First Sight Tongue Like This Would Appear to be Worth 85 Per Cent. for Syphilis. The patient uncommunicative and it w not until an in estigation for syphilis w begun that found that she had been treating whitish patches, under the instructions of physician, ith nitrat of sil er f r some months. This systematic cauterization in all probabil ty responsible for the destruction of papillæ and the scarring The plaque on the left margi almost too smooth, whit and thick for typical syphilitic leukoplakia

Darkfield and culture of both lesions w entirel negative

The patient had married t t enty-one years of age A full in estigation for syphilis as entirely negative. The leukoplakial patches ere treated ith radium.

The bacteriological examination of lesions on the mucous membranes by smear and darkfield involves important elements of error which the syphilologist must take into account. The finding of tubercle bacilli in smears as an

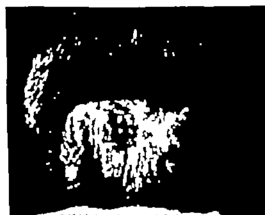

Fig. 528.—The Typical "Leukoplakia" of Lichen Planus upon the So-called "Scrotal Tongue," a Congenital Abnormality.

The term "leukoplakia" is a misnomer in lichen planus, for the lesion disappears under treatment for the general condition, as do the lichen planus papules on the skin. Remember that lichen planus clears up under both mercury and arsenic.

aid to the identification of tuberculous lesions has been mentioned. In common with all destructive lesions in the mouth, ulcerating late syphilids present a rich saprophytic flora. The Vincent symbiosis of a large spirillum and a fusiform bacillus (variations on a common type form) may be abundant in the

Fig. 529.—Periadenitis Mucosa Necrotica Recurrens of the Tongue.

This is probably an infection of the mucous glands, which may clear up under arsphenamine. This patient had had repeated acute attacks.

necrotic tissue of histologically demonstrated epithelioma and lymphoma, and there seems no intrinsic reason why, as on the genitalia, such a combination should not occasionally be found in the necrotic tissue of gummas. While we have no demonstrative evidence to offer on this point as yet, we believe that

Fig. 533.

PERFORATING GUMMA OF THE SOFT PALATE

Male, ged forty-five single, railroad man.

Perfor tion of the Hard or Soft Palate Is th Nearest Approach to Pathognomonic Sign of Syphilis to be Found on th Mucous M mbranes.

While epithelioma and Vincent angina may occasionally ca se destructive changes in these regions, perforation which does not show marked neoplastic change in gross examination is almost invariably syphilitic in origin. The active lesion is often surprisingly *inconspicuous and painless. A slightly edematous margin to the opening* may be the only evidence of activity in rapidly progressing process. W th marked involvement of bone the fetor is very pronounced.

This Patient was Wassermann Negative on th Blood, and Had Been So on Several Occasions Before Entering the Clinic. Gummas f the Hard and Soft Palate are Not Infrequently Wassermann Negative This patient syphilitic infection wa of t only eight years duration and ulcerative processes in the palat nd pharynx had begun fifteen years after onset At that time the patient received arsphenamin, the lesion healed, and he discharged as cured

Two Attempts Had Been M de to Close th Supposedly Healed Perforation by Plastic Operation, both of hich failed completely the lesion breaking dow ithin ten days The second ttempt as made following 3 arsphenamin injections and 11 injections of mercury succinimid.

It is Saf Principle to Defer Operative Interfer nc with Palatal Syphilis Even in Wassermann N gativ Cases Until Months and Years of Intensive Treatment Have Been Carried Out. These patients al ys consider relief from the annoyance of the fistula first, and their eagerness for operation occasionally lead surgeons int interfering gainst their better judgment

The Mer Fact of Wassermann Negativity Means Littl or Nothing in th Diagnosis of Syphilis from Palatal Perforations. It is Also Not Saf Guide to Fitness for Operation.

Operative interference in syphilitic nasopharynx may cause violent flare-up of gummatous process which will cause tremendous destruction before it can be checked.

diagnoses of Vincent's angina should be made with much more reserve than in the past, in late as well as early syphilis, and that the morphology of the lesion and the collateral evidence for or against syphilis quite outweigh the bacteriological findings.

Darkfield examination for Spirochaeta pallida, while of the utmost importance in early and recurrent syphilis, is useless in late lesions of the mucous membranes.

LATE SYPHILIDS OF THE PALMS

Late syphilids of the palms are not infrequently symmetric and practically never ulcerate. For that reason border configuration, induration, and atrophy are the most significant characteristics in differential diagnosis. The morphological differentiation of palmar syphilis may be a matter of the greatest difficulty. Even an almost invincible suspicion in a given case may remain

Fig. 434.—Acute eczematous processes involving the palm are, as a rule, easy to identify because of their vesicular character. Chronic eczema, in which the acute inflammatory process has been replaced by scaling, fissuring, and thickening, is the type which is apt to be confused with a syphilid.

Vesicles in palmar eczema and dermatophytosis may be small, translucent and deep, or visible only as slight, apparently papular elevations. On puncture fluid exudes. Often they may be found along the sides of the fingers, though absent elsewhere. They may contain pus, and show a tendency to confluence, with extensive undermining, producing the so-called dermatitis repens.

Fissuring is the hallmark of chronic palmar eczema. Note the fissuring in these palms.

Syphilids, even of long standing, seldom fissure. If the patient gives a history of cracking of the affected skin during the winter, which may be the only season at which this phenomenon occurs, a diagnosis of syphilis must be made with the greatest caution.

Not all eczema of the palms produces fissures, however.

Eczematous changes in the palm may range from a smooth patch of thickened skin in the hollow of the hand to plaques, patches and gyrate lines, and groups of papules involving most of the surface. The tendency to involve the interdigital spaces is marked in eczema, and eczema exhibits a distinctly greater tendency to bilateral symmetry as regards the situation and shape of individual lesions than does syphilis.

In subacute eczema moist or oozing lesions may occasionally be found in the interdigital folds when all the rest of the eruption is dry. The finding of an oozing patch means that vesicles have been present and speaks against a syphilid.

Fig 535

IMPORTANT POINTS IN THE DIAGNOSIS OF PALMAR SYPHILIDS

1 The patient usually comes with a diagnosis of eczema.

2. Never be content with an examination confined to the local lesion. Insist on seeing all parts of the body

3 Look t the backs of the hands well the palms, and at the interdigital spaces, wrists, forearms, and flexures. The clue t the whole situation may lie in the finding of vesicles or indurated border in lesions in these places.

4 Vesicles eliminat syphilis for all practical purposes in adults. This does not mea that the patient may not have coincident syphilis, or palmar syphilid ith coincident eczema.

5 An indurated cord-like border suggests syphilid.

6. Take careful nd detailed history ith special reference t ( ) familial occurrence of the condition and (b) vesiculation t some earlier stage or previous outbreak of the eruption, ( ) itching, and increased irritation by w ter nd soap.

7 Study the nails. Look especially for psoriatic pitting

8. Take scraping if even the slightest scale can be raised on the lesion, and after soaking the scales for hour on slide in drop or two of 20 per cent potassium hy droxid, examine for trichophyton spores and mycelium, even though there be other evidence of syphilis. It takes familiarity and practice for this test.

9. The response of palmar syphilids t mercury has been slow in my experience, but rapid to arsphenamin and fairly rapid t bismuth.

10. If provocative procedure is carried out, see the patient daily for eek. If by the end of that time the lesion is not more than half involuted, better be cautious in basing diagnosis on the palmar lesion without supporting evidence.

11 Call an expert, and do not dismiss doubtful cases without rranging for observation and reconsideration.

Fig. 536.—This figure presents fairly good example of the diffuse erythematous syphilid of the palm which is most often regarded eczematous. The entire palm is red, rather doughy and infiltrated, perfectly dry and moderately scaling. Here and there suggestions of mottling or spotting with slight trophic changes can be recognized, especially where the skin is normally thinner as at the base of the thumb. Th border is the crux of the whol matter Note the sharp raised margin along the wrist and the index finger On palpation distinct cordlike subcuticular resistance could be felt in the margin which wa distinct from the "feel" of the rest of the eruption. The left palm wa involved, but less extensively tha the right.

wholly unconfirmed while the ability of a palmar syphilid to simulate other dermatoses is so perfect that the most expert may be thrown wholly off his guard. The inexperienced should be quick to suspect, slow to diagnose palmar syphilids.

The ubiquity of ringworm infections of the palms and soles is little realized. Halsey and Jordan found 67 per cent of 100 students to present clinical lesions, 5 per cent culturally demonstrable and 15 per cent with definite histories of previous attacks. The ringworm of the palm is

Fig. 537

THE MORPHOLOGIC DIAGNOSIS OF A WASSERMANN NEGATIVE PALMAR SYPHILID

Late syphilids induce permanent changes in the skin which they involve. On the palm, *atrophy rather than scarring is the expression of this change.* Atrophy shows itself as a loss of substance in the cutis without destruction of the overlying epidermis. The epidermis collapses into the shrunken base, and is both thinned and flattened in the process which leads to the atrophy. The predilection of syphilis for destruction of the elastica, plus the shrinkage of the base and the thinning and flattening of the epidermis, leads to the wrinkling which occurs in the skin that has been involved by a syphilid. **On the Palm this Atrophy Appears as Wrinkling and Thinning—an Aging of the Palm. Eczema, It Should Be Remembered, Produces Thickening of the Palm.**

Why Has This Young Woman a Syphilid and Not an Eczema of the Palm, she and her physician thought she had

1. *Note the Border.* It was distinctly cord-like, of a dull brownish-pink color. The induration was distinctly palpable. The entire process was dry.

2. *Note the Atrophy.* On one side of the dividing line of induration (toward the wrist) is the smooth, elastic, pink "rubbery" texture of the skin of a young woman. On the other side of the border is the thinned, flaccid, wrinkled, atrophic skin of an old woman, plus the faintest trace of hyperpigmentation. There is twenty years' difference between the two parts of the palm, produced by the passage of the line of induration across the surface.

3. The lesion was unilateral. There was slight involvement of the backs of the fingers, each lesion with a definite border.

4. There were no fissures or vesicles or history of either, no eczema elsewhere, no family history.

1

Fig. 537.—Continued.

5. **The Blood Wassermann Reaction was Negative** but in the presence of a lesion so definitely conforming to the morphologic characters of palmar syphilid, this does not exclude syphilis.

6. In the diagnosis of a lesion of this sort, in which syphilis is denied by the patient and not supported by the positive blood Wassermann reaction, two other aids to diagnosis may be drawn. A provocative procedure, it will be recalled, provides the opportunity to watch for a focal flare-up after the arsphenamin injection, and constitutes a short therapeutic test. A provocative test was done in this case.

7. No positive Wassermann reaction could be obtained following three decigrams of arsphenamin intravenously but the **Lesion Underwent a Marked Focal Flare-up During the Twenty-four Hours Following the Injection. It Then Subsided, and by the End of the Seventh Day had Practically Vanished.** An attempt was made to photograph this flare-up, and the sharper definition of the border and the presence of points of activity not visible in the lesion before injection could be made out by close inspection in spite of the difficulty in recording the color values. The whole palm showed a distinctly deeper blush, as well as the border.

Discussion

No positive Wassermann test on the blood has ever been obtained from this patient in five years of observation. She was forty years of age at the time the lesion was first seen, and had been married at thirty-two years of age. Her husband, apart from a duodenal ulcer, enjoyed good health. There had been no pregnancies, though no preventive measures had been used. A chronic salpingitis was found at a subsequent operation. The patient's denial of infection was made in good faith, though error might have crept into some of the collateral anamnesis. No other evidence of syphilis than the palmar lesion could be elicited in a complete examination.

The Lesions Vanished with the First Arsphenamin Injection, and Have Never Reappeared. No ringworm could be found in the scales.

Is it Justifiable to Make a Diagnosis of Syphilis on the Basis of the Palmar Lesion Here Shown, in Spite of Repeatedly Negative Wassermann Reactions and Negative General, Neurologic, and Special Examinations Including a Negative Spinal Fluid?

We Believe That it is. A Persistently Negative Blood Wassermann reaction is not a rare finding where the diagnosis of syphilis can be established beyond peradventure. It is entirely compatible with the development of active syphilids in the skin.

Syphilis in Women Runs a Traditionally Mild Course. Solitary manifestations are quite in keeping with this characteristic.

Had there been no Herxheimer flare-up, had it taken three weeks to clear up this lesion instead of one, or had she had recurrences, the diagnosis would have been in doubt. The arsenic in arsphenamin might clear up a palmar eczema if the drug were continued. The ideal procedure, had time permitted, would have been to clear up the lesion with mercurial treatment (mercury succinimid intramuscularly ⅕ grain daily).

In a Woman Within the Childbearing Age It is Sometimes Advisable to Treat "For Life Insurance" Provided It is Carefully Done Even When the Evidence of Syphilis is Less Suggestive than This. It May be Accepted as Axiomatic that Women in Whom the Suspicion of Syphilis Has Been Raised on Reasonable Grounds Should Have the Benefit of Observation at Intervals for Some Years.

best identified by its associations, though these do not, of course, eliminate syphilis. The associates of palmar ringworm are (1) the soft corn and fissure between the toes; (2) the eczematous extension from fissure with the oozing, furiously itchy patch of dermatitis on the palmar surface; and the hyperkeratotic-vesicular ringworm, in which vesiculation occurs only occasionally the lesion usually as here being keratotic plaques. At times this keratosis may be so marked as to constitute veritable armor as in the keratodermic ringworm of the heel, which should not be confused with the keratodermic syphilid. Examination of scales, while important, is less often conclusively diagnostic than are the clinical considerations.

Fig. 534.

(For accompanying text description see next page.)

Fig. 538.—*Continued.*

THE DIAGNOSTIC PROBLEM OF A PALMAR SYPHILID

Mrs. A. B., aged twenty-eight, married, husband a railroad man, sought relief for "ringworm of the hand" and incidentally was seeking opinion on the advisability of bringing suit for x-ray burn of the right palm. Three years ago circles had appeared on both palms simultaneously. A practitioner with x-ray equipment had told her, according to her story, that she had "ringworm" and had made six exposures in eight days. Later she had consulted a dermatologist of competence who had made a diagnosis of psoriasis, she said. From her description she had then apparently been given Fowler solution.

The two palms confirm the treatment story and illustrate graphically two of the most serious potential errors in the morphologic diagnosis of all cutaneous recurrent and late syphilis, but especially of palmar lesions.

The right palm exhibited the scarred, telangiectatic, and fissured surface of a typical x-ray dermatitis.

On the left wrist was an active lesion of the type which had led to the previous diagnoses. The ring was almost perfect, with a ribbon-like band of slight induration and the faintest appreciable scale. The center was fawn colored, smooth, slightly wrinkled, and atrophic.

The left palm was thickened and hard, and studded with typical small arsenical keratoses.

Why Suspect Syphilis?

1. An indurated, perfect circle with slight but definite central atrophy and almost no scale.

2. Not a vesicle in the margin or elsewhere. Too much induration, too narrow and perfect a band, too exquisite a definition, no organisms in the scales.

3. With the above considerations not a sign of psoriasis on the nails or elsewhere on the body.

The Wassermann Reaction was Positive. The lesion practically disappeared before the second arsphenamine injection. A positive Wassermann reaction was obtained later elsewhere. There has never been a recurrence in three years' observation. The history of infection was negative except for one spontaneous miscarriage at three months, no subsequent pregnancies.

If the Wassermann Test had Been Negative? It Should Be Repeated and if Persistently Negative the Therapeutic Test and Subsequent Observation as Outlined Would Have Established the Case. A lesion that would not yield to arsenic enough to produce keratoses would hardly yield to the arsenical effect of one injection of arsphenamine. But it is well to be cautious in drawing conclusions from arsphenamine therapeutic tests, especially in palmar lesions.

Fig. 539.—The hyperkeratotic ringworm of the palm. Fungus found in the scrapings

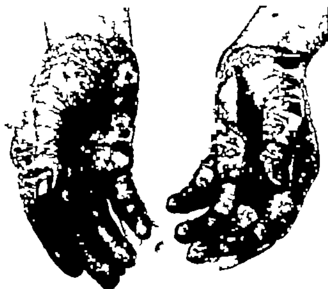

Fig 540.—An example of probable psoriasis of the palms. The geographic configurations are at times quite suggestive of syphilid. The complete lack of induration, lesions of psoriasis elsewhere (sometimes absent), the psoriatic changes in the nails (Fig 530), and the elimination of syphilis by lack of collateral evidence make the diagnosis. At times lesions of both these types are produced by ringworm fungi, and the scales should, accordingly be routinely examined.

Fig. 541

The syphilologically suspicious mind will see at once in the group of lesions on the thenar eminence a suggestively arciform configuration. The individual elements are dense, almost translucent horny papules with the faintest suggestion of pink in the tissue about the base and a central dell or crater not unlike that of a large arsenical keratosis (see Fig. 293) or the pit that *remains when the necrotic plug is extracted from* a papulonecrotic tuberculid lesion. The differentiation is given in connection with Fig. 542.

This is "laes cornée" of the palm. On the heel, where the general hyperkeratosis is more marked, the lesion is less conspicuous and may simply appear as pits i[illegible] thickened integument.

The History of This Case is as Follows:

A robust young married woman of t[illegible]enty-eight presented herself [illegible]ith [illegible] complaint of obstinate and persistent headache and backache. I[illegible] the course of her general examination the lesions show[illegible] [illegible]bove [illegible]ere recognized by her general examiner and described as looking "like corns on the fingers. The dermatologic floor consultant was [illegible]sked t[illegible] see the [illegible]arts. There [illegible]ere no other cutaneous lesions. The general examination had disclosed signs of chronic salpingitis, the eyes [illegible]ere negative and [illegible] sacro-iliac belt wa[illegible] suggested for relief of her symptoms.

Th[illegible] Blood Wassermann Reaction was Negative on Four Repetitions. The spinal fluid examination yielded the following findings: WR negative 0.4 and 1 cc [illegible]onne positive, lymphocytes 152, gold sol 4553202000. **Even with This Spinal Fluid th[illegible] Neurologic Examination was Negative.**

In the first taking of this patient [illegible] history she gave no information regarding her husband, but in subsequently discussing the matter with her husband it developed that she had separated from him [illegible]t one time and then returned t[illegible] him, that she knew he had syphilis and had been treated for it, but supposed he [illegible]as cured The subsequent examination of the husband revealed the lesions show[illegible] in Fig 414.

The larger part of this patient [illegible] symptoms were due to the high-grade meningeal neurosyphilis which she presented, and were markedly improved by treatment. **It is Worth Remembering that There is Not [illegible] Singl[illegible] Phase of Active as Well as Latent Syphilis Which Cannot Occur in Association with [illegible] R[illegible]peatedly N[illegible]gative Blood Wassermann Reaction. Only [illegible] Spinal Fluid Examination Will Disclose the Real Status of Many Cases with Neurasthenia or Indefinitely Explainable Constitutional Complaints.**

Fig. 542.—The Papulonecrotic Tuberculid of the Fingers (Folliclis)

A, Note the small brownish-black plugs and the occasional conical pits in the skin of the index-fingers. In the middle finger is a papule with a central depression not unlike that on the index-finger of the patient in Fig. 541. This is the papulonecrotic tuberculid of the hands, known technically as "folliclis."

B, Note the characteristic scarring produced by the tuberculid on the dorsums of the fingers, and active lesions on the index and middle fingers.

The Individual Lesion of the Papulonecrotic Tuberculid of the Finger Runs the Following Characteristic Course. It begins as a tender point, at which a papule forms, in the center of which a vesicle appears. The vesicle becomes dark and dries down, leaving a papule with a central conical plug which is the elementary lesion of the papulonecrotic tuberculid wherever it occurs. This plug can be picked out as the lesion heals, leaving a central conical depression which flattens in time to a small round white atrophic scar.

The Lesions Usually Appear in Crops, and the patient can often give a definite history of the vesicular stage and of the pain on pressure which resembles "a thorn sticking into the flesh." The sites of predilection are *the fingers, not the palms*, and especially the tips and the backs of the fingers. The scars can usually be found on the back of the fingers as in A, which also presents one or two active lesions. The fingers are apt to show some vasomotor disturbance in folliclis, and to be cyanotic, cold, and clammy. **The Tuberculid Has No Distinctive Configuration Such as That Usually Found in Syphilids.** The scattered character of the lesions is apparent from the scars as well as the active lesions. There is some tendency to localize at points of trauma.

A fairly rapid evolution (two weeks), showers or crops, repeated often in a seasonal manner (spring and fall), the history of vesiculation and tenderness, all of which contrast with the course of a syphilid, and the lack of configuration, the localization to the finger tips and backs of the fingers, and the formation of the characteristic small round white scar distinguish folliclis from a syphilid. In addition, there may be tuberculid lesions in other parts of the body, especially the forearms and elbows, and the legs. **The Importance of This Differentiation May be Appreciated from the Fact That Patients with Tuberculids May Have Partial Positive Wassermann Reactions on the Blood from Time to Time.**

Fig. 541

The syphilologically suspicious mind will see at once in the group of lesions on the thenar eminence a suggestively arciform configuration. The individual elements are dense, almost translucent horny papules with the faintest suggestion of pink in the tissue about the base and a central dell or crater not unlike that of a large arsenical keratosis (see Fig. 293) or the pit that remains when the necrotic plug is extracted from a papulonecrotic tuberculid lesion. The differentiation is given in connection with Fig. 548.

This is "lues cornée" of the palm. On the heel, where the general hyperkeratosis is more marked, the lesion is less conspicuous and may simply appear as pits in thickened integument.

The History of This Case is as Follows:

A robust young married woman of twenty-eight presented herself with a complaint of obstinate and persistent headache and backache. In the course of her general examination the lesions shown above were recognized by her general examiner and described as looking "like corns on the fingers." The dermatologic floor consultant was asked to see the "warts." There were no other cutaneous lesions. The general examination had disclosed signs of chronic salpingitis, the eyes were negative and a sacro-iliac belt was suggested for relief of her symptoms.

The Blood Wassermann Reaction was Negative on Four Repetitions. The spinal fluid examination yielded the following findings: WR negative 0.4 and 1 cc., Nonne positive, lymphocytes 152, gold sol 4333202000. **Even with This Spinal Fluid the Neurologic Examination was Negative.**

In the first taking of this patient's history she gave no information regarding her husband, but in subsequently discussing the matter with her husband it developed that she had separated from him at one time and then returned to him, that she knew he had syphilis and had been treated for it, but supposed he was cured. The subsequent examination of the husband revealed the lesion shown in Fig. 411.

The larger part of this patient's symptoms were due to the high-grade meningeal neurosyphilis which she presented, and were markedly improved by treatment. **It is Worth Remembering that There is Not a Single Phase of Active as Well as Latent Syphilis Which Cannot Occur in Association with a Repeatedly Negative Blood Wassermann Reaction. Only a Spinal Fluid Examination Will Disclose the Real Status of Many Cases with Neurasthenia or Indefinitely Explainable Constitutional Complaints.**

Syphilitic changes in the nails are in general, not particularly distinctive. The principal point upon which diagnosis may rest is not so much changes in the nail itself *as the association of paronychia and dactylitis of the terminal phalanx with the nail pathology.* Taken as they stand,

Fig. 545.—Lesions of the Nail and Nail Bed.

eczema of the nails, dermatophytosis of the nails, and trophic changes induced by syphilitic paronychia may at times be absolutely indistinguishable. Even the paronychia is not particularly distinctive.

Fig. 546.—The so-called "symmetric spade nail" or spoon nail, proposed by Varney as sign of syphilis. This patient had syphilis, and had sustained an operation for syphilitic gastric symptoms before coming to the clinic.

In the case here presented the friability and destruction of the nail may be quite as well due to dermatophytic infection as anything else. More commonly however the ringworm nail is thickened, friable, and raised from its bed. A suspicion of syphilis was aroused in this case by the very marked paronychia with thickening of the entire tip of the finger. The patient ad-

mitted having had genital sore fifteen months before and having been treated by intramuscular injections at the time his secondary eruption appeared. The trouble with the nails was of three months duration. *The blood Wassermann reaction was negative On provocative injection of arsphen-*

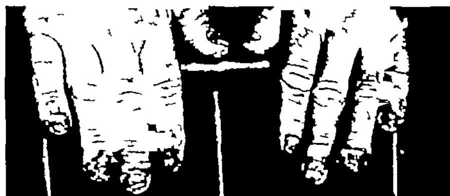

Fig 547 —Syphilitic onychia. Note the paronychial changes. (Collection of Dr William Allen Pusey)

amine however two moderately positive, one weakly positive one negative and two strongly positive tests were observed in six successive days. A well-defined local reaction (Herxheimer) with pain and tenderness followed the first arsphenamine injection. Marked improvement followed with the

Fig 548 —Tuberculosis may produce dactylitis and paronychia simulating syphilis, as well as collateral changes in the nail suggestive of trichophytosis. It is not necessary that all the nails be involved to suggest a systemic origin. In this case there was marked associated paronychia wherever the nail was involved. The nail of the right middle finger strongly suggests beginning trichophytosis. The tuberculous nature of the process was determined by biopsy from the left little finger and syphilis excluded by full investigation. The patient died of mesenteric tuberculosis two years later

institution of treatment. The paronychia disappeared, but the nails did not become completely normal even after three courses.

No dermatophytic organism could be demonstrated in scrapings from the nail but it is difficult to get positive findings in these cases

Fig. 549.—Dermatophytic nails. Note the thickening and elevation of the nail from its bed. One or all of the nails may be involved, and the process need not be symmetric. The demonstration of the fungus is best made by deep curettings from under the nail after prolonged maceration in 20 per cent sodium hydroxide on the slide.

Fig. 550.—Eczematous paronychia. Pyogenic organisms may be responsible for pictures ranging from this mild type to extensive and severe paronychial abscesses, and chronic exfoliative dermatitis of the finger ends (acrodermatitis perstans of Hallopeau). The pyogenic and impetiginous character and the greater acuteness of the inflammatory process in the nonsyphilitic conditions assist in differentiation.

MISCELLANEOUS CONDITIONS REQUIRING DIFFERENTIATION FROM LATE SYPHILIDS

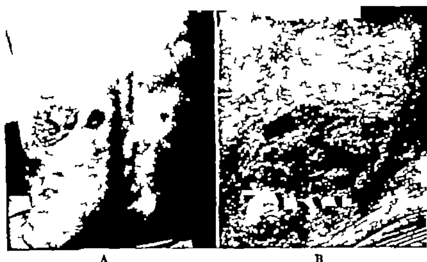

FIG. 551.—LYMPHOGRANULOMATOUS INFILTRATIONS OF THE SKIN SUGGESTING LATE SYPHILIDS, IN A PATIENT WITH HODGKIN' DISEASE.

The infiltrations are fleshy and indurated, and upon involution leave superficial atrophic scars with pigmentation, suggesting those of syphilids. There was no evidence of syphilis clinically or at autopsy

Fig. 552.—Arciform nodular infiltrations on the back of the hands, resembling syphilids, in Hodgkin disease. (Same case as Fig 551.)

A B

FIG. 453.—EARLY MYCOTIC STAGE OF M. CORIS FUNGOIDES.

The general dermatitis on which the syphilid-like infiltrations are beginning is shown in A. In B an early annular infiltrate is shown. These infiltrates are lymphogranulomas, fleshy and indurated, which on ulceration or spontaneous involution often leave pigmentation and atrophic remains very suggestive of syphilids. The infiltration of the face may suggest syphilid or lepra.

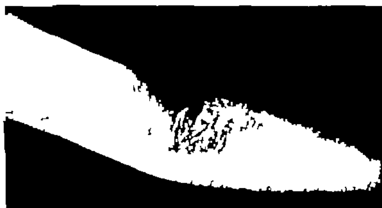

FIG. 454.—THE PAPULONECROTIC TUBERCULID ON THE ELBOW

This is one of the favorite localizations of this condition. Note the active dry necrotic-centered lesion among the scars. Compare this scar with that of the syphilid in Fig. 434. The crux in diagnosis hinges on the finding of typical papulonecrotic lesions, whether on face, hands, forearms, or legs. (See Fig. 348 for the hands of this patient.)

A B

Fig. 455.—This shows the remarkable resemblance that may exist between syphilids and tuberculids. The forearm in A shows crop of scattered late papules associated with an arciform lesion on the other arm, an aortitis, and positive blood Wassermann. Not that there are no scars, practically all the lesions being active papules without necrotic centers. I B, on the other hand, the proportion of scars as compared with active lesions is very large, and there are only few dry necrotic-centered papules. Arsphenamine therapy clears up both the tuberculid and the syphilid. The patient in B had been told he had psoriasis, the informant forgetting that psoriasis does not leave scars.

A B

Fig. 456.—Typical Lesions of Erythema Induratum Form of Tuberculosis of the Skin of the Leg

A shows the bluish-red infiltrated slightly softened plaque and B the symmetric distribution (not invariable) of the process. Not the papulonecrotic lesions adjacent t the large plaque. Erythema induratum usually occurs in women.

Fig. 487.—Scarring of tuberculids on the legs. Many of the scars in A have the configuration and peripheral pigmentation and the noncontractile atrophic character of syphilitic scars. Others, however show the scattering and lack of configuration which marks the tuberculid, as shown in B. Yet the scars in B could be mistaken for the scars of rupia, although rupia tends to appear on the trunk and face, tuberculids on the extremities. Both these patients were observed over considerable periods and the diagnoses completely verified.

FIG. 488.—THE EXAGGERATION OF TUBERCULOSIS BY SYPHILIS, PRODUCING TUBERCULO-GUMMATOUS SYNDROME.

This young woman had positive blood Wassermann reaction, and both parents had syphilis. She presents what appear to be broken-down tuberculous nodes, present since childhood (Vignolo-Lutati syndrome) and markedly indurated and extensive erythema induratum of the calf of the leg. Recovery under arsphenamine and mercury

Fig 559

Fig 560.

Fig 559.—Tuberculous gumma or gummatous tuberculosis (?) in woman with both tuberculosis and syphilis. The cervical glands were tuberculous, the blood Wassermann strongly and repeatedly positive Not the massive central slough and the involvement of the epitrochlear lymph node. Healing was rapid under combined treatment.

Fig 560.—Nodal tuberculosis of the fascia. This is a deep indurative form of tuberculosis, occasionally ulcerative, which may be mistaken for deep gumma. This young woman did not have syphilis, but made a rapid recovery under arsphenamine. Wende nodular tuberculosis of the hypoderm, hich does not ulcerate, ill also respond t arsphenamine.

Fig. 561.—Lupus Vulgaris Erythema forms

A form of cutaneous tuberculosis which may be confused with syphilis, dry type of great chronicity with some tendency to spontaneous healing. Not the entire lack of configuration suggesting syphilis, though this is not an invariable characteristic. Apple-jelly nodules may be identified Atrophic scars re visible

Fig. 502.—Tuberculosis Verrucosa Cutis.

The lesion is annular in configuration, but with typical verrucous papillomatous border

Fig 503 —Cutaneous extensions of tuberculosis (tuberculosis verrucosa cutis) from sinus opening in case of probable mediastinal tuberculosis. The scar is remarkably suggestive of that of late syphilid, and the active process was not clinically typical of tuberculosis. In attempting to make diagnosis of such lesion by examination of excised tissue, it should be remembered that tuberculosis verrucosa cutis does not invariably present typical tubercles. The scar suggests that of blastomycosis. There was slight temporary response to treatment for syphilis. The blood Wassermann reaction was negative.

Fig. 504.—A Typical Form of Sporotrichosis from Cutaneous Inoculation.

The site of inoculation is shown on the index finger Sporotrichosis of this type follows the lymphatics. The lesion on the finger is often spoken of as the sporotrichotic chancre, term which serves no useful purpose, and could well be discarded. Cultures can best be obtained from softened nodules before they discharge.

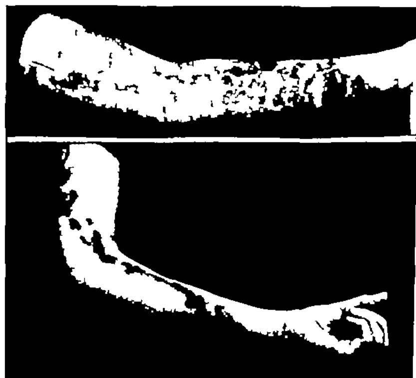

Fig 563 —A classical lymphatic distribution in sporotrichosis, showing incidentally the value of cleaning lesion before ttempting a diagnosis. Every nodule had been incised without decision. There is no object in ttempting histologic diagnosis of sporotrichosis from tissue for the picture is not specific.

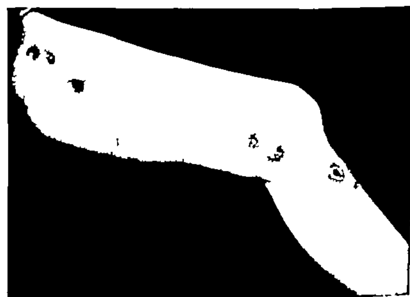

Fig 564.—Scattered sporotrichotic nodules suggesting rupial syphilitic lesions, but following the course of the lymphatics from the toe t the groin. They healed under arsphenamine and iodides.

FIG. 467.—BLASTOMYCOSIS OF THE LEG.

While the configuration may suggest syphilid, the papillomatous border eliminates it. The blastomycet was unusually abundant in the pus from the epithelial abscesses in this case.

FIG. 468.—THE IMITATION OF LATE SYPHILIDS BY BROMODERMA

The internal administration of bromides gives rise in hypersusceptible persons to pustular eruptions resembling acne (bromide acne) and to fungus papillomatous and granulomatous lesions which may occasionally suggest syphilids. Like syphilid, the fungoid bromoderma may extend peripherally involuting centrally with the formation of thin and usually somewhat crusted or scaling area of slight atrophy. The border however is papillomatous and papillomatous border practically eliminates syphilis.

This is bromoderma with papillomatous border, extending peripherally and involuting centrally with the formation of thin slightly scaling somewhat hyperpigmented scar

Fig. 569.—Fungous or hypertrophic tuberculosis in the groin, momentarily suggesting large condylomas. There were typical lesions of verrucous tuberculosis elsewhere.

Fig. 570.—Syphilids are rarely vegetative or fungous in character. The so-called frambesiform syphilid is recognized, however. (Collection of Dr. Udo J. Wile.) The decision as to the syphilitic character of the lesion must rest on collateral factors. In the groins condylomas may be found.

A

B

C

FIG. 571.—TYPICAL LESIONS OF ENDOTHELIOMA (ANGIOSARCOMA).

Note the "punched-out" ulcers in B. C, Endothelioma—tumor cells forming trabeculae; vacuoles in the cytoplasm of individual cells; the coalescence of these vacuoles forms large spaces. × 160. (Case published by *Dr G. J.* [illegible].)

FIG 572.—TYPICAL LESIONS OF SO-CALLED "GRANULOMA ANNULARE" ON THE HANDS.

The arcs and rings are infiltrated and have a granulomatous feel. Lesions may occur on face and neck, and occasionally scattered all over the body. They do not respond to treatment for syphilis. The histology is very characteristic (central caseation with radiating connective tissue strands) and fairly eliminates syphilis in case of doubt.

CHAPTER XVI

LATE SYPHILIS OF THE SKELETAL SYSTEM

The manifestations of early syphilis in skeletal structures have been touched upon in Chapter XII The present chapter deals mainly with the description and diagnosis of the later types of lesions. The rich lymphatic supply of the bone marrow and periosteum the dependent position of the long bones, the slow circulation, all tend to make the osseous structures par ticularly reservoirs for the infection, and to place bone manifestations among the most ubiquitous in the entire symptomatology of the disease.

Syphilis of bony structure occupies, moreover in the general pathology and immunology of syphilis place not unlike that of the skin in that the reaction in these tissues appears to be an important part of the general defence mechanism. DesBrisay and Stokes in study of 206 patients with untreated syphilis, largely of lat type found that syphilis of the nervous system was rare in those who had developed syphilis of the bones. Brunsting and Stokes found the highest proportion of osseous syphilis in Wassermann-fast patients to be associated with syphilis of the skin and the lowest with syphilis of the nervous system. In the Mayo Clinic series it appears that exclusive of tabetic arthropathies, only 24.3 per cent of 70 patients had abnormal spinal fluids, in contrast with 40 per cent in patients with cardiovascular syphilis. As result of the studies of Shaw (1940) and of Wassermann and Goodman (1934) there can be little doubt that neurosyphilis occurs less frequently as an accompaniment of cutaneous and osseous syphilis than it does with other forms of late visceral syphilis. Since neurosyphilis is established early in the course of the disease and late cutaneous and osseous syphilis are not manifest for some years, there is no logical reason to believe that visible lesions of skin, mucous membrane, or bone, protect the central nervous system. Instead, it is to be assumed that the absence of neurosyphilis and the presence of benign late syphilis result from some common factor which is inherent in the infecting organism of the host or which is established early in the course of the disease.

Spirochaeta pallida is, according to Neisser found in the bone marrow within few hours after it has gained entrance to the body The organism has been demonstrated in the bone lesions by Levaditi and Sauvage in 1905 and by many pathologists since then. Chesney has obtained *Spirochaeta pallida* from the synovial fluid of patient with syphilitic arthritis. There is, therefore, no apparent occasion to draw on the conception of syphilotoxin as necessary part of the mechanism of syphilitic joint manifestations.

Frequency of Skeletal Syphilis.—The available literature gives very few suggestions as to the actual frequency of skeletal syphilis. This arises in part from the undoubted existence of unsuspected and symptomless bone lesions demonstrable only by roentgen ray studies on the one hand and, in part, from a tendency on the other hand, to ascribe all bone and joint manifestations occurring in a syphilitic to syphilis. A striking demonstration of the diagnostic *importance of occult bone lesions has taken place in recent years through the* intensive roentgenological studies of the bones in infant prenatal syphilis. So far as we know no routine survey of the entire osseous system in a large number of adult syphilitic patients by all available means has thus far been published. Clinical experience, however suggests that few syphilitic patients indeed manage to escape some degree of reaction in this group of structures at some time in the course of their infection. The proportion of clinically detectable syphilis of the bones will of course vary with the stage of the disease and the thoroughness of the examination. Roentgenology will loom larger in the later than in the earlier years and from the clinical side the late manifestations, relatively

more solitary and more destructive, will seem to bulk larger in the general medical conception of the situation than will the symptomatically important but structurally inconspicuous earlier largely periosteal changes.

Available reports in the literature vary widely as to the frequency of osseous and articular lesions and there is some indication from the more recent studies that they may be becoming much less common manifestations of the disease, as might be expected with the increasingly more satisfactory application of treatment to early syphilis. Wile and Senear in survey of 163 syphilitic patients which was considered representative more than decade ago, found that 60 per cent had osseous or articular lesions. McKelvey and Turner (1934), of 10,000 cases of syphilis in Baltimore found chronic articular lesions of late syphilis in only 0.6 per cent and osseous lesions in 6.8 per cent. Speed and Boyd (1936) state that bone syphilis forms only 0.5 per cent of all admissions to the Campbell Orthopedic Clinic. Buchman and Lieberman (1941) reveal that only 5 per cent of the 2,400 syphilitic patients from among the 185,000 cases admitted in the ten years prior to 1939 to the Hospital for Joint Diseases in New York City had skeletal syphilis. Even then, they felt that the method of selecting the cases would make the proportion abnormally high and not representative of the true *prevalence of this condition.* Kuhns and Polderman (1940) (Boston) while remarking upon the excessive rarity of chronic syphilitic arthritis, state, "we

Fig. #73.

THE PATHOLOGY AND SYMPTOMATOLOGY OF BONE SYPHILIS

PATHOLOGY AND x RAY CHANGES	CLINICAL SYMPTOMATOLOGY
Early Cranial Osteoperiostitis	
This is hypothetically the pathologic equivalent of the symptoms, though not recognizable in life. x-Ray negative.	Cephalgia, intermittent, often nocturnal, sharply regional, often confined to single definitely localized point. Most common in early syphilis.
Acute Early Osteitis	
No demonstrable lesion in life.	Ostealgia or osteocopic pain. Boring in character often but not necessarily nocturnal, aggravated by heat, often relieved by movement, coming on when patient is warm in bed, often at or between certain definite hours.
Early Periostitis	
Thickening and infiltration of the periosteum, edema, chronic low-grade inflammatory changes. Tendency to involve the long bones, most frequently the tibia. Ray negative.	Doughy, non-inflammatory swelling, visible where superposed tissues are thin, as over the tibia. Elsewhere may be palpable as diffuse or fusiform enlargement or merely as tenderness. No hard points.
Late Periostitis	
Tendency to involve long bones and shoulder girdle. Thickening nd infiltration of periosteum, with formation of subperiosteal bone t points where process is chronic, p-pearing as serrations and irregularities. Ray picture of periosteal thickening and elevation, forming irregularities in the outer surface of the shaft without obliteration of the cavity If much subperiosteal bone is formed there is line of increased density along the surface of the bone beneath the periosteum.	Doughy swelling if bone is near the surface, slight general enlargement if deep. Firmer and more nodular than early periostitis, due t deposition of bone. There may be palpable serrations and exostoses. Skin may become livid and fixed at points here it is closely stretched over the bone. Tender point much less sharply marked and less exquisitely sensitive than in early periostitis. Pain may be diffuse or osteocopic in character The process is afebrile

Fig. 273 (*Continued*)

THE PATHOLOGY AND SYMPTOMATOLOGY OF BONE SYPHILIS

PATHOLOGY AND X-RAY CHANGES	CLINICAL SYMPTOMATOLOGY
Osteitis and Osteoperiostitis	
Localizations as in periostitis, but, in addition, involves the bones of the skull and face. Thickening and increased density, usually not uniform, but spotty roughened, and irregular Sequestrum formation in long bones is unusual. Destruction of bone evidenced by pitting of surface. Invasion of the cavities of long bones, with marked thickening of the shaft, but smooth inner surface. In the membrane bones of the face and skull, sequestra are common, with necroses, unaccompanied by productive or regenerative changes. x-Ray picture may range from simple thickening of the shaft of long bone and obliteration of the cavity to extensive combinations of proliferative and destructive lesions, forming exostoses and eburnations with areas of increased density and of rarefaction, and with varying degrees of gummatous destruction and occasional sequestrum formation. In the cranial bones, worm-eaten areas of destruction or sharply defined necroses with no evidence of regenerative or productive processes will be found.	Swelling as in late periostitis, with diffuse tenderness, often not very marked, but with osteocopic pain, sometimes but not necessarily nocturnal. Skin usually not involved until late or gummatous changes occur especially over skull, long bones, and clavicle. When skin breaks down, may form sharply circumscribed ulcer or a sinus with fixation. Sequestrum present in osteitis of the skull and membrane bones of the face and nasal cavity Marked fetor when secondary infection occurs. No fever except in rare cases of marked secondary infection. Sinus formation rare, but possible.
Gummatous Osteomyelitis	
Extensive involvement of the entire bone-marrow with combined proliferative and destructive changes, more marked in general in the less dense bony tissues at the ends of the bones (Dunlop) The secondary involvement of the bone may give rise t rarefactions or thickenings, exostoses, and sieve formations from gummatous destruction along the Haversian canals. Periosteal thickening may be secondary Involvement of the tissues around the affected bone, ith gummatous subcutaneous and cutaneous changes and characteristic lesions may occur. Ray shows the above changes. In the tissues about the involved bones no bone deposits are seen as in the case of sarcoma. Sequestrum may form, but is unusual.	Indolent swelling with pain, but comparatively little constitutional reaction considering the extent of the lesion. Pronounced constitutional reactions are usually associated with secondary infection. Tenderness on pressure rarely marked. No suppuration as rule. If such occurs, it is usually secondary to the formation of cutaneous lesion with gummatous breakdown. N associated glandular involvement. Cutaneous lesions if present may give clue to the identity of the process. Sinus formation possible, but unusual.

were unable to establish diagnosis of syphilitic arthritis in any of our patients. New and Brittingham (1938) report that of 8000 patients consecutively admitted to the syphilis division of the Out-Patient Department of the University of Georgia 61 (0.71 per cent) presented the clinical picture of arthritis.

Importance of Prenatal Infection in the Background of Skeletal Syphilis.—There is probably no single phase of syphilis in which the student of bone

Fig. 874.

THE PATHOLOGY AND SYMPTOMATOLOGY OF JOINT SYPHILIS

PATHOLOGY AND x RAY CHANGES	CLINICAL SYMPTOMATOLOGY
Arthralgia	
No demonstrable changes in the joints. x Ray negative.	An accompaniment of early syphilis. Pain without loss of mobility Worse when quiet, relieved by motion. May be and often is nocturnal. No heat or swelling tenderness, limitation, or crepitation. Slight fever only as an accompaniment of the syphilitic infection.
Hydrarthrosis	
Simple effusion without inflammatory changes in the joint or periarticular tissues. x Ray negative except for enlargement of the joint cavity in marked examples. Little or no impairment of function, though if prolonged may be more marked.	An accompaniment of early and recurrent syphilis and of heredosyphilis. May be sudden of onset, intermittent, and of long duration. Usually bilaterally symmetric and involving knees, elbows, and ankles in order of frequency Peri-articular signs nil no redness, heat, infiltration. Patient afebrile little or no constitutional reaction.
Arthritis, Polyarthritis, and Synovitis (Syphilitic Pseudo-rheumatism)	
Inflammatory changes in the joint with much less destruction than in the infectious arthritides. -Ray often negative, or showing only mild destructive changes.	An unusual accompaniment of early syphilis, though perhaps more common than reported. Tendency t involvement symmetrically of the larger joints, ith little tendency to shift from joint to joint. Less impairment of mobility than would be expected from the degree of involvement. Joint indolent and non-inflammatory compared with the usual acute arthritis. Pain disproportionately small for extent of process. Fever and constitutional disturbance slight considering degree of joint involvement, as compared ith acut infectious arthritis.
Gummatous Osteo-arthritis and Osteochondrodystrophies (Pseudo White Swelling)	
Usually results from extension of gummatous osteomyelitis of the shaft into the joint cavity and almost never occurs as a separat lesion. The destruction of the joint surface is usually at the end of the involved bone and rarely extends to the opposit surface of the joint cavity I extreme cases granulomatous involvement of the periarticular tissues and skin may occur Less destruction than in the corresponding type of tuberculous joint.	Involves large isolated joints, especially knees and elbows, often asymmetric. Enlargement of the joint, pale tense shiny skin. Surprisingly little impairment of mobility for the apparent extent of the process. Ankylosis rare unless secondary infection occurs. Breakdown and suppuration rare but may occur with sinus formation and extension of the process t the skin ith the configuration of lat syphilids. Pain absent or slight. Little constitutional reaction unless due to secondary infection.

lesions should be better versed from the clinical side than in the diagnostic earmarks of prenatal syphilitic infection (Chapter XXI) Particularly in childhood and in the differentiation of tuberculosis, osteomyelitis and sarcoma from syphilis, unfamiliarity with the clinical field and stigmas of prenatal infection has led to almost innumerable and too often serious mistakes. The perfection of roentgenological diagnosis (see p 774) and the increasing tendency to apply serological tests routinely to the study of all bone lesions is fortunately reducing the seriousness of this factor of error in diagnosis. The two types of processes, acquired and prenatal, resemble each other closely osteochondritis and epiphysitis in infancy being the chief distinctive lesions of the prenatal type.

THE PATHOLOGY AND SYMPTOMATOLOGY OF BONE SYPHILIS

The parallel column summary must be invoked here for condensation purposes and the pathology and symptomatology of bone syphilis are therefore reviewed in this fashion in Fig. 573 and of joint syphilis in Fig 574.

Atypical and Rare Conditions.—Articular and periarticular conditions furnish the chief variants on the typical pictures described. The acute syphilitic arthritides may be extremely confusing Chesney Kemp, and Resnik have reported two cases of pseudo-infectious arthritis with fever marked general lymphadenopathy and eosinophilia in which *Spirochaeta pallida* was demonstrated by inoculation in the joint fluids in one of the cases and from an inguinal lymph node draining the knee joint in the other case.

Syphilitic bursitis, described by Verneuil and studied by Churchman, who collected 27 cases, and more recently by Lane, and Garner and Schoch is a gummatous infiltration, usually symmetric, of the bursae over the patellae

Fig. 572 —Macroglossia, with woody infiltration of the base of the tongue and diffuse involvement of buttocks, thighs and calves in patient with an old syphilis. Slight improvement with treatment.

and the olecranon processes. The infiltration may break down or become hard and fibrotic Other bursae when involved present no distinctive signs, the syphilitic factor being discovered by collateral evidence, if at all.

The myopathies of syphilis consist of the myalgias of the secondary period already mentioned and of late gummatous infiltrations, quite rare which may

leave deep deforming scars. Benign infiltrations of the biceps may cause contracture which involutes spontaneously or on treatment.

A diffuse syphilitic myositis is also recognized affecting many of the muscles of the body producing woody infiltration with fibrosis which in its late stages when it is usually recognized is beyond improvement by treatment, although the patients experience some gain in well-being. This type may be relatively nonnflammatory and may even involve the musculature of the tongue as in Fig. 575 In this patient, who had an old syphilitic infection recognized at age sixty-eight, the buttocks, thighs and calves were of wooden hardness, though not resistant to the needle. The condition of the tongue was mistaken for Hodgkin infiltration. Although the serological tests were positive, no biopsy was obtainable, so that the condition could not be differentiated with certainty from diffuse amyloidosis as discussed by Gerstl although there was definite though not marked improvement under treatment with bismuth.

Nodosities occurring about the joints and in the tendon sheaths have aroused much interest, to judge from the recent literature.

According to Jeanner Lutz recognized the condition in the Hawaiian Islands in 1891 and the first complete description of juxta-articular nodules was published by Jeanselme in 1904. Under this designation and that of fibroid gummas of the extremities, a considerable literature collected by Jessner with American examples reported by Goodman and Young, Kalz, Fox, and Brunsting, has accumulated. The condition is rare, perhaps because seldom diagnosed.

The essential lesion is a hard fibrous nodule occurring in some cases along the course of tendon sheaths, particularly on the fingers, and in others as subcutaneous fibrous nodes, often of considerable size, on the extensor aspects of joints, such as the elbows. The lesions must be distinguished from multiple ganglia, simple fibromas, rheumatic and gouty nodules, and xanthomas. The response to treatment for syphilis is usually satisfactory but in one case which we observed, a multiple spondylitis and arthritis in a patient with a positive Wassermann reaction accompanying the condition had apparently not responded as satisfactorily to treatment as did the nodules themselves. The histologic picture is not necessarily characteristic for syphilis.

THE CLINICAL PICTURE OF LATE OSSEOUS AND JOINT SYPHILIS

The analysis of the original Mayo Clinic Group of 239 cases, the essential features of which are summarized in Fig 576 does not differ materially from the 1929–1938 series of Buchman and Lieberman (1941) based upon a somewhat smaller number though more recently studied cases

The Buchman and Lieberman series shows preponderance of males 61 per cent as compared with the Mayo Clinic series 57 per cent a ratio of joint to bone involvement of 1:4, 86 per cent of their congenital syphilis cases and 14 per cent of their acquired bone and joint syphilis had synovitis; previous history of syphilis was obtained in 45 per cent and positive Wassermann in 91 per cent (excluding the Charcot joint cases where the Wassermann was negative in 68 per cent, cf Fig 577) Speed and Boyd (1936) report 90 per cent positive bloods in untreated acquired bone syphilis and also obtained history of definite trauma in 30 per cent.

As result of the review of the older and the current literature, Buchman and Lieberman conclude, "The high incidence of lesions of the bones and joints due to acquired syphilis noted in the literature refers to the older age groups, in which Charcot joints are the predominant lesions; to years past when the diagnostic acumen with reference to lesions of the bones and joint was not as sharp as it is at present, and to the days when any unknown lesion of bone or joint was attributed to syphilis.

If we set aside for the moment consideration of the Charcot joint which forms at the present time the preponderant recognized lesions of skeletal

syphilis (38 per cent in the Buchman and Lieberman series) periostitis is the most frequent bone lesion of late as of early syphilis. Involvement of the periosteum occurred in 53 per cent of the Mayo Clinic series and in 45 per cent of Buchman and Lieberman's series.

Sante points out that *only the lacework or filiform type of periostitis as it* appears in the roentgenogram is characteristic of syphilis, the parallel veiling occurring with trauma and pyogenic infections. Clinically late periostitis dif-

Fig. 270.

LATE BONE AND JOINT SYPHILIS
A Survey of 239 Mayo Clinic Cases

1. Males 57 per cent; females 43 per cent. The latter is one of the highest proportions of women in any late manifestation of the disease.
2. Manual labor more frequent than sedentary type (traumatic factor?)
3. Cranial bone (12 per cent) and tibial lesions (20 per cent) head the list.
4. Shoulder girdle lesions (including sternum and ribs) rank next (10 per cent) and are most destructive (clavicle 7.5 per cent).
5. Spondylitis 6 per cent femur 4.5 per cent; humerus 3.5 per cent, fibula 4 per cent forearm and hand 2.5 per cent.
6. Ratio of joint to bone involvement 1 7 (20 to 130). Wile and Senear 1 3 (21 to 60)
7. On relative frequency of involvement of joints, no agreement on details in the literature but knee always leads, ankle or wrist next (Clark found hip and shoulder at autopsy 26 cases), spine and fingers last.
8. Periostitis is overwhelmingly th commonest lesion (53 per cent)
9. Osteomyelitis (20 per cent); arthritis 12 per cent; osteitis, spondylitis 6 per cent each; synovitis 2 per cent (chronic) Acute synovitis, not one case in 12,000 syphilitic patients (rare).
10. Pain and swelling the chief symptoms (71 per cent, 21 per cent). Tumor 10 per cent; ulceration 9 per cent; "rheumatism 8 per cent.
11. Nocturnal pain (overemphasized in literature?) 14 per cent.
12. Traumatic factor (overemphasized in literature?) 25 per cent only
13. Wassermann positiv after entry 88 per cent. (Would probably be higher by more sensitive tests.)
14. Wassermann had been taken before entry in only 24 per cent.
15. Syphilis diagnosed before entry 7 per cent. History positive (chancre) 26 per cent. Gonorrhea only 25 7 per cent.
16. Roentgen-ray made the diagnosis outright in 48.3 per cent; was negative in 28 per cent.
17. Characteristic syphilids of skin present on entry 18 per cent; active 43 per cent; scars 4 per cent; genital scars 11 per cent.
18. Liver enlarged 11 per cent.
19. Abnormal spinal fluids 24.5 per cent.

Pain and swelling in characteristic location, with disability slight and little constitutional reaction in proportion to the marked roentgen-ray changes; an bsence of suppuration and no local glandular enlargement, arouse strong suspicion of syphilis.

fers from early periostitis in a greater tendency to production of bone which is responsible for the visible roentgenological findings, and yields on examination a distinct thickening and irregularity of the bone surface, often in the older parts of the process not even tender to pressure. It is this diffuse proliferative process *which produces the marked palpable, sometimes almost* fusiform thickening of the tibia and in the shoulder girdle, the thickened inner third of the clavicle which is often so effective as a suspicion-arouser The tibia and the shoulder girdle stand out as the two bony structures detailed exami-

nation of which should never be overlooked in a general examination where syphilis is to be detected

Next after the periosteal lesion comes osteomyelitis. Sante points out that the roentgenological appearances of syphilitic osteomyelitis are distinguished with difficulty from those of the pyogenic process, the difference being based in diagnosis upon the comparative mildness of the clinical manifestations in syphilitic osteomyelitis

Syphilitic osteitis, the least common of the bone lesions of late syphilis, assumes either a diffuse or a localized gummatous form. In the former a dense thickened irregularity of the cortex develops, seldom attended, according to Sante by periosteal reactions. In the localized gummatous process, an area of cortical necrosis and destruction appears, a sequestrum being formed and the periphery of the process presenting a scalloped circinate border about which a dense sclerosis of bone develops.

Syphilitic joint lesions with the exception of Charcot joint apparently tend to become less frequent later in the disease. They constitute only 12 per cent of the lesions, in our experience. As in the case of bone lesions, the traumatic factor appears to be of less importance than the older literature tends to indicate There are none the less, unescapable instances of the relationship, as in the case recently described by Lanyar Steinbrinck has well summarized the special diagnostic features of joint syphilis (1) the localization, on which, however there is widespread disagreement as to frequency (2) The contours of the joints are lost, sometimes with sometimes without the presence of fluid, and sometimes through marked thickening of the capsule (3) The indolence of the joint is striking and comparative freedom of movement should always arouse suspicion of syphilis. Steinbrinck emphasizes in joint syphilis the importance of nocturnal pain and periods of complete remission, which cannot be regarded as entirely trustworthy in the pain of bone syphilis as such. The pain is described as boring tearing throbbing, or cutting and disappears usually toward morning and is not invariably confined to the joint. Schlesinger (cited by Steinbrinck) emphasizes the characteristic tender points, particularly at the condyle and epicondyle of the knee, more frequently found in syphilitic than in other joint involvement. Good functional use of a joint is more characteristic of active syphilis than any other arthritic lesion, and fluid is, on the whole, absent rather than present.

Great importance is attached to the resistance offered by syphilitic arthritides even to intensive treatment for articular rheumatism. This refractoriness involves the fever and constitutional symptoms quite as much as the local joint manifestations.

In the performance of therapeutic tests, special importance attaches to the Herxheimer flare-up which however may be entirely absent, the pain often disappearing at once in the earlier types of lesion The constitutional concomitance of fever and systemic reaction should be watched for Relapse follows promptly upon a premature suspension of treatment.

The Charcot Joint.—Evidence has been accumulating in recent years to indicate that this type of joint lesion formerly accepted as an exclusive concomitant of tabes dorsalis is in reality a neuro-arthropathy with several possible causes. The clinical characteristics of this type of joint which should not properly be described as an example of syphilis of the articular structures as such, is summarized from a combination of the literature and especially Wile and Butler's observations on 88 cases and Stokes's on 30 cases in Fig 577

Steindler in an excellent review of the tabetic arthropathies emphasizes the importance of spontaneous fracture as an early warning of tabes. He urges early recognition with protection, stabilization and alignment of the Charcot joint. The general diagnostician and the orthopedist should be cautious, we believe in making diagnoses of "*burnt-out tabes*" in patients with negative

Fig. 577

THE CHARCOT JOINT

1. Described by Charcot in 1868.
2. An associated manifestation of tabes dorsalis, though not invariably so (Wile Butler Stokes) (Syringomyelia, spina bifida, cord injury leprosy (Soto-Hall and Haldeman) idiopathic. For bibliography see Wile and Butler)
3. Two types, hypertrophic, atrophic.
4. Clinical characteristics
   (a) Sixty to 90 per cent males.
   (b) Onset gradual.
   ( ) Knee 60 per cent, ankle 25 per cent (Wile and Butler). Our experience puts foot and ankle first. Any *joint* may be involved.
   (d) Hydrops at onset 63 per cent—usually the first symptom.
   (e) Pain at onset 30 per cent. Often relieved by treatment for syphilis.
   (f) Loss of contours, hypermobility painlessness, "bag of bones feel mark the fully developed joint.
   (g) Multiple joint involvement not common (23 per cent)
5. Roentgenological diagnosis—78–100 per cent. Often worth while to examine apparently uninvolved joints (Dunlop, Wile and Butler)
6. Roentgenographic characteristics in the early stages shows only collection of fluid within the synovial sac, which is difficult to recognize except after considerable study especially in the smaller joints. As the process progresses there is a thinning of the articular cartilages, with sclerosis of the subchondral bone which is so slight at first that it is easily overlooked by the inexperienced. When marginal fractures occur the process of osteosclerosis just mentioned will be marked in some areas alternating with atrophy in others. From this point the process progresses to complet disorganization of the joint with loose bodies in the joint cavity and the formation of new (parosteal) bone outside the joint cavity
7. Trauma a predisposing cause in only 17 to 24 per cent. More often occurs as consequence in previously diseased joint.
8. Recent views of etiology include Eloesser Wile and Butler (trauma and loss of protective pain sense), Philips Rosenbeck (peripheral nerve degeneration).
9. Blood Wassermann reaction negative in 44–76 per cent.
10. Spinal fluid negative in 50 per cent.
11. Indubitable tabes or taboparesis in 81 to 97 per cent (Wile and Butler)
12. Asymptomatic neurosyphilis, spinal fluid positive in 12 per cent (Wile and Butler)
13. All other causes and associations 3 per cent.
14. Commonest diagnostic errors (20 per cent of cases) arthritis, tuberculosis (including Pott disease), dislocation.
15. While usually inactive or only slightly active, the tabes is not always "burnt out.
16. For treatment see p. 790.

EXAMINE THE PUPILS IN EVERY CASE OF SWOLLEN JOINT

blood serologic reactions and negative spinal fluids associated with joint conditions, and in particular with Charcot joints. A rather large proportion of our cases of Charcot joint present this peculiarity and exhibit in the course of years of observation definite evidence that the tabes is progressive. Treatment for tabes should not, therefore, be withheld merely because of negative serologic findings (see Management of the Charcot Joint, p. 790)

O'Leary (1936) as spokesman for the coöperative clinic group found that the prevalence of Charcot joint as a symptom of tabes dorsalis was 48 in 775 males (6.2 per cent) and 16 in 210 women (7.6 per cent). One fifth had completely negative blood and spinal fluid when Charcot joint first appeared, one fifth had Group III spinal fluid, 55 per cent Group II and 5 per cent Group I. As Soto-Hall and Haldeman (1940) have pointed out, therefore, the preponderance of Charcot joint among males does not result from increased susceptibility to joint involvement as such but to the underlying predisposing cause (tabes dorsalis) which is much more frequent in men than in women. For similar reasons tabetic arthropathy is uncommon among the colored as compared to white, even though bone and joint syphilis as such is approximately five times more frequent among the colored. (Pomerantz and Rothberg (1941)) The average age of onset of Charcot joint is between forty and fifty years, though cases are reported from congenital syphilis in the second decade and some cases have their onset infrequently as late as the seventh decade.

THE DIAGNOSIS OF SYPHILIS OF THE SKELETAL SYSTEM

Tradition and therapeutic exigency have made bone lesions primarily surgical matters, and as such a somewhat too ready appeal is often made to therapeutic instead of diagnostic procedure. The first impulse seems to be to aspirate, to open up, to drain, to immobilize, to embed in plaster, to put on a brace, instead of to take a careful history, to make a complete physical examination, to study the pupils and reflexes, to perform serological tests on the blood, and microscopic and inoculation studies of exudates and so forth. *The first approach to bone lesions must be medical and diagnostic,* rather than surgical and therapeutic, if serious blunders with respect to syphilis are to be avoided. Our personal experience with diagnosis in this field has indicated a rather low index of suspicion with reference to syphilis, as the case histories will show.

Syphilitic lesions of the bone are less specific in their characteristics than are those of the skin. Clear-cut though verbal description may appear to be, particularly when based on the developments of roentgenology, yet so far as specificity is concerned, much still remains to be desired. Speaking from the experience of the Mayo Clinic series, the outright diagnosis of syphilis of the osseous system cannot be made by any one method in a higher proportion than 50 per cent. We have repeatedly been told by roentgenologists that the only genuinely specific picture in roentgenological syphilology is that of the Charcot joint. In infancy, the parallel or line type of periostitis of the long bones is often accepted as almost pathognomonic of syphilis, but the fact remains that the lower specificity of the clinical picture in syphilis of the bones compels constant and close attention to collateral evidence, and the *utilization of all possible aids to a diagnosis of syphilis. It is therefore particularly worth while to analyze in a little greater detail the items of procedure which* are of the greatest service in its recognition.

The Routine Blood Serological Test the First Essential.—When called upon in routine teaching to offer the nearest approach to a touchstone in this field, experience compels us to place the absolutely routine performance of blood serological tests on all patients with bone and joint lesions without exception, as the most valuable guide to a syphilitic factor in the situation. With the inclusion of the Charcot arthropathy, the emphasis shifts somewhat toward the systematic and complete physical examination with a special reference *to pupillary reflexes, deep reflexes, station* and so forth in older patients, for in the Charcot joint of all others the serological test may fail.

The Roentgenographic Factor in Diagnosis.—Next to the routine use of serological tests should be placed the skilled interpretation of the roentgeno-

gram. In the Mayo Clinic series, abnormalities appeared in 72 per cent of the cases, the symptom-producing structure being negative to roentgenogram in 28 per cent. This figure will of course vary upward and downward with the type of material, being lower in a material rich in early syphilis and higher where the proportion of prenatal syphilitic cases is large. While abnormalities appeared in 72 per cent, in only 48 per cent was a diagnosis made outright, the opinion being couched in merely descriptive terms in 21 per cent of cases but being erroneous in only 1 case a truly enviable diagnostic record

It is impossible here to go in detail into the roentgenographic differentiation of syphilis, osteomyelitis, sarcoma and tuberculosis by the roentgen-ray as was done in the case of the skin for the method is essentially too special to be available to the average physician. He must take the assurance of a competent roentgenologist as to whether or not the plates from a clinically observed lesion suggest syphilis or not. It is none the less useful for the diagnostician to have some conception of the appearance of a bone or joint lesion in the roentgenogram as a guide to the inspection of such plates as he may have the opportunity to see in conjunction with his clinical work. The following brief description collected from the literature is, therefore, offered in addition to the descriptive comments already made.

Syphilis Preponderantly Constructive, Osteoplastic Process.—The best account of the changes induced by syphilis in the bones and joints as seen by radiologist, with which we are familiar is that of Skinner He points out that the radiographic findings are explained by the fundamental pathology of the disease. Syphilis is usually constructive, osteoplastic process. Even in the osteoporotic changes of the cranial bones he believes that there is an early osteoplastic phase followed by later destructive changes. Bone lesions in general are divisible into two types, preponderantly constructive, as in osteomyelitis and syphilis, and preponderantly destructive as in tuberculosis and malignancy Constructive or bone-producing lesions are therefore open to the suspicion of being syphilitic or osteomyelitic in origin. The chief exception to the constructive or productive rule in syphilis is in the case of the cranial bones, in which the ultimate destructive process, without reconstruction, leaves the diagnosis suspended between syphilis and malignancy Since primary malignancy of the cranial bones is uncommon, it follows that destructive process in the cranial bones is, in the absence of primary malignant focus elsewhere, almost surely of syphilitic origin, especially in patient of precancerous age.

Differentiation of Specific from Nonspecific Periosteal Lesions.—In syphilis of the long bones, Blaine, Diefenbach, and Brickner (quoted by Carman) point out that syphilitic periostitis is sometimes distinguished with difficulty from nonspecific inflammatory changes in the periosteum. Essential points in the differentiation include

1. Irregular contour of the periosteum.

2. Moth-eaten or reticulated appearance of the tissue hen the contour of the periosteum is destroyed.

3. Sclerosis or increased density of bone shadow constant accompaniment of syphilitic invasion.

4 Bulging of the periosteum along such surfaces as the anterior aspect of the tibia. Brickner states that syphilitic periostitis begins next to the bone as subperiosteal infiltration, so that the periosteal shadow which in the early stages is usually narrow is lifted way from the bone. In advanced conditions, as in localized periostitis gummosa, the shadow acquires considerable density hile palpable periosteal gumma, being merely inflammatory causes no shadow Skinner calls attention to the parallel veiling of the shaft between the osteogenetic zone of the periosteum and the normal bone cortex, hich he interprets as diagnostic of syphilitic periostitis. So long as no gummatous degenerative changes occur this veiling is maintained, but once the process invades the cortex proper there is an immediate reaction with the formation of new deposits which, as throughout the entire picture of bone syphilis and osteomyelitis, exhibit the richness in lime salts hich leads to the production of sharp contrasting shadows to represent the new formation, side by side with the thinning and decalcification hich represent the destructive phase. Bone destruction due to gumma, as Brickner points out, produces light areas surrounded by dark shadow of reactive bone formation or thickening, which distinguishes this condition from osseous tumors and tuberculosis. When gumma surrounds an island of bone

it appears in the roentgenogram as sequestrum, which, however is unusual in unmixed syphilitic osteomyelitis, and forms a contrasting point with tuberculous and pyogenic osteomyelitis. Hodges, Phemister and Brunschwig (1941) point out that the presence of a large sequestrum is strong evidence of pyogenic osteomyelitis and against syphilis. If sequestra from syphilis are demonstrable, *they are usually located in the cancellous regions. The only exception to this is the vault* of the skull where large masses of bone may be sequestrated. Erdheim (1932) remarks that in syphilis of the skull, the outer table is usually much more extensively involved than the inner table valuable point of distinction from tuberculosis of the skull in which the reverse is usually true.

Syphilitic Dactylitis.—In syphilitic dactylitis, as distinguished from tuberculous dactylitis, the shaft usually escapes involvement in syphilis, but is invaded by the destructive process in tuberculosis. In tuberculosis the periosteum bulges in sharply defined area about a destructive lesion in the shaft. In syphilis, on the other hand, the veiling runs parallel to the cortex, and the shaft remains relatively clear Skinner believes that the herringbone serration of the cranial bones, with accentuation of the diploic channels and thickening of the skull, with ill-defined scalloping of the inner table is suggestive of cerebrospinal syphilis.

Radiographic Changes in Joints.—Syphilitic involvement of the joints early in the disease does not, according to most authors, present a characteristic picture, or one that can be safely distinguished by roentgen-ray alone from acute articular rheumatism Hydrops of the joint, according to Skinner is an important early sign. Ely differentiates synovial form, bony form, multi-articular variety and the Charcot joint. The changes observed are usually markedly *less than the clinical pathology would lead one to expect. The outlines of the articulation* (excluding Charcot joint) tend to remain clear and distinct periosteal thickening is apparent at the line of junction of epiphysis and diaphysis. If the bone proper is involved, the changes follow the rules for bone changes elsewhere. There is characteristic increase in shadow density above the seat of the active osteitis, with thinning in the center of activity Destructive areas, according to Young, are sharply defined and do not have the mottled, spotted, or indistinct and grossly irregular ppearance of malignancy Gummatous changes except gummatous chondritis are easily recognized by the same signs of destruction in the light areas surrounded by denser reactive deposits. The identification of syphilitic change in pseudotuberculous joint in an adult may depend upon the finding of signs of old periostitus, thickening and striation t the junction of epiphysis and diaphysis. Some syphilitic joint pictures may according to Ely be differentiated from tuberculosis, radiographically only with the greatest difficulty if at all, the diagnosis depending on collateral findings. The proliferative tendency of the syphilitic process may make the differentiation from nonspecific inflammatory joint processes other than tuberculous quite difficult.

The radiographic differentiation of syphilis from tuberculosis of osseous structures in general then, as Skinner points out, rests upon the contrast between a productive picture as seen in syphilis and a destructive lesion producing rarefaction and general myelomalacia with a notable absence of proliferative reaction, as seen in tuberculosis. The radiograms of tuberculous processes reveal a thinness and lack of definition which is an important differential aid. Skinner emphasizes, however the importance of avoiding confusion with the atrophic changes of disuse. The roentgenologic picture of Charcot joint is summarized in item 6 Fig 577

Th Osseous Lesions of Prenatal Syphilis from the Roentgenological Standpoint.—Stafford McLean (1931) comprehensive and clinically helpful study of the roentgenographic diagnosis of early congenital syphilis, embracing report of 102 cases with more than 1600 roentgenograms, still remains the most significant contribution in this field. Pehu and Policard have contributed extensively t the French literature Excellent summaries of the literature and of the authors experience with the report of case of cystic bone changes in prenatal syphilis, are those of Pendergrass and Bromer and Pendergrass, Gilman and Castleton. The latter report deals primarily with the changes of late syphilis, while the work of McLean deals with prenatal syphilis in the first year of lif

Th Early Lesions.—Of McLean patients, 72 per cent were in the first three months of life and 90 per cent ere not over six months of age. During the first six months of life the sites of predilection of osseous syphilis are the temporary zones of calcification (metaphyses) and the periosteum. After the age of six months, in the infants who survive, the early bone lesions tend to

regress spontaneously even in the untreated case and roentgenologic evidence tends to become insufficient without collateral help. After the first and up to the fourth year of life, prenatal syphilitic bone lesions are probably largely due to relapse of an incompletely healed lesion of early life. They are generally manifested as subperiosteal overgrowth which cloaks osteomyelitis. The favorite sites are the metacarpal bones and the phalanges, but other long or flat bones may be involved. I 53.3 per cent of McLean series in which the clinical manifestations were rated as severe, and *in an additional 27 per cent, the diagnosis* could have been made by scrupulous clinician in nearly every instance, but in third group of masked symptoms, constituting 16.4 per cent, the combined aid of the roentgen rays and laboratory data was required.

Inability or definite disinclination to move one or two extremities, constituting or simulating the Parrot pseudoparalysis, appeared in 32.3 per cent of the children, but could not be interpreted as definite evidence of epiphyseal separation, which occurred in only 23.5 per cent of cases. The blood serological test was positive in 85 out of 96 patients. Spirochetes were obtained by the darkfield method in less than 10 per cent of the cases from the skin lesions. The mortality in the group was high, attesting the severity of the process, 42.1 per cent dying, including 46 5 per cent of those in the first three months of life. Prematurity seems to be marked by definite tendency in the first two months of li t present deep zones of submetaphyseal rarefaction. There is also an absence of marked subperiosteal thickening of the bones in these cases. Severe anemia in prenatal syphilis as found to be associated with severe osseous lesions.

Osteochondritis appeared in 90 per cent of the cases; periostitis in the form of exaggerated subperiosteal bone production, in 70 per cent, osteomyelitis in 46 per cent, and osteitis in 7 per cent. Periostitis was the only discoverable roentgen lesion in only 5 per cent. A combination of rickets and syphilis occurred in 8 per cent. The tibia was demonstrably involved in 87 per cent, the ulna in almost exactly the same proportion the radius in 91 per cent; the femur in 79 per cent; the humerus in 74 per cent, the fibula in 78 per cent. The distal ends of the radius and ulna are the metaphyses most frequently involved.

McLean gives as practically pathognomonic of prenatal syphilis the following types of roentgen lesions hen recognized in the first months of life.

1 Well-defined saw-tooth metaphyses in well-calcified bones.

2. Deep zones (in the longitudinal axis) of submetaphyseal rarefaction.

3. Multiple separation of epiphyses, with or without impaction in bones which are not rachitic.

4 Bilateral symmetrical osteomyelitis of the proximal mesial aspects of the tibiae.

5. Multiple circumscribed osteomyelitis of the long bones. Shown by the roentgen rays as patchy areas of rarefaction.

6. Multiple longitudinal areas of rarefaction (osteomyelitis) in the shafts of the long bones sometimes resulting in fractures.

7 Destructive lesions at the mesial or lateral parts of the metaphyses (foci of rarefaction).

8. Multiple areas of cortical destruction, generally seen within centimeter of the ends of the bones.

9. Double zone of rarefaction at ends of bones.

10. Localized periosteal cloaking occurring in more than one bone.

He states that periostitis (abnormal subperiosteal bone production) does not equal in diagnostic importance the changes at the ends of the bones, since it rarely occurs alone in the first months of life, the age period most important in diagnosis, and in most instances *it initiates* the healing of osteochondritis or osteomyelitis. Periosteal veiling may be of rachitic origin, while in marked syphilitic subperiosteal thickening in the first months of life, metaphyseal lesions always coexist. Subperiosteal multilayered cloaking, the most spectacular roentgen observation, may be present as the predominating lesion after the fourth month and as the sole active lesion after the fifth month of life. At this age and up to the early part of the second year it is of great diagnostic importance.

Lesions of the tarsal, metatarsal, and metacarpal bones and phalanges, in our experience, do not occur in the first months of life except when the larger bones of the extremities are involved. Likewise, lesions of the scapula, clavicle, ribs, ilium, and vertebrae are seen only when the long bones of the extremities are involved. The discovery of such lesions is of greater academic than practical importance

Syphilitic lesions are always distributed bilaterally and in the first months of life lesion of single bone has, in McLean experience, never been due to syphilis.

In his conclusions McLean points out that the roentgenogram may offer means of excluding the diagnosis of prenatal syphilis without apprising the parent of the fact that the infant suspected of having the condition. This is especially true in infants in the first weeks of life with weakness of one or more extremities. In 2 of 102 cases the roentgen rays revealed the diag-

nosis before positive tests of the serums were obtained. Bone lesions roentgenologically recognized may also produce evidence of the severity of the infection in cases with mild cutaneous manifestations. Although the lesions will sometimes involute spontaneously they form valuable guide to the effect of treatment. Roentgenological diagnosis is more valuable than microscopical section.

More recent work has tended to show that many of the bone lesions of early congenital syphilis lack absolute specificity as is the case with similar lesions of acquired syphilis, but these observations have tended to strengthen rather than reduce the value of roentgenographic diagnosis in early infancy as has been shown by Ingraham, Shaffer Spence and Gordon (1941) The work of Ingraham (1936) suggests that the lag phase from infection of the fetus in utero until roentgenographically demonstrable lesions appear approximates five weeks for syphilitic osteochondritis and four months for syphilitic periostitis The presence of irrefutably syphilitic osteochondritis or periostitis in the absence of a positive blood serologic test for syphilis, although it occurs (Ingraham, 1935 McCord, 1936) is an excessively rare clinical finding (Black, 1939). Some of the conditions which must be carefully considered when interpreting the roentgenogram of an infant suspected of having syphilis, shortly after birth are (1) antepartum bismuth therapy in the mother (Caffey 1937 Christie, 1939 Whitridge, 1940) (2) bacteremia, including septicemia, pneumococcemia, gonococcemia and hematogenous tuberculosis (3) malnutrition, including rickets (4) erythroblastosis foetalis (5) trauma, including birth injuries from difficult deliveries (Caffey 1939 Evans, 1940) All of the foregoing may produce changes in the roentgenogram which may under certain circumstances, be confused with syphilis.

The application of these studies to the diagnosis of early congenital syphilis will be discussed in Chapter XXI, Familial and Prenatal Syphilis.

Park and Jackson (1938) have done much to correlate the roentgenographic with the pathologic findings of syphilitic osteochondritis. They have found that a well defined saw tooth appearance in the ends of the long bones is not constant feature of infantile congenital syphilis. It is usually absent hen syphilitic involvement of the bones is slight and may be absent even if the involvement is severe. The most rapidly growing bones are commonly affected and this almost pathognomonic type of syphilitic osteochondritis is found in decreasing order of frequency in (1) Anterior ends of middle ribs (2) lower end of the femur (3) upper end of the femur (4) both ends of the tibia (5) upper end of the humerus and (6) lower ends of the radius and ulna. It is never found in the upper end of the ulna, occasionally only in the upper end of the radius and rarely in the lower end of the humerus. Other factors affecting the demonstrability of these lesions, however make their practical demonstration often easier in the distal metaphyses of the radius and ulna (Ingraham (1935))

Prior to birth the involvement of the ends of the bones is generally proportional to the rat of growth, but after birth the bones are no longer affected so uniformly because trauma and muscle strain alter the vascular supply and with it bone growth and the distribution of *Spirochaeta pallida*.

Th Late Lesions.—Pendergrass, Gilman and Castleton, in discussing the late bone manifestations of prenatal syphilis, found them t occur most frequently between the fifth and the twelfth year and to involve the tibia and elbow especially Multiple bone involvement is often seen with joint changes, usually secondary while in infancy osteoperiostitis, hen it occurs, is found as generalized lesion affecting mainly the ends of the long bones. The tendency in later childhood is involvement principally or solely of the shaft. Here injury plays an increasingly important part in the bone selectivity directly proportional to the age of the child. The onset is gradual and generally accompanied by pain (orse t night) often described by the parent subsequently as rheumatic or growing pains Weber has called ttention to the absence of or but relatively slight pain that is seen in some instances. A symmetrical and tender swelling comes with functional disability proportionat to the pain or to the proximity of the joint. Subsidence of the acut process may be followed by secondary osteomyelitis or gummatous ulceration, but more commonly the typical bone deformities develop, ranging from but slight roentgen changes to the markedly bowed nd thickened saber tibiae. The less common gummata, osteoporosis, and Charcot joint changes are recognized and diagnosed exactly as in the acquired form of the disease. Additional evidence of prenatal syphilis may often be the deciding factor in the early recognition of minor bone changes (i. eyes facies, teeth) and while the complement fixation test is valuable adjunct in children, it tends to be of considerably less value in the older patient.

The bilaterally symmetrical synovitis and periarticular infiltration more or less characteristic of prenatal syphilis were described by Clutton in 1886. The roentgenological findings are not typical but do show some periarticular swelling and possibly some effusion into the joint. The clinical manifestations of Clutton joints are described in the chapter on familial nd prenatal syphilis.

Hypertrophic and atrophic changes, with or without loose bodies diaphysitis, periostitis, and dactylitis occur in late prenatal syphilis, together with condensing osteitis of the skull. The new formation of bone in the syphilitic periostitis is laid down perpendicular to the shaft, or long axis of the bone and therefore requires careful differentiation from the perpendicular striation of osteogenic sarcoma, as Pendergrass, *et al.* point out. In ordinary osteomyelitis the periosteal new bone is laid down parallel to the shaft. In dactylitis or periostitis of the bones of the hands and feet, however the bone is laid down parallel to the shaft.

Diagnosis by Associated Cutaneous Lesions.—From our experience, at least, we may say that it is quite as important for orthopedists and surgeons who deal with the skeletal structures to be competent dermatosyphilologists, as good radiologists. The skin in our group furnished almost as many clues to diagnosis (48 per cent) as did the roentgen-ray and, in many cases, would, if correctly interpreted, have furnished the necessary clue to prevent a diagnostic error The case reports in this chapter contain a number of examples in which the ability of the attending physician to recognize a late syphilis *would have shortened by months or years the course of the osseous lesion. In* occasional instances the cutaneous lesion made the diagnosis over a negative blood serological reaction, especially in the earlier years of the dermatological service, when a less sensitive blood test was in use. Active cutaneous lesions were present in 43 per cent of our cases, scars in 4 per cent, and genital scars in 11 per cent. In dealing with ulcerative lesions of the lower extremities, particularly those over the tibia, a nonspecific usually asymptomatic focal periostitis may apparently develop In attempting to establish the syphilitic character of a suspected cutaneous lesion or *vice versa*, care must be exercised to avoid misinterpretation of traumatic infected and anemic stasis ulcers. The syphilitic nature of either bone or skin lesions is in such cases best determined on the individual merits of the lesion and collateral evidence. Ormsby believes that a leg ulcer which has at one time had syphilitic characteristics may through the course of years, as a result of scarring and vascular changes, assume the appearance of a banal anemic or varicose ulcer Kilbourne believes that therapeutic tests should be performed in doubtful cases with negative serological tests, using bismuth and iodide rather than the arsphenamines.

Diagnostic Value of Clinical Symptomatology—At the close of Fig 576 is an attempt to summarize in a single sentence those features of clinical symptomatology which in the presence perhaps of equivocal findings on examination, may tend to suggest syphilis and the need for a therapeutic test to the critical examiner Pain and swelling, a characteristic location (and search should be made particularly of the tibia and the shoulder-girdle regions) with disability and constitutional reaction slight in proportion to the marked x-ray changes an absence of suppuration and no local glandular enlargement should arouse strong suspicion of syphilis. One or another and combinations of several of these symptomatic criteria, are helpful especially in differentiating gonorrheal and rheumatoid arthritic processes, acute suppurative osteomyelitis (emphasized by Santo) from processes similar in clinical type but in which the etiologic agent is *Spirochaeta pallida.*

Collateral Findings.—In our résumé history of primary lesion appeared in 30 per cent and of gonorrhea only in 23.7 per cent of patients (Fig. 576). Attention might be called to the proportion of enlarged livers in our series in order to add one more to the list of suspicion-arousers in the general medical examination which may start clue leading to the detection of syphilis, if it is present. Enlargement of the spleen occurred in only one case.

Among the negative findings, one of the most interesting is the practically complete absence of cardiovascular lesions among patients with bone and joint involvement. Not more than 6 patients presented any cardiac abnormality whatever This may however be an offshoot of the

nosis before positive tests of the serums were obtained. Bone lesions roentgenologically recognized may also produce evidence of the severity of the infection in cases with mild cutaneous manifestations. Although the lesions will sometimes involute spontaneously they form valuable guide t the effect of treatment. Roentgenological diagnosis is more valuable than microscopical section.

More recent work has tended to show that many of the bone lesions of early congenital syphilis lack absolut specificity as is the case ith similar lesions of acquired syphilis, but these observations have tended to strengthen rather than reduce the value of roentgenographic diagnosis in early infancy as has been shown by Ingraham, Shaffer Spence and Gordon (1941). The work of Ingraham (1936) suggests that the lag phase from infection of the fetus in utero until roentgenographically demonstrable lesions appear approximates five weeks for syphilitic osteochondritis and four months for syphilitic periostitis. The presence of irrefutably syphilitic osteochondritis or periostitis in the absence of positive blood serologic test for syphilis, although it occurs (Ingraham, 1935, McCord, 1933) is an excessively rare clinical finding (Black, 1939). Some of the conditions which must be carefully considered when interpreting the roentgenogram of an infant suspected of having syphilis, shortly after birth are (1) antepartum bismuth therapy in the mother (Caffey 1937 Christie 1939, Whitridge, 1940.) (2) bacteremia, including septicemia, pneumococcemia, gonococcemia and hematogenous tuberculosis (3) malnutrition, including rickets (4) erythroblastosis foetalis (5) trauma, including birth injuries from difficult deliveries (Caffey 1939 Evans, 1940) All of the foregoing may produce changes in the roentgenogram which may under certain circumstances, be confused with syphilis.

The application of these studies to the diagnosis of early congenital syphilis ill be discussed in Chapter XXI, F milial and Prenatal Syphilis.

Park and Jackson (1936) have done much to correlate the roentgenographic ith the pathologic findings of syphilitic osteochondritis. They have found that a well defined sawtooth appearance in the ends of the long bones is not constant feature of infantile congenital syphilis. It is usually absent when syphilitic involvement of the bones is slight and may be absent even if the involvement is severe The most rapidly growing bones are commonly affected and this almost pathognomonic type of syphilitic osteochondritis is found in decreasing order of frequency in (1) Anterior ends of middle ribs (2) lower end of the femur (3) upper end of the femur (4) both ends of the tibia (5) upper end of the humerus and (6) lower ends of the radius and ulna. It is never found in the upper end of the ulna, occasionally only in the upper end of the radius and rarely in the lower end of the humerus. Other factors affecting the demonstrability of these lesions, however make their practical demonstration often easier in the distal metaphyses of the radius nd ulna (Ingraham (1935))

Prior t birth the involvement of the ends of the bones is generally proportional to the rate of growth, but after birth the bones are no longer affected so uniformly because trauma and muscle strain alter the vascular supply and with it bone growth and the distribution of *Spirochaeta pallida*.

The Late Lesions.—Pendergrass, Gilman and Cartleton, in discussing the late bone manifestations of prenatal syphilis, found them t occur most frequently bet een the fifth and the t elfth year and t involve the tibia and elbow especially Multiple bone involvement is often seen with joint hanges, usually secondary while in infancy osteoperiostitis, when it occurs, is found generalized lesion affecting mainly the ends of the long bones. The tendency in later hildhood is involvement principally or solely of the shaft. Here injury plays an increasingly important part in the bone selectivity directly proportional to the age of the child. The onset is gradual and generally accompanied by pai (orse t night) often described by the parent subsequently as rheumatic or growing pains Weber has called attention t the absence of or but relatively slight pain that is seen in some instances. A symmetrical and tender swelling comes with functional disability proportional to the pai or t the proximity of the joint. Subsidence of the acut process may be followed by secondary osteomyelitis or gummatous ulceration, but more commonly the typical bone deformities develop, ranging from but slight roentgen changes to the markedly bowed nd thickened saber tibiae. The less common gummata, osteoporosis, and Charcot joint changes are recognized and diagnosed exactly as in the acquired form of the disease Additional evidence of prenatal syphilis may often be the deciding factor in the early recognition of minor bone changes (eyes, facies, teeth) and hile the complement fixation test is valuable adjunct in children, it tend to be of considerably less value in the older patient.

The bilaterally symmetrical synovitis and periarticular infiltration more or less characteristic of prenatal syphilis were described by Clutton in 1886. The roentgenological findings are not typical but do show some periarticular swelling and possibly some effusion into the joint. The clinical manifestations of Clutton joints are described in the chapter on familial and prenatal syphilis.

the range of manifestations between Fig 607 diagnosed as tuberculous, but actually syphilitic, and Fig. 612, diagnosed as syphilitic on the basis of a response to arsphenamine, but probably tuberculous, seems in the present state of knowledge to be too hazardous for full acceptance. Congenital and child hood syphilitic infections associated with tuberculous adenitis and white swelling of the knee or Pott s disease of the spine, produce pictures in which it is difficult to unravel the respective instrumentalities of the two infections. Alexander and Schoch (1942) have rediscussed this question in the light of their recent case reports.

Confusion of Syphilitic Osteochondritis and Tuberculous White Swelling.—Probably the commonest error in borderline cases is that of confusing syph ilitic osteochondritis of the knee with tuberculous white swelling History and regional findings in the joint itself should be subordinated to a complete general examination of every such case, including of course a routine blood Wassermann reaction. The local pictures in the two conditions may be practically indistinguishable. Sinus formation, sequestra, ankylosis may be late features of the syphilitic as well as the tuberculous process The blood Wasser mann reaction may be completely negative in syphilitic arthritis and yet therapeutic restoration be rapid and satisfactory (Fig 595) Absence of fever relative painlessness, preservation of the mobility of the joint and absence of local adenopathy all tend to suggest syphilis. Skinner directs attention to the value of repeated radiographic studies of joints under therapeutic test for syphilis. Within a few weeks the response of a syphilitic joint is readily dem onstrable in the plate, while that of a tuberculous joint is slight or absent. Here again the nonspecific arsphenamine factor may temporarily confuse the outcome. As in Figs. 607 and 611 the correct interpretation of cutaneous syphilids associated with the bone or joint lesion may make all the difference between correct and incorrect diagnosis. The association of a tuberculid such as lichen scrofulosorum with an aphlegmasic joint or a hydrarthrosis, as in Fig. 609 may on the other hand, have almost pathognomonic value in identifying as tuberculous a joint which might otherwise have been considered syphilitic. The resemblance of lichen scrofulosorum to the grouped follicular secondary syphilid must not be forgotten (Chapter XII)

In the differentiation of syphilitic from tuberculous tenosynovitis the commonly mentioned criteria of bilateral character in syphilis and failure of the process to involve surrounding tissues have not been sufficient. The concomi tant partial positive blood Wassermann occasionally seen in tuberculous processes and their response to arsphenamine must not be forgotten. The identification of a tuberculid will at times prevent an erroneous diagnosis of syphilis, a statement that applies to a variety of arthralgias and myalgias as well as to the more outspoken lesions. A tuberculid of the fingers (Fig. 542) may aid in identifying and correctly interpreting a bilateral tenosynovitis which will disappear under the nonspecific effect of arsphenamine therapy The differentiation of syphilitic from tuberculous involvement of bones of the skull is mentioned on p. 776

Confusion of Osseous Syphilis and Round-cell Sarcoma.—The erroneous diagnosis of sarcoma in syphilitic lesions of bone and periosteum was undoubt edly much more frequent in the past than at the present time with the wider application of the Wassermann test (Fig 578) One of us (J H. S) recalls vividly a case presented in 1914 before one of the larger dermatological societies of this country in which a young woman had been reduced almost to a

torso by successive operations for the removal of supposed sarcomas of her extremities. Finally when a crutch had replaced one leg and she was all but armless, an interstitial keratitis, veritable dispensation of Heaven in her case made the correct diagnosis unescapable. Even so small a group of cases as that here reviewed, contained two such errors in diagnosis, one of them well illustrating the fact that the ablest diagnosticians and competent pathologists may be deceived by this source of error

Additional cases of this sort are scattered through the literature (see Cabot Case [illegible], New England Med. J 1940, Westermark and Hallerström, 1937 Ungerman, Vicary and Eldridge, 1938). These latter authors point out that, while it is characteristic of syphilis that bone production exceeds bone destruction (see section on roentgenologic factor in diagnosis p. 774), when

Fig. 578 —Deposition of new bone in the soft tissues in osteosarcoma, the most distinctive single feature of the roentgenographic picture.

syphilitic involvement of the cortex occurs without involvement of the medulla or periosteum, the roentgenographic evidence may be solely of bone destruction without the characteristic bone production. When the periosteum is involved there may be a marked similarity between syphilis and sarcoma, the principal difference being that the periosteal reaction from sarcoma is more in the nature of an irritative reaction with new bone striae perpendicular to the axis of the shaft. In syphilis the new bone formation, as shown by the roentgenograph, is more laminated, the laminations lying parallel to the shaft and tending to unite with it at the margins of the process

In our experience mistakes of this kind arise from too implicit reliance on clinical signs, with neglect of the routine Wassermann test too credulous acceptance of the results of the frozen section biopsy from tissue removed by an operative incision for diagnosis and from the fact that the rapidly destructive processes of sarcoma as shown in the roentgenograph, may under certain

circumstances as just stated be simulated by syphilis. Systematic and invariable application of the blood Wassermann test before exploration would reduce the percentage of avoidable error in this field almost to the vanishing point. The apparent confusion of the microscopical pictures of gumma and sarcoma, may be due to the rich round-cell infiltration of the early gumma. The perivascular distribution of the infiltration in gumma and the presence of plasma cells even in the earliest cases, should arouse the suspicions of the careful observer. That the combination of radiologic and clinical findings exclusive of the Wassermann result may fail to make the correct diagnosis is apparent in Figs. 96 and 617. Roentgenologic study of other bones than the one under dispute may in doubtful cases cast some light on the situation by identifying a more distinctly specific but asymptomatic lesion elsewhere. The fact that osteogenic sarcomas metastasize early to the lungs should likewise not be lost sight of in looking for differential diagnostic clues. Most of the therapeutic tests were negative in Wassermann-negative disputed cases referred to the Syphilological Section for opinion. If the Wassermann reaction be positive and the lesion appear none the less to be sarcomatous, an arsphenamine therapeutic test is quite specific and can be rapidly given. It should be borne in mind in general however that it is better on the whole to call a syphilid a sarcoma than to allow a sarcoma to progress to inoperability in a leisurely mercurial or iodide therapeutic test for syphilis.

Malignant Metastases to the Bones.—These must be considered among the differential diagnostic possibilities of bone syphilis. The frequency of invasion of the bones of the pelvis and thighs by carcinoma of the prostat and of the spine by cancer of the breast are well known. Ovarian, renal and thyroid malignancies not infrequently metastasize to bone. Metastases of carcinoma t the vault of the skull are usually late enough and associated with enough collateral evidence of the primary origin to identify them. The presumption in cranial osteoporosis lacking obvious signs of malignant origin is, therefore, in favor of syphilis. Metastases of hypernephroma, however which may appear comparatively early have in our experience caused confusion in 2 cases.

Confusion of Hemangio-endothelioma and Syphilis.—Hemangio-endothelioma or angiosarcoma, mentioned in connection with the diagnosis of cutaneous syphilids, is likewise source of error in the diagnosis of osseous syphilis because of its attack on bone (Fig. 616). The identification of angiosarcoma or endothelioma of this type is discussed on page 710.

Confusion of Syphilis and Multiple Myeloma.—Moore has given us the details of case in hich multiple myeloma producing lesion simulating gumma of the sternoclavicular articulation was confused with syphilis until the Bence-Jones protein was discovered in the urine.

Hodgkin's disease, through its occasional invasion and destruction of bone may also cause confusion in diagnosis (Dresser and Spencer 1936) and the proliferative changes of isolated lesions of atypical Paget's disease (osteitis deformans) may cause diagnostic error particularly hen are concerned with early lesions radiographically demonstrated (Cophey 1941, Alexander and Schoch, 1948)

Confusion of Certain Cardiovascular and Osseous Lesions.—The symptomatic resemblance between the precordial pain of angina pectoris (coronary sclerosis) and the pain of osteoperiostitis of the sternum and periostitis of the left humerus may be confusing. While the pain of angina is the more spasmodic, it is well to make careful palpation for periosteal tender points, along the sternum at the sternochondral junctions for edema and points of tenderness, and for pressure pain over the humerus, with radiologic study if indicated. Aneurysm presenting through or bove the sternum, or t the sternoclavicular junction, may be confusing, for an neurysm incarcerated or containing clot may not pulsate. Even fluoroscopic examination may fail to disclose pulsation. Careful study of the physical signs may be necessary to prevent mistakes. Radicular pain due to aneurysmal pressure may cause erosions of the vertebrae due to pressure to give the external impression of Pott disease, thoracic or lumbar and periostitis of the ribs may be simulated likewise. A very careful study of the physical signs may be necessary to prevent hasty diagnosis of tuberculous spondylitis. In the same way the pain of subdiaphragmatic aneurysm may be confused with radicular pain secondary to hypertrophic changes in syphilitic spondylitis or t pressure caused by destruction of the vertebrae In thoracic and abdominal

aneurysms the fluoroscopic examination will usually assist in identifying the pulsating tumor but in subdiaphragmatic aneurysm the liver shadow may so obscure the findings that the diagnosis becomes at times extremely difficult, and depends on the detection of bruit, pulsation, and collateral signs. Aneurysm of the popliteal artery unless the bruit and pulsation be searched for may be misleading

"Syphilitic Pseudo-arthritis Deformans."—A modified arthritis picture calling for careful diagnostic interpretation is that of so-called syphilitic pseudo-arthritis deformans described by Mericampe, Fournier Dumesnil, and others. This picture has gathered form largely about the coincidence of a positive Wassermann test, and favorable reaction to treatment for syphilis with arthritis deformans. There seems to be little of specificity in the joint picture. Three of the most typical cases we have seen developed mental symptoms, and one of them was found to have a paretic spinal fluid. Psoriasis was coincident in several cases, and was especially marked in the patient who was discovered to have an early paresis. These patients have secured improvements in their arthritis under treatment for syphilis ranging as high as 65 per cent, but none has been

Fig. 579

SUMMARY OF DIAGNOSTIC MAXIMS IN THE CLINICAL DIAGNOSIS OF SYPHILIS OF THE SKELETAL SYSTEM

1 Have blood Wassermann test on every bone or joint case.
2. Examine the patient completely—not merely the lesion. Syphilis eludes the partial or subjective examiner
3. Suspect especially tibial, cranial bone and shoulder girdle lesions of being syphilitic.
4. In early cases much pain, little structural change suggests syphilis.
5 Remember the point of exquisite tenderness over early periosteal lesions.
6. Nocturnal pain is significant, but not infallible or invariable.
7 A roentgenogram is indispensable, but not infallible It ranks next t the blood Wassermann test.
8. Do not operate or incise for diagnosis until the Wassermann report is at hand.
9 Suspect syphilis in the won t heal" syndrome, whether spontaneous or after operative interference
10. The abnormal but mobile or hypermobile joint should arouse suspicion.
11 Watch neurologic signs and symptoms, especially pupils, reflexes, impotence bladder signs, lightning pains, and slight taxia with eyes closed or after dark.
12. Suspect bilateral hydrarthrosis, especially if recurrent.
13 Know the earmarks of heredosyphilis and apply the knowledge to every patient, young or old.
14. Know cutaneous syphilids and their scars Never lightly dismiss destructive skin lesion or scar associated with bone or joint disease. Concomitance occurs in as high as 40 per cent.
15. Look for tuberculids as well as syphilids in association with bone and joint pathology
16. Recall the nonspecific effects of treatment for syphilis, especially with arsphenamine on some periosteal processes, infectious arthritis, tuberculosis.
17 Never think of tuberculosis, sarcoma, or "rheumatism without thinking of syphilis.

completely cured or even permanently relieved, which leads to the inevitable suspicion that the effect was rather a nonspecific one upon the systemic infection background of an arthritis deformans than upon syphilis as the sole cause of the condition.

Nonspecific Periostitis.—Periostitis as a nonspecific diagnosis raises the question as to whether there is any response on the part of nonsyphilitic periosteal lesion t treatment for syphilis undertaken as a diagnostic test. Uncertainty in regard to this question as the occasion for several erroneous diagnoses in our earlier experience with bone lesions, as shown in the case histories. A nonspecific periosteal lesion may present distinctly the yelling of syphilitic periostitis, and the response of the pain to a single injection of arsphenamine may be immediate and complete (Fig. 585), yet no evidence of syphilis be found after the most painstaking and repeated investigation with observation of the patient and his family over a period of years. While this phenomenal response is not common, the frequent use of blue ointment, for example as nonspecific treatment for osseous lesions lacking evidence of syphilitic origin suggests that these cases would be found on fuller study to be a definite and not unimportant group among the factors of error in diagnosis.

Rost (1942) has called attention to the roentgenographic manifestations of the bone involvement from Bejel (endemic syphilis as observed in the Euphrates river valley). The picture described is similar if not identical to the proliferative and periosteal and endosteal changes described as resulting from late acquired syphilis. Bone changes as seen in early congenital syphilis and as associated with the neurotrophic joint are thought not to occur.

THE TREATMENT OF BENIGN LATE SYPHILIS (OSSEOUS AND CUTANEOUS)

The treatment of acquired late syphilis of the bone and of late cutaneous syphilis is essentially similar It is, as a rule, simple and successful if the process be an actual active syphilid The exceptions include those lesions which have recurred in nonregenerative bone, such as the skull, or which involve trophic factors such as the tabetic arthropathies. Superficial structures which have been destroyed by the disease likewise cannot be restored though healing takes place with the arrest of the active process and the development of a characteristic scar Old and neglected syphilids of the bones which have been heavily secondarily infected or repeatedly subjected to operative or traumatic insult, and occasionally the bone lesions of so-called malignant or highly resistant syphilis, may prove refractory to treatment. Sequestra, when they occur may offer temporary impediments to complete recovery and require surgical intervention for their removal

Fig. 580.

RESULTS OF TREATMENT OF 250 PATIENTS WITH BENIGN LATE SYPHILIS
(after Wasserman and Goodman, *Am. J Syph. and Neurol.* 18: 458, 1934).

Amount of Treatment	Percentage Results			
	Blood Serologic Test		Clinical Outcome	
(arsphenamine and heavy metal, 6–8 injections per course)	Wass. fast	Wass. Reversed	Satisfactory	Relapse
One course or less	68.8	19 7	68.2	31.8
Two to four courses	47 1	44.1	86 9	13.1
More than four courses	49.3	31.5	94 6	5 4

The following discussion is based upon 108 cases (Fig. 581) observed in the Mayo clinic series and on Wasserman and Goodman s (1934) excellent report of 250 cases followed from two to fifteen years (average five years)

Treatment of Uncomplicated Benign Late Syphilis.—Late cutaneous or osseous syphilis is almost never encountered in patients who have had adequate treatment for early syphilis. It may be assumed, therefore, that benign late syphilis may be prevented for the most part by the adequate treatment of early syphilis.

The plan of treatment for uncomplicated osseous or cutaneous syphilis need make no provision for an injurious Herxheimer reaction or for the therapeutic paradoxes discussed under *visceral and vascular syphilis. It will be re*membered however that coexisting syphilis of other systems in about one fourth of these cases is more serious than is involvement of the skin or the bone In these instances initiation of treatment too rapidly may be contraindicated. The management of benign late syphilis, as with all other phases of the disease requires complete appraisal of the patient and the immediate institution of arsenical treatment only if vital structures and systems are not involved.

The delayed Herxheimer reaction in bone lesions has been mentioned, and may give a deceptive impression for as long as two or three weeks that the patient is getting worse (Fig 617) This is true rather of later lesions than of earlier ones, in which the relief of pain and the rapidity of regression even in a marked hydrarthrosis or synovitis is sometimes almost miraculous. Complete subsidence of the active process may be expected in from one to three courses, except in syphilis of the palate and septum in which extraordinary resistance is sometimes encountered requiring years of heavy metal and iodide. In treating patients with osseous syphilis, it is important as in all aspects of the disease, to envisage the entire process and to treat for arrest of the infection, not merely for symptomatic relief of the bone lesion. This will seldom require less than four to five courses of 6 to 8 arsphenamine injections each, within a year and a half 40 to 60 bismuth injections *ad interim* and following the arsenical.

Wasserman and Goodman have pointed out that with bone lesions of the proliferative type, it is the exception rather than the rule t note any appreciable change in the roentgenograph as result of treatment even though the active progress of the lesion has been arrested. If the syphilitic process has been predominantly destructive, on the other hand, treatment will usually result in roentgenographic evidence of repair Interruption of the bone structure is usually perma-

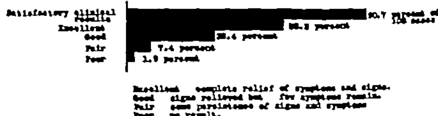

Fig. 461

nent and increased density results from deposition of calcium in the diseased area, over period of years, rather than in a regrowth of vitalized bone.

Management of Resistant Osseous Syphilis.—In the management of resistant osseous syphilis we have seen some of the best examples of the superiority of the coincident administration of heavy metal and arsphenamine over their alternate use

The effect of rest and increase of general resistance is apparent in the old processes, in which secondary infection is often more serious as an obstacle to healing than the syphilis as such Cases of this sort include patients with the tibial osteomyelitis and positive blood serologic reactions that one meets on the wards of charity hospitals, who never accumulate sufficient resistance to shake themselves free of their combination of handicaps.

Resistant Positive Serologic Reactions in Osseous Syphilis.—The resistance offered by the blood Wassermann reaction in 63 patients who received three or more courses of arsphenamine treatment with interim heavy metal is of interest. Fifty per cent remained persistently positive in both the Mayo Clinic and the Wasserman and Goodman series. Individuals who develop negative blood serologic tests as a result of treatment of benign late syphilis

Moore calls our attention to the value of the increased pai of Herxheimer reaction as a means of directing attention to the involvement of other bones not previously recognized.

are apparently no less likely to relapse clinically than those whose Wassermann remains persistently positive. It may be assumed, therefore, that the clinical outcome (satisfactory or unsatisfactory) is not dependent upon the serologic response to treatment. The object of treatment is symptomatic relief the healing of lesions, the avoidance of progression or relapse in any structure in the body and the prolongation of life in those in whom there is

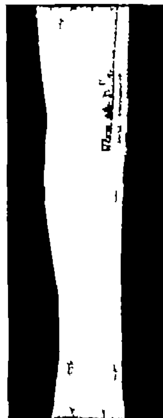

Fig. [illegible].—Periostitis of the tibia in woman whose chief complaint was aching pain in the lower leg. The blood Wassermann reaction was positive. The response to treatment was prompt, but spinal fluid examination year later showed latent neurosyphilitic involvement which it required another three years to reduce to normal. She has been under observation seven years, and is apparently well. The mere discovery of syphilitic bone lesion, and symptomatic relief under treatment, should not discourage the complete study of the patient for evidence of other types of syphilitic involvement. Treatment should be directed at the most serious type of involvement found and not merely at the bone lesion.

associated involvement in the vital structures. This will require the maximum treatment outlined above.

Four fifths of relapses when they occur will be within six years after the cessation of therapy (average 5 1 years) will usually be of the same type as the initial lesion and in the same structure but not necessarily at the same location.

Surgical Treatment of Gummatous Osteitis of the Skull.—The treatment of gummatous osteitis of the skull, of the Charcot joint, and of the long bone

lesion with sequestrum offer special therapeutic problems, with an important surgical aspect. Gummatous osteitis of the skull, involving extensive necrosis, heals with the greatest difficulty the dead bone preventing the restoration of the soft tissues of the scalp above it. Adson has described a method used in some of our cases, in which the necrotic bone of the outer table, or if necessary even deeper is removed with a chisel until free bleeding occurs. Granulations then develop and epidermatization occurs if the edges of the healed scalp wound are freshened or grafts made It goes without saying that systematic treatment for syphilis should precede and follow this measure.

Palate and Septum.—Necroses of the bones of the face offer at times very difficult problems, and extensive operations may be necessary to remove

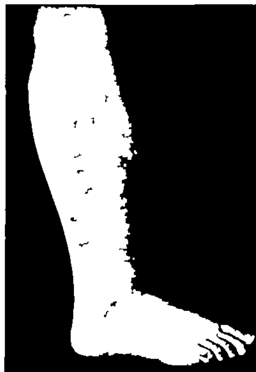

Fig 483.—The enormously hypertrop... ...s of ...syphilis producing picture suggesting so-called "nonsuppurative osteitis of the tibia. This patient was young girl ...th strongly positive blood Wassermann reaction.

sequestra whose suppurative accompaniments may drain into the frontal and other sinuses, maintaining a continuous and resistant pyogenic infection. Such patients have in our experience shown a special susceptibility to cutaneous irritability and reaction under treatment, possibly merely coincidental, but again perhaps due to the chronic infection of which they are victims.

Avoid Incising Sca p Gummas.—A caution is perhaps valid in connection with the tendency to incise nodules in the scalp Surprising resolution will sometimes follow vigorous treatment in patients with gummas of the skull and scalp that have not been exposed to secondary infection and retraction of the scalp tissues by early incision. We believe it to be wise therefore to delay drainage of even softened nodules as long as possible, and to limit such drainage as is d ne to the smallest possible openings.

Fig. 864.

A CASE OF OSGOOD'S (SCHLATTER'S) DISEASE OF THE TIBIA SHOWN BY OBSERVATION OPERATION AND INVESTIGATION TO BE OSSEOUS SYPHILIS

A railroad man, aged thirty-four

Examined 2/3/19.

Chief Complaint Poor extension of the left knee of fourteen month duration.

History Swelling of the entire knee without previous injury Reducible by poultices and rest. Fluid aspiration six months ago. Pain and limitation of movement has persisted. No history of syphilis. Gonorrhea at twenty-two.

Examination Heat and swelling t insertion of ligamentum patellae. Pain and marked weakness on extension. Area affected was the size of fifty-cent piece. Heart slightly enlarged to left. Urine negative. Blood Wassermann reported negative, but *clears slowly* Roentgen-ray report, Osgood' disease Avulsion left tibial tubercle.

Consultant's Diagnosis:

"Osgood' disease left tibial tubercle. Explore and trephine and follow with stiff legged brace for two months.

After Operation. Relief and fair comfort for four months. Six months later lump recurred in the region of previous operation with pain and limitation of movements.

Re-examination Slight enlargement and irregularity of head of tibia. Slight roughening of left anterior aspect of upper tibia. Advised re-examination in one year.

Re-examination: Fifteen months later Pain and soreness, middle and inner aspects of left tibia. Pain is severe, sharp, and shooting Relief by hot packs. N history of injury Diffuse thickening and enlargement of tibia. Roentgenogram Bony overgrowth from the outer aspect of the outer tuberosity Slight periostitis near the border of the tibia. Probably old osteomyelitis. Leukocytes 8900. Blood Wassermann test negative.

Second Operation Tumor of the upper end of the tibia cartilaginous and resembling exostosis. Area near the border of the middle third of the tibia explored. Periosteum thickened and bone hard, but in the middle of this area was granulating portion which was chiseled aw y entirely

Pathologic Examination Tissue removed at operation showed marked perivascular infiltration and fibrosis. Occasional foreign body giant-cells ere found. Send for syphilologic investigation.

Serologic Results: Three positive and two clears slowly Wassermann reactions in 7 tests. Spinal fluid negative.

Therapeutic Test Arsphenamine and mercury Marked improvement. Mobility of knee completely restored.

Discussion

At the time this patient was first seen it was not generally understood that clears slowly report on the Wassermann reaction (delayed negative) is in all probability positive Wassermann result. Had this been known the syphilitic factor in the picture ould have been earlier recognized.

The development of new bone complications *in situ*, like the refusal to heal after operative trauma, unless malignancy is suspected, is suggestive of syphilitic factor, and should lead t investigation before a second operation is undertaken.

The provocative procedure showed the blood Wassermann reaction to be definitely but not strongly positive.

There is again a possibility that some of the effect of treatment for syphilis was nonspecific, for there was marked focal infection of the tonsils.

The pathologic picture of the tissue removed supports the diagnosis of syphilis, as established by the provocative test.

Since one operation had merely resulted in extension and more serious involvement, the treatment is probably responsible for the permanent good result after the second.

Is avulsion of the tibial tubercle necessarily due to syphilis? Of course it is not. The syphilitic process probably appeared upon prepared soil.

Management of the Charcot Joint.—The Charcot joint should not theoretically if it is a pure trophic degenerative phenomenon, respond to treatment for syphilis. On the other hand it does at least show symptomatic improvement in our experience. A brace or an amputation is too often the only therapeutic proposal when intelligent treatment for the neurologic condition would have increased the patient's comfort and effectiveness and arrested the progressive spinal degeneration. Treatment for tabes should not, therefore, be withheld even if there are negative serologic findings. O'Leary (1938) as spokesman for the Cooperative Clinical Group found that of 43 cases of Charcot joint followed two to twenty years, 7 per cent improved and 56 per cent remained stationary as a result of treatment giving a total of 63 per cent in which progress of the disease was arrested

Treatment is not necessarily however offered as a preventive of Charcot joint and the patient cannot be assured that it will stop the development of multiple joint involvement. In 37 per cent of the C C G group of cases there was progression in spite of antisyphilitic therapy In general the physical changes of the Charcot joint, when well advanced are not in the least affected by treatment for syphilis The accompanying trophic ulcer of the toe or foot (mal perforans) however may occasionally heal even though the joint is not affected

Mechanical support with a hinged brace is, as a rule, the only palliative to offer the patient with a well-developed Charcot knee or ankle So long as the joint is reasonably rigid or the patient manages to adapt it to his needs, amputation may be postponed If however the joint becomes a seat of infection a rapid decline in the general condition of the patient follows, often out of all proportion to the apparent severity of the joint condition. In such cases amputation as soon as the process can be brought to quiescence with hot dressings has in the cases we have observed had excellent effect.

Weinberg (1930) Key (1934) and Epstein (1936) have summarized the orthopedic treatment of Charcot joint. Pomeranz and Rothberg (1941) feel that the value of surgical fusion or stabilizing operations for this disease as described by Cleveland and Smith (1931) Cleveland (1935) Seto-Hall (1938) and McCauley (1939) hardly justifies optimistic claims. They stat that no hip joint can be successfully fused and that the end results of fusion of the knee can be determined only as result of prolonged observation. "Several of our cases which were considered successfully orthodesed, subsequently 'unfused' after months or years. (In one case seven years)

Casts.—The premature application of a cast in cases with syphilitic hydrops of a joint has seemed at times actually to delay the progress of the case partly no doubt, because the cast was applied in ignorance of the correct diagnosis and as a substitute for specific treatment. It has sometimes been necessary to take more trouble to reeducate such patients to the use of their limbs after removal of the cast than would have been required had systemic treatment been allowed to meet the situation unaided.

Removal of Sequestra.—Removal of sequestra in syphilitic bone lesions should not be undertaken until the patient is well under the influence of treatment for the operative provocation simply extends the syphilitic process, often with more sequestrum and repeated operation. The vicious effect of such a cycle was seen in the astonishing hypertrophic changes of the much operated syphilitic tibia in a woman of forty-seven. The bone had almost reached the dimensions of the patient's forearm after nine operations and "scrapings." Her hereditary infection had been neither diagnosed nor treated.

DRY CLINIC ON BONE AND JOINT SYPHILIS

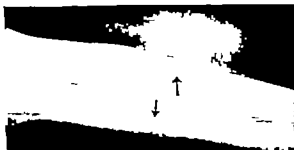

Fig. 583

PERIOSTITIS AS A DECEPTIVE SIGN OF SYPHILIS

A male aged thirty-one, married.

1915 Backache relieved by baths.
1916 Aching Pain Right Thigh and Knee, Constant, Worse at Night. One Year's Duration.
- Wf and 2 children well. No miscarriages.
- No history of syphilis, primary or secondary or of gonorrhea. Exposure admitted.
- Robust male. Never been ill.
- SWR negative June, 1916.
- Roentgenogram of right femur periostitis, lower half.
- Provocative injection neoarsphenamine 2 dg.
- Pain Disappeared Within Twenty-four Hours and Has Never Reappeared.

1916 Provocative series of Wassermann test negative throughout.
- Wife Wassermann negative.

1917 Eight injections neoarsphenamine 3 to 6 dg 20 injections mercury salicylate gr 1 to 2 intramuscularly

1918 SWR negative
- Cerebrospinal Fluid—SWR negative Nonne negative, 15 lymphocytes.
- Neurologic Examination Pupils slightly oval.
- Anal and abdominal reflexes reduced.
- Epigastric and testicular tenderness reduced.

1921 SWR negative.
- CSF negative (1 lymphocyte).
- Pupils as above.

Discussion

1. Nocturnal bone pain, with the x-ray picture of periostitis, constitutes strong evidence for syphilis in spite of the negative serology. The immediate and permanent relief of the pain by the first arsphenamine injection is even more suggestive. A pleocytosis of 15 cells in the spinal fluid in a healthy person even with trivial neurologic signs, after two years of observation and treatment, is contributory evidence of syphilitic infection. Taken alone, however it has little weight.
2. None of this evidence, however can be rated as conclusive, especially in view of the evidence cited for nonspecific effect of treatment for syphilis on nonsyphilitic bone processes.
3. A reexamination of this patient five years after his first examination, and of his wife, discloses no evidence of syphilis in the latter nor of activity in the former
4. Did this patient have syphilis? It is impossible to give a conclusive answer.
5. Periostitis of any type cannot be accepted unqualifiedly as evidence of syphilis, but it justifies at least a blood Wassermann test and often fuller investigation.
6. In this case the existing uncertainty would, if treatment were begun at all, justify complete therapy with prolonged observation. Otherwise the patient might be left with impaired resistance, prepared for some form of relapse. For meaning of effective treatment see Fig. 580. This patient would not cooperate to that extent.

Fig 586.—Gummatous involvement of the sternoclavicular articulation and upper end of the sternum, for comparison with Fig 587 (aneurysm) B shows the effect of treatment. While the signs of aneurysm are usually pronounced enough to prevent mistake incarcerated or clotted aneurysm may not pulsate, and exploration or incision may be considered. It is almost as serious to begin routine intensive treatment for syphilis on cases of this kind without eliminating aneurysm, for the effect of arsphenamine on patients with aneurysm, especially at the outset, may be disastrous.

Fig 587 —Aneurysm of the aortic arch, presenting through the upper end of the sternum Compare with Fig 586. The infection was of twenty-five years duration and the signs of aneurysm obvious enough to preclude error The substernal dulness was 18 cm. across. The pain of mild angina pectoris and aneurysm and that of osteoperiostitis of the sternum and humerus may be confused.

Fig. [illegible].—This patient, aged sixty-three years, gave history of penile lesion forty years ago. Throughout long and active life he had been absolutely free from any symptoms of the disease. His only complaint at the time of examination was swelling of the right side of the neck of one year duration with occasional slight tenderness. The blood Wassermann reaction was repeatedly strongly positive. Spinal fluid was negative. H had never had any treatment for syphilis. Roentgenographic study as practically negative. The patient was given mixed treatment by mouth and warned not to allow any young medical enthusiast to try modern treatment methods on him. The lesion as apparently gumma and by subsequent report promptly disappeared.

Fig. [illegible].—This patient was sent for syphilological examination because of the presence of bone lesion in the "suspicion-arousing region of the shoulder girdle and upper sternum. The tumor was smooth, firm, not tender and had been present, though smaller, for many years. Of late it had grown more rapidly The patient could give no history of syphilis, though he admitted frankly that he might have been exposed. A tentative diagnosis of chondroma had been made, and he was advised not to undergo operation. He was so conscious, however of the fact that such lesion might suggest syphilis, that he insisted upon operation. The lesion proved to be sarcomatous, and postoperative hemorrhage cost him his life. Not every enlargement at this point is syphilitic in origin.

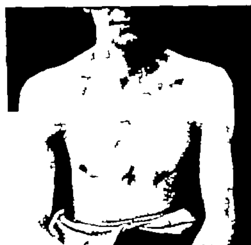

Fig 490.—This woman t fifty years of age began to show signs of a general breakdown. It was presently found that she had hypertension, that the aorta showed aneurysmal dilatation, that there was some myocardial insufficiency and that the blood Wassermann reaction was strongly positive. On examination, note was made of the enlarged right sternoclavicular articulation. It was the sign upon which surgeon of the past generation had evidently based diagnosis of syphilis long before the day of the Wassermann and given her drops. She was never informed as to the situation, and went on to lat complications, again in accordance with the syphilological technic of her day. Her children are apparently normal. She has since been asked by physician when her collar bone was broken. Under conservative but thorough treatment she ha reached her seventieth year

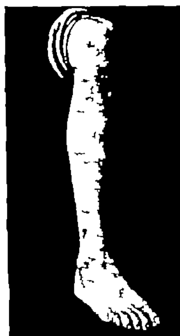

A B C

Fig 491.—This patient is veritable parade ground for osseous syphilis. His chief complaint was rheumatism and loss of voice. The laryngeal condition came on suddenly after shouting and consisted of double fixation of the cords in slight abduction, possibly due to gummatous infiltration. The bone condition caused him less concern. He presented osteitis and periostitis of the left parietal bone, both clavicles, both scapulae all the sternochondral junctions, and dorsal spondylitis. The tumor formed when the gummatous lesion of the skull developed, was promptly lanced by physician, without Wassermann test. The clavicular process was initiated by injury. The massive thickening of the clavicles and scapulae was astonishing. The blood Wassermann reaction was positive. Further study could not be carried out, and the patient could not remain for treatment.

A

B

Fig [illegible].—This young man (aged thirty-two) gave his chief complaint as "stomach trouble which had inspired the needless surgical intervention shown by the abdominal scar In his preliminary examination very little of importance appeared, but his blood Wassermann reaction, routinely taken because of his age, was returned as positive. His case was then reviewed, with the discovery that he had greatly thickened saber tibiae, the right one showing the scars which the patient then recalled as having been due to operative scraping of the bone in childhood. Through failure completely to strip the patient in his first examination, these almost pathognomonic tibiae had been overlooked, and only the routine Wassermann test saved the diagnosis. On examining A, visible ground for suspicion, independent of the tibiae, can be readily recognized. This patient weighed 138 pounds. His clavicles, especially the inner third, would have suited man of 200 pounds weight. There was marked old osteoperiostitis with changes demonstrable by roentgen-ray The patient apparently had congenital infection. His surviving parent declined examination. The stomach symptoms completely disappeared after treatment, though the stomach roentgen-ray was negative, and there was no evidence of neurosyphilis.

Fig 593

SYPHILITIC PERIARTICULAR ARTHRITIS FOLLOWING TRAUMA WASSERMANN NEGATIVE. THERAPEUTIC TEST POSITIVE.

Boy aged nine.

Chief Complaint "Broken left elbow Fell down stairs seven weeks ago striking left elbow on banister No symptoms until two days later Aching of elbow joint.

X-Ray Diagnosis Fracture? Placed in cast, with subsequent manipulation under anesthesia.

Examination Arm placed at right angles, slight motion, some effusion but the joint with palpable thickening X-Ray shows slight periostitis lower end of femur with erosion of articular surfaces.

Patient otherwise negative except for left internal strabismus and congenital cataract.

Syphilologic Examination: Mother had 8 miscarriages following this child.

SWR negative direct and on provocative.

Therapeutic Test: 6 arsphenamin injections 1 to 8 dg and 30 inunctions. "Beautiful result. Swelling disappeared, mobility largely restored.

After another 40 inunctions full motion restored and no effusion.

Father denies syphilis, refuses examination. Took the patient home without final advice.

Discussion

1 The x-ray changes (second examination) can hardly be regarded as absolutely specific.

2. This is as good an example of Simon-pure therapeutic test as one usually finds. Examination of the spinal fluid was not permitted. The mother history of miscarriages, even though they followed the child' birth, wa valuable clue. The child showed no stigmas of heredosyphilis. His infection probably occurred at birth or in early childhood.

3. No better example of the effect of trauma in producing flare-up of quiescent syphilis t point of lowered resistance could be desired.

4 **Whenever an Unfavorable Reaction to Injury is Out of All Proportion to the Gravity of the Injury or th Seriousness of th Exciting Cause Suspect Syphilis, Especially If th Onset of Reaction Symptoms is Delayed.** This boy fell down three steps, with bump on the elbow that was of so little moment that symptoms did not begin for three days following the injury

Fig. 504.—An aviator bumped his knee in leaving his machine. Thereafter it was persistently sore to touch and painful on movement. The x-ray showed inflammatory changes in the bone of the internal tibial tuberosity that led to the taking of a blood Wassermann test, which was strongly positive. Recovery was immediate under treatment for syphilis.

Fig. 505.

SYMMETRIC SYNOVITIS OF BOTH KNEES IN THE COURSE OF NEUROSYPHILIS RELIEVED BY ARSPHENAMINE TREATMENT. PROBABLE NON SPECIFIC EFFECT. BEGINNING CHARCOT JOINT(?)

A married woman, aged twenty-eight.

Examined 2/16/19

Chief Complaint Headache, gastric distress. No history of syphilis.

Examination Wassermann reaction on the blood was strongly positive. The spinal fluid Wassermann was strong positive with positive Nonne, 40 lymphocytes, gold sol 0055545443. Osseous system negative. Favorable response to treatment. Note that there was no osseous disturbance at the outset.

Treatment Following the first course of arsphenamine treatment patient went home, neglecting the removal of three abscessed teeth. She began inunctions and became stiff in the joints, sick, and confined to bed. The abscessed teeth were then removed, with recovery. One year later the knees enlarged symmetrically three weeks after a fall. A large amount of fluid was aspirated by her physician. Returned for examination. Clinical appearance of the knees suggested Charcot joints. Marked synovitis, moderate effusion of both knees, crepitation. Radiogram negative. Arsenical therapy was resumed. The synovitis cleared up immediately although already of four months' standing. Dr Henderson suggests the hydrops is possibly a symptom of an early Charcot joint.

Discussion

On two or three occasions in patients with syphilis synovitis of this type improved remarkably under treatment, but in at least one case the joint later developed Charcot changes in association with neurosyphilis.

This patient had had, however, mercurial arthritis, and on this occasion there was some suspicion that the entire picture was that of an infectious multiple arthritis rather than syphilitic process.

Great care must be used in interpreting the action of arsphenamine on arthritis as demonstration of syphilitic origin. Nonspecific effects are quite common.

The amount of treatment which this patient had had previous to the synovitis would seem to make syphilitic multiple arthritis impossible.

Note that she came originally for "stomach trouble," which was found to be referable to neurosyphilis.

Fig [illegible]. (See next page.)

Fig. 506 (*Continued*)

HYDRARTHROSIS OF THE KNEES (CLUTTON'S JOINT), JUVENILE TABES, AND STIGMATA OF HEREDOSYPHILIS. VALUE OF A COMPLETE EXAMINATION IN IDENTIFYING UNUSUAL TYPES OF OSSEOUS SYPHILIS.

A schoolboy aged twelve.

This boy's syphilitic infection was brought to our attention incidentally to the diagnosis of his mother's case.

In the course of a routine inquiry as to the health of her living children she stated that her first child (this patient) had had his legs placed in casts for swelling of the knees. She remarked incidentally and without prompting that the pupils of his eyes did not seem to be of the same size. This at once aroused the examiner's suspicions, and when the child was subsequently seen he presented the following findings: Facies 80 per cent. Suggestive upper central incisors. Pupils unequal, irregular, left larger and fixed to light. Remains of old interstitial keratitis. Bilaterally symmetric hydrarthrosis of the knees (Clutton's joints). Spleen palpable. Well-marked sabering of the tibiae. Blood Wassermann reaction strongly positive. Spinal fluid Wassermann negative with 0.4 and 0.6 c.c., weak positive with 1 c.c. Nonne positive; 14 small lymphocytes. Colloidal benzoin 000,111 221, 000,000. Patient was placed on treatment as follows: First course: 6 arsphenamin injections, 2 to 3 decigrams each. Mercury succinimid intramuscularly 20 injections, ⅙ to ¼ grain daily. The plaster casts were gradually removed, and as the hydrarthrosis subsided the patient was able to walk about with crutches. Interim treatment 40 inunctions, four months interval. A flare-up of the interstitial keratitis occurred which subsided during treatment. Second course: Casts completely removed. Knees almost normal. Third course: 6 arsphenamin injections, 2 to 3 decigrams; 40 inunctions at home. Boy now in excellent general condition. No symptoms of any kind.

DISCUSSION

This case is an excellent illustration of the value of looking beyond the immediate presenting symptom or lesion for the etiology of the patient's condition. This boy presented a number of stigmas of heredosyphilis which would have made a diagnosis even without a Wassermann reaction. Symmetric hydrarthrosis of the knees as a manifestation of heredosyphilis is not as familiar to the profession at large as it might be. On the other hand, it is of interest to note that in this boy's case the onset was febrile so that the process might readily have seemed to be infectious in origin.

Symmetric hydrarthrosis of the knees without manifestations of heredosyphilis may occur, but as a rule the tuberculous or septic process may be distinguished by the presence of an arthritis which is absent in the typical Clutton joint.

A point of some interest in this boy's case is the fact that part of his pupillary rigidity was due to posterior adhesions of the iris margin to the lens and not to the true Argyll Robertson syndrome. There were, however, other signs supporting the diagnosis of neurosyphilis, including the spinal fluid findings.

Only a definite search of the familial history for evidence of syphilis in this mother's children brought this case under our observation. A Wassermann reaction had just been taken by the home physician, although the result had not been reported to the family.

In our experience it has not been necessary to place syphilitic joints in plaster if intensive antisyphilitic treatment be promptly applied. Symmetric hydrarthrosis in heredosyphilis is not necessarily confined to the knees, but may also involve elbows and wrists.

Fig. 498. (See next page.)

Fig. 508 (*Continued*)

BILATERAL CHARCOT KNEES IN A BENIGN TABES

A man, aged forty-eight.

Examined: August 16, 1922.
Chief Complaint: Pain and disability affecting both knees.
History: In this patient general examination he denied syphilitic infection. When questioned later by the syphilologist he recalled genital sore thirty years ago which was burnt off without further treatment. He has always been in robust health until five years go, when his right knee as cut ith scythe Four months later swelling began, and six months later the knee as operated upon, the patella lifted up, and the trouble scraped out. He was told that it was tuberculosis. Three years later the left knee beg to swell. Four months after this both knees became obbly but the patient recalls that his right knee had wobbled before the first operation.
Examination Pupils unequal. Right larger than left. Right "frozen to light. Left sluggish. Both knees enlarged, marked lateral motion. Knee-jerks and nkle-jerks absent. *Ray of knees* Bilateral Charcot joints. *Eye examination.* Mild per iphoral chorioretinitis. Slight hypertension changes. Blood Wassermann reaction negative. Spinal fluid Wassermann negative, 0 4, 0.6, and 1 c.; Nonne negative; 4 small lymphocytes. Neurologic examination Tabes dorsalis.

DISCUSSION

In endeavoring to obtain history of syphilis it is well t question the patient more than once. H may recall something bet een times.

This patient gave typical history of lightning pains of fifteen years duration, but apparently no inquiry had ever been made regarding them.

The pupillary reactions and absence of deep reflexes were detectable upon ordinary physical examination. It is conceivable but not probable that they were normal at the time of the first operation.

The negative blood Wassermann reaction and negative spinal fluid is not unusual in tabetic arthropathies.

Not the extraordinary good health enjoyed by this patient without symptom of syphilis over long period of years.

The -ray and consistent search of every patient for the neurologic signs of tabes are the most effective means of diagnosing tabetic arthropathies.

The blood Wassermann reaction is no substitute for clinical signs in these cases especially

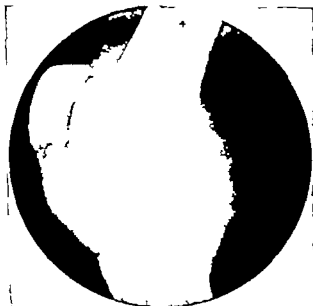

Fig. 509 —Typical Charcot knee (patient shown in Fig. 508)

Fig. 602.—The history and roentgen-ray findings on this patient are given on page 804

CHARCOT SPINE IN LUES HEREDITARIA REGARDED AS POSTURAL DEFORMITY

A schoolboy aged sixteen.

Examined 6/20/22.

Chief Complaint: Becoming round shouldered.

History: Onset one year ago. Painless. Regarded as due to faulty posture No other symptoms. Family and past history apparently negative.

Examination: Left pupil fixed t light. Right pupil normal. Marked lower dorsal kyphosis with slight lateral curvature in the lumbar region. Facies suggests lues hereditara. Knee-jerks absent. Roentgenogram. Scoliosis dorsal and lumbar spine Partial destruction body of eleventh and t elfth dorsal vertebrae Destruction body of first and second lumbar and fourth and fifth dorsal vertebrae. N muscle spasm, no limitation of motion. N pain on jarring Blood Wassermann reaction strongly positive.

Treatment: Six arsphenamine injections, no change in spine. Spinal fluid examination (second arsphenamine course) Wassermann strongly positive; Nonne positive; 100 small, 25 large lymphocytes, 10 polymorphonuclears gold sol 5555432100. Sixteen intravenous arsphenamine injections, three Swift Ellis treatments—spinal fluid reduced to normal after third arsphenamine course. Remarkable grow th and general improvement. N change in back. Gives mental impression of paresis, however Neurologic examination, juvenile tabes.

Discussion

Rapidly developing postural defect in young people here served as a clue t heredosyphilitic processes the spine and should not be lightly dismissed as merely postural.

This bone lesion, at first regarded spondylitis in view of neurologic signs and destructive changes, was later interpreted a Charcot spine in association with juvenile tabes. Rest in bed nd a brace had practically no effect on this lesion.

The spinal fluid is not that of the conventional long-standing juvenile tabes, but suggests rather that of a juvenile paresis. The patient mental make-up suggested early juvenile paresis, but the remarkable and complete response to intensive arsphenamine and intraspinal therapy rather weakens this supposition.

Fig. 603.—Roentgenogram of the Charcot spine of the patient shown in Fig 602.

Fig. 604.—The syphilitic bursopathy of Verneuil. Note the suggestive group of pigmented scars about the right knee in A. (Collection of Drs. Keidel and Moore.) In B (collection of Dr John E. Lane) the gummatous infiltration has broken down. A blood Wassermann test should be taken on all cases of chronic "housemaid's knee" before incision or removal of the bursa is attempted.

Fig. 605

SYPHILITIC SYNOVITIS OF THE LEFT KNEE. REPEATED ASPIRATION WITHOUT WASSERMANN TESTS, AND REPEATED RECURRENCE. NON-SPECIFIC OR SEPTIC FACTOR (?). PERMANENT RESULT FROM TREATMENT FOR SYPHILIS

Clergyman, aged thirty-five

Chief Complaint. Swelling of the left knee. History of iritis one year ago. Cleared up by 2 injections in the arm. Penile lesions seven years ago (history obtained later). Had marked rheumatism at the time. Four attacks of synovitis in seven years. Usually painless. No limitation of movement.

Examination. Obviously fluid in the left knee-joint. X-Ray negative. Calcareous spur right foot. Tonsils slightly septic. Three bad teeth. No blood Wassermann reaction taken.

First aspiration of left knee-joint. Injection 1 to 2 ounces iodoform in olive oil. Prompt recurrence synovitis.

Second aspiration 4 ounces fluid was removed—1 to 2 ounces iodoform in olive oil.

Recurrence aroused suspicion and history of iritis with response to intravenous injections led to taking of blood Wassermann reaction. Blood Wassermann reaction strongly positive. Placed on treatment with arsphenamin and mercury. Synovitis promptly disappeared. Did not recur.

DISCUSSION

The taking of a blood Wassermann test on every patient who has a bone or joint lesion, regardless of its character is a standing order for every diagnostic and surgical service.

A social criterion (clergyman) was responsible for the inadequate taking of the history of syphilis in this patient.

The story does not, however, lack evidence of a septic influence. The intravenous injections may have been phylacogens. There were, moreover, occasional recurrences of joint trouble affecting the fingers even after treatment for syphilis was well under way.

This patient proved later to have what seemed to be a neurosyphilis of the paretic type, but which at autopsy was found to be a frontal lobe glioma. The history of this phase is detailed in the chapter on Neurosyphilis. He had an undoubted syphilitic infection.

Fig 606.—This is fairly good example of the effect of incising gumma. Note the radial extension of typical group of serpiginous ulcers from the line of incision. The raised border momentarily suggests epithelioma, but it is fair test of the "instinct of student of syphilis to "feel" as well as see the elements in the gross appearance of this lesion that make syphilis almost unescapable *A positive Wassermann reaction should not be necessary in case like this to raise suspicion to the point of therapeutic test, to say nothing of full investigation for syphilis* (provocative procedure etc)

The outstanding facts of this case are as follows

1 The patient, widow of fifty-three came with a chief complaint of stiff shoulder with pain in arms, neck, and legs.

2 The original medical diagnosis in her case was apparently "neuritis, first in one arm, then the second arm.

3 The preliminary medical history was apparently taken in such haste that the fact that her husband had died of tabes, and that while there had been no miscarriages there had been mortality of more than 75 per cent among her children in infancy was overlooked.

4 Radiogram of the wrist showed an old arthritis involving trapezoid and trapezium with destruction of articular surface

5 The wrist had begun to swell five months before was lanced three months later and was still open and draining, with the development of the lesion illustrated above without the index of suspicion rising to the point of having Wassermann test.

6. *The first Wassermann reaction taken the case was strongly positive*

7 The neurologic examination, cardiovascular examination, and spinal fluid were all negative

Suspect syphilis with every tumor especially if it develops slowly is indolent, and undergoes softening.

Redouble suspicion if after incision the lesion does not heal, but begins to extend with a serpiginous border. This is an excellent example of associated cutaneous and osseous lesions.

Vague pains, often diagnosed neuritis, are not uncommon feature of latent and late syphilis.

The family history is often better arouser of suspicion than is that of the individual patient, especially if she be woman.

Fig. 607

SYPHILITIC PSEUDO-TUBERCULOSIS AND THE WASSERMANN TEST

Male, aged thirty married, railroad brakeman.

A Cutaneous Lesion is Often the Best Guide to Syphilitic Process in th Bones or Joints. This patient came to the Clinic with chief complaint of loss of voice. H supposed that he had tuberculous laryngitis, and had been treated on this supposition by physician for tw and half months. H had been hoarse continuously for six months following severe cold. In the first three months of this period he had lost 30 pounds in weight.

In the collateral history it developed that he had been troubled with abscesses in the arms nd legs for four years, the right leg had been placed in cast for supposed tuberculous knee nd that the right elbow-joint had also become involved, ith several draining sinuses and good deal of scarring of the skin about the joint.

He Carried His Diagnosis on the Posterior Aspect of th Right Thigh. The classical group of sharply marginated punched-out ulcers along the dvancing edge of the process with superficial pigmented scar is diagnosis of syphilis on sight. Scarring on the front of the right knee is equally characteristic. The scars left by the draining sinuses are also pparent. While scarcely necessary for diagnosis it is interesting that the W ssermann reaction was repeatedly positive.

A most surprising therapeutic response followed six injections of arsphenamin. The patient regained his voice, the cutaneous lesions healed, nd year later movement had been so completely restored t all the affected joints that the patient was able to pass the draft examination for the army

Why Did This Patient Sustain Repeated Diagnoses of Tuberculosis in the Face of so Much Ground for Suspicion of Syphilis, to Say Nothing of Indubitable Evidence of Its Presence?

1. The fact that one sister had had tuberculosis was pparently partly responsible.
2. Few physicians realize that syphilis may produce bone and joint involvement with the formation of hat ppear to be tuberculous sinuses.
3. The index of suspicion in this patient medical attends ts was pparently low Certainly no one familiar ith the fundamental characteristics of lat cutaneous syphilids could have treated this patient for tuberculous osteo-arthritis and tuberculous laryngitis without Wassermann reaction. H had, moreover his tory of genital lesion twelve years before

The Index of Suspicion is What Makes the Diagnosis of Syphilis, Not Laboratory Tests.

Fig. 608.—This patient, aged fifty-one, illustrates the clue that may be furnished by a cutaneous scar adherent to bone in suspicious region (right clavicle) His chief complaint was backache of two months duration. Syphilitic backache has been emphasized in a publication by Klauder Roentgenographic study of the lumbar spine and stomach was negative. The stomach acids were low The blood Wassermann reaction was strongly positive. There was a scar of the ala nasi somewhat suggestive of syphilis. Immediate and complete relief of the backache followed treatment for the syphilitic infection.

Fig 609 —Importance of cutaneous lesion in diagnosis. This boy had bilaterally symmetrical hydrarthrosis of the knees which was referred t the syphilologist for an opinion as to the presence of stigmas of heredosyphilis, in which this picture may occur While there were no signs of syphilis, the eruption on the thorax quite positively identified the process as tuberculous. This is the grouped follicular eruption of lichen scrofulosorum tuberculid. The von Pirquet test w violently positive. Evidently tuberculous hydrarthrosis may closely simulate Clutton joints

Fig. 610.—This series illustrates (A) the nonunion of fracture in patient with syphilis who under treatment for the disease, without other measures, secured very rapid union (B) and functional restoration (C). The practice of taking blood Wassermann tests on ununited fractures led to the detection of this case, but syphilis as such need not be necessary cause of nonunion. The patient had been nurse, and on inquiry gave clear history of extragenital infection following the care of child ith pemphigoid syphilid, of whose infectiousness she had not been warned. In ununited fractures in which the blood Wassermann may present an equivocal result, roentgenograms of the entire bone or other bones may occasionally present periosteal lesions suggestive of syphilis.

Fig. 611.—Syphilitic pseudotuberculosis, with multiple sinuses and scrofulodermatous changes in the skin. The patient had been treated for four years as tuberculous, without Wassermann test. He presented pathognomonic cutaneous lesions of syphilis around other joint lesions. (See Fig. 607.)

Fig 612.

WILLIAMINOFF SYNDROME (?) BORDERLINE BETWEEN SYPHILIS AND TUBERCULOSIS, OR NON-SPECIFIC TREATMENT EFFECT AND HERXHEIMER REACTION IN GLANDULAR AND OSSEOUS TUBERCULOSIS (?)

A male, aged t enty-five.

Examined 1/17/1921.

Chief Complaint Swelling and redness of left knee. Old glands in the neck. Lumps on the back.

History Measles and lung trouble at age eight followed by enlarged cervical glands. Glands removed t operation, drained one year Numerous recurrences. Inflammation of the eyes age twelve. Running sores on neck age eight t t enty Good health age twenty-one to twenty-three. Mumps at age twenty-three followed by swelling of ankles, knees, and hands. Joints cleared up following injections for rheumatism. Back sprained two years ago, followed by pain in the legs. Thumb broken open following blow ith hammer Blood Wassermann reaction negative four months ago. *Diagnosis Congenital syphilis* based upon gummatous (?) swelling of the cheek and therapeutic response of neck lesions with local Herxheimer reactions to arsphenamin.

Examination Undersized male with Websterian dome, facies not suggestive. Extensive scarring of neck and face. Limitation of motion and sores over first t third lumbar vertebræ Metacarpophalangeal joint left thumb destroyed with false joint and sinuses. Left knee swollen, feverish, tender Afternoon temperature 100° F *x Ray*, multiple destructive arthritis of left thumb, right foot, spine and left knee. Hemoglobin, 65 per cent. *Blood Wassermann reaction negative* *Eye examination* Old interstitial keratitis with pigment deposits anterior surface right lens. No other osseous stigmas of heredosyphilis. *Special tuberculosis examination* chronic bronchitis, no evidence of tuberculosis in chest. *Sputum examination* negative Carbolfuchsin stains of pus from sinuses negative for tuberculosis.

Treatment Five neo-arsphenamin injections and 8 mercury salicylat injections ere given before coming t the clinic. Marked improvement took place in gummatous (?) lesions on face and neck. A Herxheimer reaction was observed. Further treatment, 6 injections neo-arsphenamin 0 3 t 0.5 gram, no mercury Progress was unfavorable. Treatment discontinued A tuberculous abscess in the left knee was drained, heliotherapy employed, and the patient improved.

Discussion

1. The suspicion of heredosyphilis rests entirely upon the patient general underdevelopment, his interstitial keratitis, and the initial improvement in the neck and face lesions under arsphenamin and mercury
2. Are these sufficient grounds for diagnosis of heredosyphilis? The process came on after measles and lung trouble. The patient ha never had positive blood Wassermann. The keratitis may have been tuberculous and the response to treatment non-specific. A Herxheimer reaction, moreover may occur in purely tuberculous lesions hen arsphenamin treatment is begun.
3. The possibility of syphilitic factor rests, therefore on rather slender basis. Everything which observed as contributing t diagnosis of heredosyphilis is almost equally applicable t diagnosis of complicating tuberculosis. The subsequent course of the case showed the tuberculous factor to be the more important. One must learn t distrust arsphenamin therapeutic tests.

FIG. 618.—THE CONFUSION OF SYPHILIS AND SARCOMA.

Left shoulder of woman who had sustained two surgical explorations with two diagnoses of sarcoma of the humerus. One of these diagnoses was given her in large diagnostic and teaching service, following examination of tissue. She was told her condition was inoperable, and radiotherapy advised, but refused. The report was confirmed by a second examination elsewhere. N blood Wassermann test seems to have been performed as part of either examination. When the blood Wassermann *test was finally taken it was strongly positive, and the* "sarcoma" vanished under treatment for syphilis. She has been under observation more than three years and is in excellent health.

The confusion of syphilis and sarcoma was much commoner and more distressing problem in pre-Wassermann days than it need be at the present time. Especially in heredosyphilis the appearance of painful swelling on long bone was the signal for surgical intervention. The obvious course nowadays is to take a routine blood Wassermann test as part of the medical examination to which all bone and joint cases should be subjected. The acceptance of a roentgenologic report without Wassermann test, or of biopsy report from tissue excised at exploration, especially from frozen section, without Wassermann test, opens the way for grave diagnostic error and neglects the most important single suspicion-arouser in the field of skeletal syphilis.

THE CONFUSION OF SYPHILIS AND SARCOMA.

Photographic reproduction of part of letter accompanying patient to the clinic.

GUMMATA OF JAW AND PALATINE BONES. PATHOLOGIC DIAGNOSIS "ROUND-CELL SARCOMA. OPERATION WITH RECURRENCE. RECOVERY UNDER ANTISYPHILITIC TREATMENT

Boy aged ten.

4/20/16 Bone scraped for tumor of jaw
6/17/16 Dead bone and more scrapings removed.
Pathologist reports "Round-cell sarcoma.
9/23/16 Entered clinic. Tissue removed for diagnosis—no sarcoma found. Inflammatory tissue only
2/20/16 Two arsphenamin injections and treatment by mouth Improved.
3/19/17 Swelling lower end right humerus. Ray report Probably specific Mercury rubbed on locally
7/28/17 SWR ++++
7/30/17 7 injections arsphenamin 0 05 to 0.2 gm.
9/27/17 Improved. SWR +++
Mother SWR negative.
11/20/17 Nose and throat—large masses and crusts.
1/1/18 Interim on inunctions.
Much deformity perforation of palate, septum destroyed.
1/22/18 to 9/28/18 Seven injections arsphenamin 0 3 to 0 4 gm
SWR negative Process arrested

DISCUSSION

1 Syphilomas especially early before healing sets in, because of their high lymphocyte content, seem peculiarly susceptible to confusion with the pathologic picture of round-cell and lymphosarcoma. A Wassermann test and search for further evidence of syphilis will often prevent an error in diagnosis and needless operative interference.

2. Notice the inability of inunctions alone to hold the process in check (1/1/18).

Fig. 618.

CONFUSION OF EPITHELIOMA OF THE NASAL SEPTUM WITH POSTOPERATIVE SYPHILITIC OSTEITIS

A man, single, aged twenty-three years.

Examined 7/7/1919.

Complaint Repeated ttacks of swelling and inflammation in nasal side of left eye, with discharge of pus. Duration of symptoms, one year

History of Gonorrhea, 1918. No history of syphilis. Wassermann reaction negative.

Submucous Resection; intranasal dacryocystotomy

Good Results for Several Months.

Swelling and Crusting Within Nose. Foul discharge.

Blood Wassermann Reaction Negative Provocative negative. Marked destruction, nasal septum. Pieces of bone in discharge.

Diagnosis Syphilitic osteitis, nasal septum.

Returns After Six Arsphenamin Injections and 2 injections of mercury salicylate per week.

Hemorrhagic Nephritis (mercurial type), secondary to treatment (?). Small amount of albumin, many casts. Weight loss 40 pounds.

Wassermann Reaction Negative.

Rest in Bed. N improvement.

Secondary Antrum Infection Fever, further loss of weight.

N Response to Iodid or Arsphenamin.

Collapse of Nose.

Increased Edema of Face.

Septic Symptoms Nasal hemorrhage, steady decline in weight, increasing anemia, extreme fetor

Crusting and Ulceration appear at the ala nasi. Septum completely gone. Palat perforated.

Excision of Tissue from edge of alar ulcer

Diagnosis Epithelioma.

Intranasal Biopsy Squamous-cell epithelioma. Highly malignant.

Radium Intranasally Too late to vert fatal outcome

Discussion

1. In highly malignant syphilis of the osseous system the Wassermann reaction may be negative on the blood. On the other hand, persistent Wassermann negativity in rapidly progressive, destructive bone lesion should suggest error in diagnosis.
2. Syphilitic lesions hich progress in spit of combined treatment with arsphenamin, mercury and iodids should be searched for malignancy
3. The malignancy may be the primary condition, or secondary to the malignant degeneration of gumma. This is particularly likely to happen in lesions in the mouth, nose, and throat.
4. W were led astray in this case by the clinical picture and too ready an acceptance of the Wassermann negativity
5. While malignant syphilis undoubtedly exists, it seems probable that some of the reported cases may have been true malignant neoplasms instead of or in addition to syphilis.
6. An early biopsy should be made of tissue from the active margin inside the nose if the lesion resists treatment.
7. This case presented good general clinical picture of malignant syphilis, and was accepted as such on sight by several outside consultants.

Fig. 616.

HEMANGIO-ENDOTHELIOMA (ANGIOSARCOMA) SIMULATING LATE SYPHILIS OF THE SOFT TISSUES AND BONE. FALSE THERAPEUTIC TEST

A girl, aged fifteen.

Examined 10/27/16.

Chief Complaint. Deformity of the right wrist.

History. Broke right thumb at age of one year. Deformity of wrist appeared without symptoms at the age of twelve. Increasing weakness of the hand developed. Dislocation of wrist took place to the radial side with shortening and loss of movement, and slight crepitus. Radiogram showed cystic destruction of the lower end of the radius.

Treatment. Bone-graft done with good absorption and firm union. Blood Wassermann reaction at this time was negative. The patient returned three years later with skin broken down over the old operative wound. Numerous ulcers were appearing. She was then referred to the syphilologist. The lesion showed several draining sinuses, and considerable swelling, but nothing distinctive of syphilis. Provocative procedure was negative. *The lesion then healed completely under six injections of arsphenamine.* Another ulcer reappeared four months later. Biopsy which had been taken in 1918 was reported fibrous tissue, no osteoblasts. Biopsy taken from the relapsing ulcer was reported nonspecific chronic inflammatory tissue. Two more arsphenamine injections were given with immobilization, and gradual healing then took place. Patient returned home. Three years later patient again returned to the clinic. Ulceration was then much larger than at any previous time. Small subcutaneous nodules and dimpling of the skin near the scar and elbow were found. A clinical diagnosis of hemangio-endothelioma was now made. Pathologic diagnosis from a small fresh nodule was reported as hemangio-endothelioma. Amputation at the middle third of upper arm was performed. Radium treatment was applied to the lymph nodes.

DISCUSSION

This lesion definitely originated in bone if the history can be trusted. The clinical characteristics include onset in childhood or youth, antecedent trauma, a very prolonged course, late metastases, and a slow invasion of all tissues, with necrosis of bone and formation of hemorrhagic necrotic ulcers. The serpiginous outline often suggests syphilis.

Pathologic examination of tissue from old ulcers shows little except granulomatous changes, associated with secondary infection. The diagnosis must be made from fresh cutaneous nodules as discussed in connection with Fig. 871 and on p. 710.

The response of what is fundamentally a malignant process to arsphenamine seems remarkable but undoubtedly occurred on this occasion in this case. Some improvement was noted in Fig. 871.

Fig. 617

(See Fig. 96 for illustration.)

GUMMA OF THE RIBS ILLUSTRATING TRAUMATIC ONSET AND DELAYED HERXHEIMER EFFECT IN BONE LESIONS

A man, aged fifty-two.

Examined 4/10/21

Chief Complaint Pain in the right chest at the site of a bruise.

History Injured by being thrown against a window ledge ten months ago, striking ribs on right side of chest. Soreness began one week later but continued work for one month. *x*-Ray taken, opinion given as "broken cartilage." Second *x*-ray opinion "blood-clot." Laid off from work five weeks. Pain and tenderness continued on breathing and pressure. A diffuse swelling the size of a hand appeared two or three days after injury. Lumps began to appear, softened, were lanced and drained, and packed with gauze. Blood Wassermann reaction taken one week ago was strongly positive. History of penile lesion thirty-four years ago. Mixed treatment for one year.

Examination *Subcutaneous, doughy induration of right eleventh and twelfth ribs and* intercostal spaces in the posterior axillary line. Ulcer 1 cm. in diameter with greenish slough. *X*-Ray of chest and ribs negative. Blood Wassermann reaction negative, but three plus two days later. Blood, urine, eyes, ears, blood-pressure all normal.

Consultant's Opinion Gummatous osteomyelitis of eleventh and twelfth ribs with sinus formation.

Syphilologic Examination

Wassermann series three strong positive in seven tests.

Spinal fluid negative.

Treatment *Mercurial therapeutic test* of ten injections of mercury succinimid, with definite improvement, pain and induration subsiding. *Arsphenamin* 0.2 to 0.5 gram, 6 injections. Discharge much increased with second arsphenamin injection. New sinuses, more induration, and more discharge with third arsphenamin. No marked improvement with fourth arsphenamin. Much drainage. Surgical exploration showed no changes in the ribs, and a diffuse doughy inflammatory infiltration, with much pus. Gland inflammatory. Four months later on mercury and potassium iodid, the lesion had completely healed. Marked weight gain. Spinal fluid negative. Blood Wassermann reaction now negative. Cardiovascular examination negative.

Discussion

1. This is a typical traumatic history in osseous syphilis.
2. Note that the pain and swelling do not begin for some days after the injury. The differential diagnosis included tuberculosis, which is not uncommon in this location, and carcinoma.
3. The mercurial therapeutic test was employed to differentiate the process from tuberculosis, which might have responded to arsphenamin.
4. Bone gummas, as in this case, frequently give a prolonged severe Herxheimer reaction with a steady increase in the severity of symptoms over three to five weeks. This may deceive the observer in a therapeutic test.
5. The Herxheimer reaction in this case was so prolonged that the syphilologist himself distrusted the result and called for a surgical exploration.
6. The fluctuating blood Wassermann reaction still further aroused a suspicion of non-specificity.
7. Six weeks to three months may be necessary to establish syphilis as the cause in cases of this type.

CHAPTER XVII

THE GASTRO INTESTINAL TRACT IN SYPHILIS

As W J Mayo has remarked, 95 per cent of patients who complain of trouble with the stomach have nothing the matter with the stomach. So in syphilis, the term syphilis of the gastro-intestinal tract" covers less than 5 per cent of the symptoms from the gastro-intestinal tract for which syphilis is directly or indirectly responsible. For purposes of clinical discussion, the subject is here differentiated into gastro-intestinal symptoms in syphilis and actual syphilis of the gastro-intestinal tract.

The Literature.—Contemplation of the literature which, especially in recent years, has burgeoned forth into wealth of contributions, at once gives the impression that syphilis of the gastro-intestinal tract is an affair of everyday occurrence. It offers an excellent illustration of the remarkable literary incrustation which accumulates about medical rarities t the expense of the commonplace and, for everyday practice, at least, far more important conditions. Hartwell has estimated that the literature on gastric syphilis as such contains approximately 200 reported cases. The increasing interest in the subject and improved diagnosis is rapidly extending the field, and experienced observers such as Eusterman are now demanding that every gastric lesion not indubitably malignant which is associated with coincident syphilis shall have the benefit of therapeutic test before operative intervention is permitted. Unquestionably such course as this will, especially in the field of gastric ulcer materially enlarge the recognized share of syphilis in pathology of the gastro-intestinal tract. The larger part of the accumulated literature deals with late manifestations, for the gastro-intestinal symptoms accompanying functional derangement conceivably traceable to lesions of the nervous system especially are relatively little understood. The particularly important contributions of the past decade include Wile's summary of the subject, the publications of Eusterman and Carman of the Mayo Clinic, of LeWald, the summary of the Continental literature by Gigon in the Jadassohn Handbuch, which contains practically no reference to the important American contributions, the contributions of Bensaude in the French literature, and the papers of Bockus and Bank, O'Leary Hartwell and Eusterman. The series of 93 cases from the Mayo clinic reported by Eusterman is the largest single group extant. Special aspects, including the association of duodenal ulcer with syphilis and particularly tabes have been presented by Hunt and Lisa and by Gougerot. *Spirochaeta pallida* is said to have been identified in 6 cases of syphilitic ulcer by Warthin, one of which has been reported. McNee found the organism in tumor mass in the stomach. Singer (1933) Williams and Kimmelstiel (1940) Freedberg and Barron (1940) have demonstrated the presence of other types of spirochetes in the gastric mucosa and glands but Harris and Morgan succeeded in proving the presence of *Spirochaeta pallida* by animal inoculation and transfer Gorham, in discussion of Freedberg and Barron, stated that bismuth therapy intramuscularly gave satisfactory results in gastric ulcerative lesions not of syphilitic origin, so that it is evident that syphilis of the stomach has its nonspecific margin of error in diagnosis by therapeutic test. Williams and Kimmelstiel stress the extensive phlebitis observed histologically as of differential importance. The histopathology has been fully considered by certain of the authors mentioned. Roentgenological criteria have been particularly analyzed by LeWald, Carman, and Moore and Aurelius. The literature of intestinal syphilis has been reviewed by LaGuardia, and Gigon gives an excellent summary of established conceptions. The gastroscopy of syphilis of the stomach has been dealt with by Schindler (1937), Moutier (1935) and in the American literature by Carey and Ylvisaker (1936) and Patterson, Rouse and Bagwell (1942)

Gastro-intestinal Symptoms and Lesions Associated with Syphilis.—In Fig 618 we have listed as completely as possible from our own experience and the literature the various manifestations of syphilis involving or alleged to involve the gastro-intestinal tract. Except for the functional disturbances and

Fig. 616.

GASTRO-INTESTINAL SYMPTOMS AND LESIONS ASSOCIATED WITH SYPHILIS

1. Neurosyphilitic concomitants.
   (a) Functional disturbances disappearing on treatment associated with symptoms of "neurosis" and abnormal spinal fluid.
   (b) Syphilitic dyspepsia and bulimia.
   (c) Duodenal ulcer associated with tabes.
   (d) Coelialgia.
   (e) Tabetic crises.
2. Syphilitic parotitis.
3. Syphilitic oesophageal secondary lesions, gummatous infiltration, and stricture.
4. Syphilitic cardiospasm ("achalasia," Hurst, Bockus and Bank)
5. Gastric hypochlorhydria—60 per cent of young adults with syphilis (Neugebauer)
6. Gastritis, acute syphilitic—during secondary period, rare.
7. Gastritis, chronic catarrhal—vomiting, achlorhydria, hypermotility therapeutic test positive, secretory function sometimes restored (Wile, Bockus and Bank).
8. Syphilitic idiopathic gastric hemorrhage (varices?)
9. Syphilitic solitary gastric ulcer (cases observed by Warthin, Blackford, Eusterman, Stokes, Gougerot, Bockus and Bank)
10. Syphilitic multiple ulcers—the usual manifestation of gumma of the stomach.
11. Diffuse syphilitic fibrosis ("syphilitic linitis plastica")
12. Duodenal ulcer in syphilis (existence unestablished)
13. Syphilitic duodenitis (Alvarez in discussion, existence unsettled)
14. Syphilitic enteritis.
15. Syphilitic jejunal infiltration and ulcers (Warthin, personal communication, MacCallum, Gutman, LaGuardia) The commonest form of the excessively rare intestinal syphilis.
16. Syphilis of the sigmoid and rectum—anal chancre, proctitis, solitary gumma, infiltrated syphilid (gummatous proctitis and periproctitis with stricture) anorectal elephantiasic syphiloma of Fournier

neurosyphilitic concomitants presently to be described, all the remaining items belong essentially in the category of rarities, some of them still unproved. Syphilis of the small intestine is among the rarest known lesions of the disease.

GASTRIC SYMPTOMS AND FUNCTIONAL DISTURBANCES ASSOCIATED WITH SYPHILIS

The demonstration of the direct anatomicopathologic link between the symptoms or signs of gastro-intestinal disturbance and the syphilitic infection often lacks completeness, and may be confined to proof of the presence of syphilis in the patient and the disappearance of his symptoms under therapeutic test.

It is essential to recognize the pitfalls of this *post hoc* type of reasoning which is nowhere more striking than in the controversy over the existence of syphilitic duodenal ulcer. No one with any considerable experience in the treatment of syphilis has failed to see examples of the striking symptomatic response of duodenal ulcers in syphilitic patients subjected to treatment for syphilis without, however, the slightest structural change apparent in the lesion, so far as it is roentgenologically recognizable. This controversy extends itself into the field of syphilitic etiology in solitary gastric ulcer and to the diagnoses of syphilitic enteritis and syphilitic ulcerative disease of the colon, sigmoid, and rectum. In a similar way one may ascribe "functional" gastric derangements to syphilis of the nervous system, as revealed by an examination of the spinal fluid, and note the recovery of the patient coincident with the return of the fluid to normal. But it must be conceded that none of these chains of reasoning has the merit of absolute conclusiveness. One group of observers has therefore taken the stand that only through tissue examination, and if possible, the identification of *Spirochaeta pallida* can a diagnosis of structural syphilis of the gastro-intestinal tract be substantiated. From this perhaps ultraconservative viewpoint a consistent breaking-away is now apparent as diagnostic methods improve; and observers such as

Eusterman can, as we have already noted, feel justified in the stand that properly performed therapeutic test carries very great weight in the diagnosis of syphilis of the gastro-intestinal tract. In the effort to solve the problem, the presumptive character of the reasoning must first be recognized the demonstration of the concomitant syphilis must be as complete as possible; an organic lesion must be searched for with the utmost thoroughness; and when such lesion is found it must be closely observed during treatment and its disappearance noted, provided the method of examination is capable of showing healing as distinguished from scar. Where operative intervention is justified on general grounds, an effort must be made to secure tissue from lesions and to demonstrate the presence of *Spirochaeta pallida*, recalling, of course, the necessity for special fixation in neutral formalin of tissues to be used for this purpose. Singer has reported, however the presence in a gastric granuloma and in gastric carcinoma of what he regarded as nonsyphilitic spirochetes, in the latter instance in association with fusiform bacilli. Every precaution against *nonspecificity must be thrown around any therapeutic tests which are undertaken, and this* applies particularly to the indiscriminate use of the arsphenamines in inflammatory and ulcerative lesions of the upper and lower intestinal tract, a number of which are known to give a definite nonspecific response to the use of these arsenicals. Only one method of treatment should be used at a time and each should be given sufficiently long trial under observation to assure the negativity of the result, or the permanence of any improvement. Particularly in decisions involving the diffuse infiltrative syphilids with fibrosis in the stomach, prolongation of the therapeutic test in the absence of contraindications or danger to the patient from neglected operation for operable carcinoma, is essential.

Gastric Symptoms of Early Syphilis.—Wile estimates that, in one third of the early cases of syphilis which he has seen symptoms from the gastro-intestinal tract were part of the clinical picture the incidence in women being higher than in men In McFarland and Stokes s series of 230 early cases there were gastro-intestinal symptoms in 7 per cent.

The instrumentality of these symptoms in confusing the clinical picture of early syphilis with that of tuberculosis in patients, especially young women, in whom no florid exanthem may appear has been commented on (Chapter XII). Indirectly a variety of factors in early syphilis may be responsible for gastro-intestinal phase that fills the whole symptomatic horizon, as in basilar meningitis with eighth nerve and vestibular involvement in secondary syphilis. Early serious involvement of the liver is usually accompanied by gastric symptoms, especially gastric hemorrhage *Anorexia, epigastric distress, and so forth, are associated with severe febrile syphilis* as with any acute infection.

As a rule gastric complaints in cases of early syphilis are a minor element, seldom elicited without questioning, and readily responsive to effective systemic treatment for syphilis (Fig. 435)

The question of direct involvement of the gastric mucosa in early syphilis is largely speculative. Wile states that erosions and hemorrhagic areas have been found at necropsy but the occurrence of roseola of the mucous membranes of the stomach has not been determined, although the demonstration of eruptive lesions in the bladder with secondary syphilis of the skin makes it strongly probable that similar lesion may appear on other mucous-lined viscera.

Functional derangements of the stomach as detected by the test meal rest, however on the well-established basis of Neugebauer s study of 200 patients with florid exanthems, in whom a hypo-acidity was demonstrated in 62 per cent and hyperacidity in only 17 per cent. Luna has found subnormal secretory values in syphilitic patients Dorne and Tumpeer found hypochlorhydria in 91 per cent of prenatally syphilitic children between 4 and *15 years of age.* This functional change is thus demonstrable in a large proportion of patients with syphilis at all stages.

Neugebauer points out that the hypo-acidity may occur without gastric complaint. Whether the condition is due to changes in vagus tone or to an actual lesion of the mucosa, as various

authors suggest, is uncertain, but the high incidence of neurosyphilis among patients with syphilis without cutaneous manifestations, who complain of stomach trouble, leads us to support the neurogenic view

Gastric Symptoms of Latent and Late Syphilis.—Inasmuch as gastric complaints make up no small part of consultant medical practice, Stokes and Brown undertook an analysis from Mayo Clinic records, of the meaning of "stomach trouble" in persons with syphilis, based on a cross-section of 200 patients with syphilis seen in the Section on Dermatology and Syphilology in 1920 and 1921 who gave this as one of their complaints. Eighty-seven per cent of them gave stomach trouble as their *chief* symptom. The following is a summary of this study which is still a practical résumé of the diagnostic relations of the problem of functional gastric symptoms in syphilis

Summary and Discussion of Symptoms and Treatment.—Of 200 patients with syphilis who complained of gastric trouble, 75 per cent had neurosyphilis, 20 (10 per cent) had organic lesions (syphilitic or nonsyphilitic) of the gastro-intestinal tract, 9 (5 per cent) had lesions of the heart, and only 8 (4 per cent) had true syphilis of the stomach. The remaining 6 per cent had miscellaneous functional abnormalities.

The history of syphilitic infection is unreliable. Men give such a history three times as often as women. Sixty per cent of the men and 70 per cent of the women in this series did not give histories of secondaries. Only two thirds of those with histories of infection were given a diagnosis in the primary stage.

In only 36 per cent of the whole series of patients was syphilis recognized before they came to the clinic.

The medical diagnoses made before examination in the clinic were apparently largely based on histories (90 per cent) and blood Wassermann reactions (65 per cent) After examination in the clinic the diagnoses were based most often on histories (60 per cent) spinal fluid examinations (59 per cent) and blood Wassermann reactions (44 per cent)

Only 10 per cent of the patients had had spinal fluid examinations before entering the clinic, yet the findings were positive in 59 per cent. This test deserves greater popularity

Only 44 per cent of the patients gave positive Wassermann reactions on the blood when they entered the clinic 56 per cent gave negative reactions, largely as a result of treatment elsewhere. The greater diagnostic importance of the spinal fluid examination is obvious.

Seventy per cent of the patients with persistently negative Wassermann reactions on the blood not due to treatment had positive findings in the spinal fluid.

Neurosyphilis is not excluded as a cause of gastric complaints by negative blood Wassermann reactions and negative findings in the spinal fluid. Of 32 such patients, 40 per cent had gastric crises with neurological evidence of tabes dorsalis.

We suggest that the seat of the lesion in patients with gastric crises and negative spinal fluid findings is in the vagus, the abdominal ganglia, and the sympathetic system.

Fifty per cent of 122 patients had hypo-acidity· in 38 per cent the findings were normal. Hyperacidity was rare. The findings practically coincide with those of Neugebauer in early syphilis.

Eighty-four per cent of the roentgen-ray examinations of 132 patients were

negative, and only 16 per cent of the patients had definite or doubtful syphilitic lesions revealed by roentgenograms.

"Gastric neurosis" and "functional stomach" are dangerous diagnoses if any suggestion of syphilis is present. In 50 per cent of such cases blood Wassermann reactions were positive, and in more than 50 per cent the spinal fluid findings were positive.

Eighteen per cent of the patients with gastric trouble had had needless operations, 80 per cent of the latter before entering the clinic. In all but 2 of 35 patients there were clues to the underlying syphilis, which were not followed, or a negative blood Wassermann reaction that had been accepted as final when other evidence of syphilis could have been found.

One third of the needless laparotomies were on patients with gastric crises (see p. 1141).

The extraordinarily misleading influence of syphilis in the production of operable complexes to serve as pitfalls for the unwary surgeon is nowhere better illustrated than in the domain of "stomach trouble." Much of the discredit reflected on abdominal surgery by operations for gastric crises, and on functionally disturbed stomachs, associated with neurosyphilitic paresthesias simulating chronic conditions of the gall-bladder and appendix, pancreatitis, and so forth, is the result of a merely symptomatic approach. Too much emphasis is laid on the patient's story; hasty or snapshot examination and consultation are accepted, and a low index of suspicion for syphilis sends the patient for operation without a routine serologic test and the elementary checkup of pupils, reflexes, and sensory changes that should be an invariable preliminary to any decision to operate on the abdomen. The positive blood serologic reaction is too often overridden or ignored. The surgeon should not ignore positive evidence of the presence of syphilis from whatever source unless obvious emergency or the question of operable malignancy is really paramount. Therapeutic tests can give so prompt and definite a result in many cases of gastric complaints in which there is no need to rush the patient to the operating table that there is no reason for not employing them under proper guidance.

In 100 cases in which patients remained for treatment of syphilis the results were gratifying. Seventy per cent improved and 43 per cent were relieved of their complaint.

Treatment for syphilis underlying a gastric complaint must be directed according to the special indications in the case and must not be merely general. Different methods will be required for underlying syphilis of the nervous system, the stomach, or the heart, for example.

We observed striking symptomatic improvement in certain cases of gastric and duodenal ulcer in patients with neurosyphilis in whom the roentgen ray after treatment, revealed the lesion itself to be still present.

The spinal fluid examination stands out from this investigation as a procedure of the highest importance, outranking the serum serologic reaction in diagnostic syphilology as applied to internal medicine. In all suspicious gastric cases it should, with a neurological examination and full investigation for syphilis, be used before and not after diagnosis.

ORGANIC SYPHILIS OF THE GASTRO-INTESTINAL TRACT

Syphilis of the Salivary Glands.—Giron states that Veillet in 1913 collected the 41 cases in the literature, 30 of which were examples of parotitis, 7 involved the submaxillary glands

and 6 the sublingual glands. Congenital syphilis of the salivary glands is excessively rare but the *Spirochaeta pallida* has been demonstrated in one case. Neumann collected 5 examples of the acute parotitis of congenital syphilis. Gigon distinguished the condition from the syphilitic examples of Mikulicz syndrome which, in his opinion, is not invariably syphilitic. Pain, functional disturbance hard, indurated gummatous mass, and possible formation of salivary fistula are among the symptoms. Ankylosis of the jaw articulation may occur The therapeutic test is the chief diagnostic reliance.

Syphilis of th Esophagus.—Fournier observed this lesion four times in 5000 cases and Gaston collected 40 cases from the literature in 1906. In the beautiful example which Stokes had the opportunity to observe on Wile service, the process was evidently continuous with gummatous interstitial glossitis producing characteristic scarring of the tongue. Stokes has also observed 3 cases of stenosis apparently of syphilitic origin. The lesion presents nothing morphologically distinctive, though identification of gastric syphilid may assist in the diagnosis Esophagoscopy is responsible for the recognition of number of lesions of the esophagus, including some characteristic of the secondary stage of the disease, and this form of examination is stated by Gigon to be preferable to roentgenization. Gummatous cases are occasionally observed in conjunction with mediastinitis with the formation of fistulae, including tracheal fistula. Kampmeier and Jones (1941) reviewed the literature and reported 4 cases, with diaphragmatic involvement.

Acute Syphilitic Gastritis.—Syphilitic gastritis, usually regarded as one of the types of late syphilis of the stomach, is clinically so ill-defined that it is lost in the group of cases, already considered, of latent syphilis with gastric symptoms, but no roentgenologically demonstrable lesion of the stomach.

Eusterman states that, in association with gummatous syphilids of the stomach, pathologic changes of benign catarrhal gastritis are not uncommon. The clinical proof of the existence of the lesion must be its response to treatment, and when this is undertaken without adequate control, especially of the neurological factor It is difficult to determine just which of the gastric cases without organically demonstrable lesions should fall into the gastritis group.

Syphilitic Chronic Catarrhal Gastritis.—*This condition, considered by number of observers* as an early stage of diffuse gastric syphilis, is indistinguishable from gastritis associated with such conditions as chronic alcoholism or hepatic cirrhosis. It responds, often surprisingly to treatment and sometimes with partial or complete restoration of acid secretory function, even though absent to histamine test before treatment was begun (Bockus and Bank).

Gastric Hemorrhage in Syphilitics.—I general, syphilitic lesions of the stomach do not bleed readily the nature of the pathologic process with its obliterative endarteritic changes tending to prevent this. Sudden hemorrhage from the stomach is known, however, to occur in syphilitic patients without the presence of demonstrable lesion, though the presumption, of course, is alw ys in favor of varices associated with splenic or hepatic changes as the cause. Such sudden hemorrhages have been observed after treatment in patients without apparent stomach lesions (p. 408).

Late Syphilids of the Stomach.—Diffuse gummatous infiltration, nodulo-ulcerative lesions, with single or multiple ulcers, especially the latter essentially homologous with the nodulo-ulcerative late lesions of the skin and mucous membranes and often strikingly resembling them in configuration, are well recognized. Larger solitary gummas are also known to occur Diffuse syphilitic fibrosis such as one observes in parenchymatous organs, may also involve the stomach, giving rise to the clinical pictures confused with scirrhous carcinoma of the stomach and with "linitis plastica," whose syphilitic form was described by Singer In the tissues immediately surrounding the stomach, perigastritis with adhesions and inflammatory probably gummatous, lymphadenitis may occur

Syphilitic Solitary Gastric Ulcer—In the first edition of this work, Stokes somewhat timidly called attention to a group of 10 per cent of the Mayo Clinic cases in which clinician and roentgenologist united on the diagnosis of non syphilitic gastric ulcer Because it had become more or less routine in the *Mayo Clinic to subject patients with syphilis to treatment before operation,* he was able to prove these lesions to be syphilitic gastric ulcers by therapeutic

test before operation. The possibility of nonspecific effect was not at that time considered The process of opinion, while unanimity is by no means reached, has tended more and more to bring forward this possibility as one of practical importance in diagnosis. The earlier estimates of Ewald and Fenwick of 5 and 10 per cent as expressing the etiologic influence of syphilis in typical round

Fig 619

CLINICAL CHARACTERISTICS OF GASTRIC SYPHILIS

After Eusterman, Stokes, O'Leary Bockus and Bank

1 A rarity—69 cases in 25,000 syphilitic patients (O'Leary); 8 in 8000 cases of digestive tract disease (Moutier) More frequent as better understood. Largest series, Mayo Clinic, Eusterman 93 cases.
2. Men 70 per cent, women 30 per cent.
3. Age period thirty-six years in contrast to verage ulcer age of forty-five and cancer age of sixty-four years (Eusterman)
4 Averag duration of symptoms, two years.
5 Course progressive not intermittent, except t onset.
6 Four types: (1) epigastric pain or discomfort immediately after eating from the start made worse by solid food, 65 per cent, (2) pseudocancer group (15 per cent) gradual onset, mild, later pain, no food or alkali relief; (3) ulcer type (23 per cent) "pain-food-ease syndrome slightly atypical throughout course (4) no symptoms (history unreliable?).
7 Preservation of appetite or ravenous in contrast with cancer anorexia.
8. Patient not ill or emaciated i proportion to the extent of roentgenographic change or duration of clinical symptoms (Eusterman); (especially in diffuse syphilitic fibrosis, Bockus and Bank)
9 Achlorhydria, achylia (even to histamine) subacidity (Eusterman); normal or even high acid values in pyloric stenosis (primary retention) and gastrojejunal ulcers (Bockus and Bank)
10. Evidence of low gastric capacity (stomach inelastic) sense of fulness or bursting, ability t eat only small amounts, relief by vomiting.
11 Retention infrequent. Pylorus may be patulous and stomach empty rapidly (Eusterman, LeWald)
12. Hemorrhage uncommon (Eusterman) but absence not absolutely reliable differential point (Bockus and Bank)
13. Anemia mild, less frequent (10 per cent) e marked than in carcinoma.
14. Gastroscopic study reveals diffuse infiltrative nd ulcerative types of lesion ith fairly definit characteristics.
15 Doughy tender palpabl plastic infiltration rather than localized tumor suggestive. Presence or absence of tumor however not diagnostic (Stokes, Bockus and Bank).
16. Collateral evidence of syphilis symptoms and signs 27 per cent positive blood Wassermann reaction 92 100 per cent (Eusterman, Stokes, Bockus and Bank) spinal fluid Wassermann positive 11 per cent (O'Leary)
17 Therapeutic test rapidly and convincingly positiv in localized gummatous ulceration (improvement in t eeks) slower in diffuse infiltration (six weeks upward).
18. Essential features of positive test slow (sometimes spectacular) gain in weight, increase in food capacity decrease in anemia (O'Leary) Roentgenologic improvement may appear later

ulcer of the stomach have been regarded as an overestimate though Smithies has recently given 8 per cent as his personal impression of the proportion of round ulcers which are syphilitic in origin. Individual cases have been reported by Blackford, Eusterman and Bockus and Bank. Gougerot states that he has observed the condition repeatedly and Warthin is quoted as having found *Spirochaeta pallida* in 8 cases, one of them reported Bockus and Bank give

as important points favoring the diagnosis of syphilitic round ulcer the following

1 Failure of ordinary ulcer management.

2. The symptomatic relief marked weight gain and disappearance of anatomic defects following antisyphilitic treatment.

3 The presence of multiple roentgen-ray defects (*i. e* deformities other than and in addition to the gastric ulcer niche)

4 The lack of difference symptomatically from simple peptic ulcer except for a tendency toward greater weight loss.

5 The fact that gastric acidity is not necessarily altered.

Syphilitic Multiple Ulcer.—This, with diffuse syphilitic fibrosis, is the common picture of structural late syphilis of the stomach as comprised in the commonly used term "gastric syphilis." In Fig. 619 we have summarized from the literature the clinical characteristics emphasized in the larger reported series and in Fig 620 the roentgenological characteristics as worked out by Carman, LeWald, Moore and Aurelius, and Bockus and Bank, among other observers.

Fig. 620.

THE ROENTGENOLOGICAL CHARACTERISTICS OF GASTRIC SYPHILIS

After Carman, Moore and Aurelius, Bockus and Bank, LeWald, et al.

1. Filling defect of gastric outline, often but by no means always without corresponding palpable mass (presence not infrequent, LeWald)
2. Location, prepyloric 70 per cent; median or dumbbell (hourglass constriction) 22 per cent, diffuse 8 per cent.
3. Majority of lesions concentric or symmetrical (carcinoma eccentric)
4. Upper loculus may be tubular due to concentric extensive contraction.
5. Diminished gastric capacity with almost immediate evacuation of stomach (Carman, LeWald).
6. Six hour barium retention less common (15–40 per cent) than in carcinoma.
7 Lesion disproportionately extensive for ( ) general condition of patient (b) diagnosis of simple ulcer ( ) diagnosis of carcinoma.
8. Presence of multiple defects here symptoms are those of solitary gastric or of duodenal ulcer (Bockus and Bank)
9 Stiffening and lessened pliability of the gastric wall.
10. Absence of peristalsis from the involved area.
11. Compensatory dilatation of the esophagus in dumbbell types (Carman, LeWald)

W should like t this point to pay tribute to the remarkable and, in fact, unique cooperative work of Eusterman and Carman. The clinical observations of the former, and the roentgenologic acumen of the latter brought the diagnosis of gastric syphilis to an extraordinary level of accuracy and have made it seem essentially work of *supererogation to review the large* experience of the Mayo Clinic with gastric syphilis except by citation of their findings, methods and results. Stokes has, however ventured on summary of *25* cases in which the section on Dermatology and Syphilology had been called on to manage the actual treatment, or the therapeutic differential diagnosis, with view to orienting the problem from the syphilological standpoint.

It should be understood that multiple ulceration and diffuse gummatous infiltration of the wall of the stomach with cicatricial repair give rise to distortions of the gastric contour and to clinical symptoms which, in the main, are pathognomonic in their diagnostic value. As the experience of roentgenologists and clinicians with the condition increases, the accuracy of diagnosis and the positiveness of statements made in the literature as to the value of individual criteria steadily increase The critical issue for the patient is, of

course the differentiation of syphilis from cancer of the stomach. In order to examine this differential problem personally from the syphilological standpoint a cross section of 55 Mayo Clinic cases were reexamined with especial reference to diagnostic and differential considerations. This material still presents, in conjunction with Fig. 619 all of the essentials of the problem as we understand it today

DIAGNOSTIC AND DIFFERENTIAL CONSIDERATIONS BASED ON THE CROSS SECTION OF 55 CASES

The 55 patients who serve as the basis for the ensuing discussion of the diagnostic syphilology of gastric syphilids were referred to the Section on Dermatology and Syphilology either with diagnoses fully made by the cooperative work of the Eusterman and Carman groups in the clinic, or for therapeutic investigation when the diagnosis had reached an impasse. There are, however a few patients included in the series who were referred routinely because syphilis had been discovered in the examination, and others in whom surgical intervention had already been carried out with the finding of evidence which made further consideration of syphilis necessary The records were taken at random from the files. The opinions quoted are those of the gastroenterological consultants under Eusterman, the roentgenological consultants under Carman and

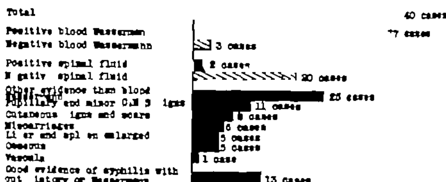

Fig. 621.—Collateral evidence of syphilis in 40 patients with gastric syphilids.

Moore, occasional surgical opinions, and the observations of the staff of the Section on Dermatology and Syphilology of the Mayo Clinic.

Of 55 patients studied, 40 had gastric syphilis, 13 carcinoma, 1 fibroma of the stomach, and 1 duodenal ulcer with false positive therapeutic test. No absolute sex predominance was apparent. Only 33 of 55 patients had had adequate histories taken with regard to venereal disease, a point on which improvement is possible. A high proportion of these 33 cases yielded positive histories of syphilis, a fact which always arouses some question as to whether the diagnosis is not being influenced too much by this rather untrustworthy criterion. It should be noted that in more than half of the 14 neoplastic cases there was likewise a history of syphilis, which explains most of the suspicion that led the patients to us. Forty of the 55 patients in the group proved, after the fullest possible study, to have gastric syphilis. The collateral evidence for syphilis in their histories is summarized in Fig. 621

The Wassermann Reaction.—The remarkable worth of the positive Wassermann reaction as a guide to gastric syphilis is certainly suggested by its presence in 37 of 40 cases. False positive blood Wassermann reactions in cases of cancer of the stomach are so unusual in our experience as to be of negligible importance. Eusterman and O'Leary have, however, both stressed the existence of seronegative cases. A single negative test cannot be trusted.

A conservative technic was used in most of these cases. The three negative reactions represent: (1) A case in which there were unmistakable residua of a severe rupial syphilid and scarring with bone destruction in the palate and pharynx; (2) a case in which the pathologic finding on tissue obtained at operation was a granuloma with vascular changes suggesting syphilis; and (3) a case of leather-bottle stomach in which, it must be admitted, little hope of establishing the diagnosis of syphilis existed, since the patient was a woman and the lesion not one which might be expected to respond to treatment.

The Spinal Fluid.—The remarkable immunity of the nervous system in cases of true visceral syphilis is substantiated by the very low proportion of cases in which the spinal fluid was abnormal—2 of 20 cases of gastric syphilis. O'Leary in a more recent survey found 11 Wassermann positive spinal fluids among 89 proved cases. The minor neurological signs did not appear to be the expression of an active neurosyphilis at the time of the gastric lesion.

Other Collateral Evidence of Syphilis.—The character and proportions of the general clinical evidence for syphilis are sufficiently indicated in Fig. 621

COMPARISON OF THE SYMPTOMATOLOGY OF GASTRIC SYPHILIS AND CARCINOMA (SYPHILIS PRESENT)

Figure 622 summarizes in percentages seven important points in the symptoms and findings of gastric syphilis, and compares them with those in cancer

1 Gastric Chemistry —Hydrochloric acid secretion is low in the overwhelming proportion of cases of gastric syphilid. Bockus and Bank, however believe that such a finding must be interpreted in terms of the type of syphilitic process under discussion and cannot be universally applied. There was no free hydrochloric acid in 82 per cent of the syphilitic stomachs in this series,

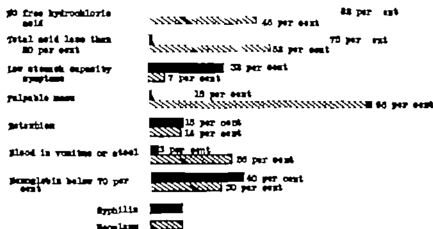

Fig. 622.—Résumé of findings in 54 patients with actual or suspected gastric syphilids.

as against 46 per cent of the small group of cases of cancer suspected of being syphilis. Total acidity is low in only a slightly smaller percentage. While the importance of subacidity is evident, normal and even high acids are not incompatible with a syphilitic gastric lesion A hyperacidity of free hydrochloric acid 84 combined 24 total 108, after six weeks of arsphenamine and mercury was reduced to free hydrochloric acid 20 combined 30 total acidity 50 Subacidity in the presence of a syphilitic lesion of the stomach likewise responds to treatment in some cases, an acidity of free hydrochloric 0 combined 20 total 20, increasing to free hydrochloric 20, total 50 and again to free hydrochloric 16, total 34

Achylia is evidently common and is more or less suggestive of syphilis of the stomach. Eusterman noted it in 80 per cent of the cases he studied

2. Gastric Capacity —This was interpreted in terms of symptoms suggestive of rigidity and loss of distensibility of the stomach (feeling of bursting with small amounts of food, ability to eat only small amounts without regurgitation or vomiting, and so forth) and appears, as Eusterman and Carman have both noted, in 26 per cent of cases of gastric syphilis.

3 Palpable Mass.—Emphasis is laid on this point in Eusterman's and Carman's differentiation of gastric syphilis and cancer on the basis of clinical findings. As Carman points out, the mass, if present, should correspond to the filling defect as seen with the fluoroscope and a filling defect with nothing palpable is strongly suggestive of syphilis. On the other hand, the criterion is not infallible and if too much relied on, may lead to error The present tendency in the literature is to give it less stress. One patient in this series with a palpable ridge was given a diagnosis of carcinoma 75 per cent, syphilis 25 per cent. There was complete symptomatic recovery under treatment, during more than four years of observation A second patient, with a palpable mass, diagnosed carcinoma, made a complete symptomatic recovery with marked objective improvement, as shown radiologically under treatment for his syphilis. A palpable ridge or mass is, of course easily possible anatomically in cases of solitary gumma of the wall of the stomach, and an impression of a mass may be given by infiltrations with perigastritis.

4 Retention.—Retention is commonly considered to be suggestive of carcinoma it occurs nevertheless in about 15 per cent of cases of gastric syphilis, as it appears in this cross section. The grade of obstruction was usually moderate, being severe in only 1 case.

5 Hemorrhage.—A history of hemorrhage, melena, and the presence of blood in vomitus, washings of the stomach, and in the stools, as detected by guaiac and benzidine tests, is definitely more distinctive of carcinoma than of syphilis. This is in accord with the general picture presented by the syphilitic ulcer in all parts of the body Obliteration, with anemic ulceration, not erosive invasion of vessels with hemorrhage, is the distinctive feature of the pathology of the syphilitic lesion.

6 Anemia.—This condition is often spoken of as more marked and of more rapid onset in carcinoma than in syphilis of the stomach. It is not the *lowness of the hemoglobin* which may be marked in syphilis, but the *lowness in proportion to duration of symptoms* that is significant of cancer

7 Loss of Weight.—Eusterman, Carman Bockus and Bank and others emphasize the significance of the good condition of the patient in proportion to the duration of the trouble, in swinging the diagnosis of a gastric lesion toward syphilis. Eusterman speaks of patients with gastric syphilis as thin, but not cachectic, which describes most cases. The loss of weight with gastric syphilis is, however pronounced, and the comments passed on the appearance of the patients in the records of our cross section suggest that caution must again be used in the application of this criterion A distinction seems to lie in the rate of weight loss which in our patients with gastric syphilis averaged 34 pounds in twenty four months or 1 4 pounds each month, and in those with carcinoma suspected of being syphilis, 24 pounds in ten months, or nearly twice the rate in syphilis. In spite of these differences, however there were some really astounding losses of weight and cachectic emaciations among the patients with gastric syphilis, some of them being positively cadaverous in appearance. Too much emphasis should not, therefore be placed by the inexperienced on this criterion in diagnosis.

Roentgenological and Clinical Opinion before Treatment.—To us the outstanding fact from the summarized consultant opinions is the high proportion of actual diagnoses made by the roentgenologist (55 per cent), usually without the aid of the clinical history and findings, and the high total accuracy of diagnosis by cooperative methods. Seventy five per cent of patients

were given correct diagnoses outright before they were sent to the syphilologist for treatment, and in only 17 per cent was carcinoma given the greater weight of probability when the condition proved to be syphilis. The advantage possessed by the clinician in his knowledge of the whole story was apparent (55 vs 75 per cent) likewise the greater tendency of the roentgenologist to diagnose carcinoma or be noncommittal (32 vs. 20 per cent) In view of the greater seriousness of carcinoma for the patient, this tendency is desirable rather than otherwise.

Gastroscopic Appearances.—These are usually recognizable earlier and persist longer than the roentgenographic findings. *Early syphilis* —F W Reynolds describes a superficial gastritis as occurring in early syphilis. This would be susceptible of gastroscopic study He mentions in addition the occurrence of an interstitial infiltration of the submucosa and muscularis with thickening of the wall and stenosis of the lumen—a form of precocious tertiarism *Late syphilis* —Moutier describes three types of late gastric syphilis: (1) the tumor form (gummatous) healing with scar formation (2) the ulcerative forms—single or multiple which lead to scarring and hourglass stomach. Schindler and Patterson, Rouse and Bagwell describe these ulcers as having a characteristic gastroscopic appearance—they are usually situated in the lower third of the stomach, have a smooth shallow yellow base, livid, purplish red serpiginous borders, comparable to the late mucous membrane manifestation *e g* in the mouth. The lack of the normal red color is due to the underlying obliterative vasculitis of syphilis. Howles (1943) has a series of color plates. (3) Generalized infiltrative gastritis which leads to linitis plastica.

Types 1 and 3 are the most difficult to differentiate gastroscopically from similar lesions of different etiology; they tend, however to show a prominence of superficial blood vessels on the borders of the lesions with a pale mucosa. There is a flattened thickened appearance of the rugae with flexibility of the stomach wall remaining In many instances the tendency to narrowing of the antrum in the diffuse fibrosis of gastric syphilis can be observed gastroscopically The lumen is difficult to distend by inflation. Complete resolution can be observed after effective antisyphilitic therapy

OTHER GASTRODUODENAL LESIONS

Associations of Duodenal Ulcer with Syphilis.—Many interesting problems await fuller study in the association of duodenal symptoms with syphilis. There seems no reason *a priori* why syphilis should necessarily exempt the duodenum. Alvarez (in discussion of Bockus and Bank s paper) calls attention *to the differences between the pyloric and the duodenal mucosa from the metabolic* standpoint, but states that he has had reason to suspect in young subjects the existence of such a condition as syphilitic duodenitis. Mortimer reviewing the literature brings out the accepted view in the literature that syphilis of the intestinal tract tends to concentrate at the jejunum and reports a case apparently of duodenal syphilitic infiltration with palpable mass, and a satisfactory therapeutic test. Eusterman, and we ourselves, have been obliged to maintain that we have never seen an authentic and unquestionable case of duodenal syphilis, and particularly of duodenal ulcer convincingly syphilitic in origin. Bockus and Bank in their discussion of primary retention associated with syphilis of the stomach, mention the similarity in symptomatology be-

tween duodenal ulcer and this group of syphilitic abnormalities in gastric syphilis. In their discussion of duodenal ulcer they observed 7 syphilitic patients with typical duodenal defects, 4 of whom sustained relief from antisyphilitic treatment. In the first edition of this work Stokes reported also having observed the often striking relief of symptoms (see Fig. 627) which syphilitic patients who are duodenal ulcer bearers sustain under treatment for syphilis. He was unable, however to be convinced that the effect was necessarily specific, though he mentioned the possibility of a response associated with improvement in syphilis of the nervous system in a definite group of duodenal ulcers in tabetics to be presently discussed. Bockus and Bank, while recognizing the very great difficulty of distinguishing between syphilis with intercurrent duodenal ulcer and duodenal ulcer due to syphilis, suggest as possible criteria for a syphilitic etiology in duodenal ulcer the following

1 Presence of other roentgen ray deformities in addition to the bulbar defect.

2. Association of achylia gastrica with duodenal ulcer This condition is so rare that it should at once attract suspicion. Two of their patients had achlorhydria.

3 A marked improvement in the duodenal ulcer defect after antisyphilitic treatment. They have had one such case. The occurrence of such a group of findings in a Negro with syphilis seems to them strong presumptive evidence in favor of the syphilitic nature of the process. We may say from our personal experience that the general effect of rest and of the tonic action of properly conducted antisyphilitic treatment may be striking, so far as the symptomatology of duodenal ulcer is concerned and that reliance must be placed almost entirely on objective criteria in judging of the validity of a therapeutic test. It is precisely at this point that the therapeutic tests that we have conducted in duodenal ulcer associated with syphilis have failed.

A type of association between syphilis and duodenal ulcer to which attention was called in the first edition of this work is that between gastric and duodenal ulcer and tabes dorsalis. Hunt and Lisa who have reported the most recent series of cases exhibiting this association, say that it is uncommon. Crohn in this country and Roux, Carnot, and Bruyere have interested themselves in the problem. Hunt and Lisa reached the conclusion that the association does not represent, as might be thought probable, a trophic type of ulcerative change in the gastric or duodenal mucosa associated with a neurosyphilis. On the other hand, the coincidence remains to be explained Camp, in discussion of Hunt and Lisa's paper had been impressed with the fact that hemorrhage occurring in what appears to be a gastric crisis might or might not be, and certainly was not necessarily an evidence of the concomitant presence of ulcer He described a case of fatal hemorrhage in a tabetic for which no clinical cause whatever could be found and stated that in his experience the vomiting of small or even larger amounts of bright blood was not necessarily a rarity in gastric crisis Oppenheim and Hunt and Lisa believe hemorrhage in gastric crises to be an exceptional occurrence

Udaondo, Casteigs and Gonalons have called attention to the occurrence of tabetiform gastric crises in the course of gastroduodenal ulcer These, according to their description, are painful attacks attributable to the ulcer but bearing a marked resemblance to the gastric crises of tabes dorsalis. The differential diagnosis requires, of course the elimination of tabes by thoroughgoing physical and serological examination, together with appropriate analysis of

the gastric and duodenal secretions and roentgenological study These authors consider the gastric crises of tabes a neuritic lesion of the general type of solar neuralgia.

It is apparent, then, that gastroduodenal ulcer symptomatology particularly with coincident syphilis of the nervous system, requires painstaking investigation of the individual case to distinguish the various possibilities involved.

Syphilitic Linitis Plastica.—O'Leary following Lyon s work in the study of 38 cases at the Mayo Clinic with 25 postoperative studies, has emphasized the undesirability of this term inasmuch as linitis plastica is, historically at least, a term first applied to the clinical picture of the small-cell carcinoma of the stomach wall with diffuse infiltration Gigon states that the term is very properly disappearing from the literature. In Lyon s series, only 1 case of leather-bottle stomach was demonstrably syphilitic in origin. The morphological homologue of true linitis plastica is produced by diffuse syphilitic gastric fibrosis, the sequel of diffuse gummatous infiltration. It produces a thick walled tube or funnel-like stomach, inelastic and relatively rigid with patent pylorus, only in occasional cases, however stenosed. Secondary dilatation of the esophagus may occur In the differentiation of syphilis from other causes of this gastric lesion therapeutic test is of comparatively little assistance, for the fibrous changes respond only to a slight degree, if at all, to even prolonged treatment for syphilis. Exploration and operative intervention are therefore usually the only resort. Even in cases in which improvement occurs following treatment, ultimate operation may be unavoidable. Gastrectomy in these cases, if the patient lives long enough is apt to lead to symptoms of pernicious anemia which, as in the case reported by Poole and Foster (with review of the literature) was successfully controlled by liver extract and desiccated hog stomach.

THE TREATMENT OF GASTRIC SYPHILIS

Technical Methods.—In no domain of syphilotherapy unless it be in tardive heredosyphilis, do greater therapeutic satisfactions await one than in the management of gastric syphilis. Fortunately the difficult combinations of a visceral lesion with involvement of the vascular and nervous systems are unusual in cases of gastric syphilis, so that the problem of treatment is usually greatly simplified Unless the process is extraordinarily chronic and involves the most extensive fibrotic transformations the results are often prompt and astonishing. O'Leary however in summarizing the therapeutic tests at the Mayo Clinic, points out that gradual, steady recovery especially with weight gain and rise in hemoglobin may be even more characteristic of the response of a gastric syphilis than the spectacular recoveries of patients with sharply localized lesions. It is practically never necessary to prepare a patient who has an uncomplicated gastric syphilis with heavy metal or iodide. Arsphenamine or if the patient is much reduced and weakened, neoarsphenamine, initial dose 0.2 to 0.3 Gm. often produces first of all an immediate cessation of pain After the second injection in which a normal dose by body weight may be used, the patient is often astonished at his ability to eat all but the most indigestible foods without distress. This change may even take place within the first week after he begins treatment. The usual arsphenamine course of 6 to 8 injections alternating with bismuth or with mercury by inunction is well tolerated by most patients, and the case should, from this point on, be managed as late benign syphilis, giving a minimum of 3 courses of ars

phenamine with interim and coincident heavy-metal therapy Mercury by mouth is undesirable, and there is no occasion to use iodides, especially at the beginning of treatment. Bockus and Bank found them both inferior to neoarsphenamine and bismuth Gains in weight and well-being are phenomenal, as will be shown, and objective improvement demonstrable with the roentgen ray is common (Fig 625) Roentgenographic changes are, however not necessarily parallel to clinical improvement, and the most striking clinical gains may be secured with little or no apparent change in the fluoroscopic picture.

Residual Damage Structural Recovery—Residual damage produced by a chronic syphilid of the stomach interferes with recovery in two ways by the mechanical obstruction produced, as by strategically situated lesions in pyloric stenosis and by fibrotic changes in the walls of the stomach with shrinkage and reduction to ultimate functional incapacity as in cases of syphilitic linitis plastica or leather bottle stomach. Here again, however clinical estimates made before treatment of the amount of improvement possible may err and patients with supposedly little prospect of improvement on account of fibrosis, may nevertheless achieve excellent results. A badly strictured, hourglass stomach in one patient may pass enough soft food and liquids to permit of marked gains, while in another practically no progress will be made until a dilation or gastro-enterostomy relieves the situation. Strictures of the stomach may in certain cases be effectively dilated with the bougie and thread, as, for example, in Fig 630 in which postmortem examination after influenza revealed a stricture still so small that a lead pencil would scarcely pass, although following dilation the patient had been able to take solid food including meat, for months. A small proportion of patients with gastric syphilis continue in spite of apparent structural recovery to be subject to slight inconvenience on eating the less digestible foods. Others, whose stomachs are markedly contracted may be obliged to eat small amounts frequently but will have no symptoms if this precaution is taken.

Functional Recovery Gastric Chemistry—A certain amount of functional as well as structural restoration occurs in the stomach after treatment, as is evidenced by return to approximately normal chemistry from low or even from high acid values. This probably accounts for the completeness of many symptomatic recoveries in patients who had exhibited marked disturbance of gastric chemistry in association with structural changes

Delayed Response—The immediacy of the good result of treatment in gastric syphilis has been spoken of as one of its most striking features. Occasionally however patients improve more gradually but none the less certainly and after from six months to a year or even more are restored to normal, *although at the outset the gain may not have been marked*. This retarded therapeutic response should not be too hastily construed within the first three weeks as a negative result (Fig. 632) in patients who are undergoing therapeutic tests for gastric syphilis in the face of signs suggesting *inoperable* carcinoma. (The problem of *operable* carcinoma is entirely different.)

Summary of Results.—The results obtained in the management of gastric syphilis are summarized in Fig. 623 It is apparent that ultimate symptomatic results are excellent in as high as 50 per cent, and good and excellent in as high as 75 per cent of the cases. Therapeutic results rated as good or excellent were obtained in 10 of 24 cases about 41 per cent, without any change in the radiogram. Practically complete recovery both clinically and roentgenologically was secured in 8 cases (30 per cent)

Weight Curve.—The weight curve of the patient under treatment for gastric syphilis presents some of the most remarkable examples of rapid gain to be found in the whole field of medical practice Part of the effect is to be attributed to the tonic action of the treatment, and not merely to a restoration of gastric function to normal for the total gain often exceeds by 10 to 15 per cent the greatest weight the patient had ever reached. In such cases there is usually a gradual decline to a point slightly above previous normal weight after treatment is stopped. Our best example is that of a patient with a loss of weight of 88 pounds extending over four years, who gained 83 pounds in six months 22.5 pounds the first three weeks, more than a pound a day· 42 pounds in forty-two days, 69 pounds in seventy days, and the balance of 16 pounds in the remaining one hundred and ten days.

All the patients with gastric syphilis in this series gained some weight under treatment. Fifteen ultimately gained more than 30 pounds each. The average weekly gain during the first course was, in most cases, from 1.5 to 2.5 pounds.

Fig. [illegible].

THERAPEUTIC RESULTS IN LATE GASTRIC SYPHILIS

	Results.					
	None.	Slight.	Fair	Good.	Excellent.	Total cases.
Immediate symptomatic improvement in gastric syphilis during the first course (six weeks)	0	6	7	11	5	29
Ultimate symptomatic improvement in gastric syphilis (one to three years of treatment)	0	3	5	11	19	38
Structural improvement shown by ray in gastric syphilis	10	0	4	4	6	24
Symptomatic improvement in cancer suspected of being gastric syphilis.	4	2	3	0	0	9

The blood serologic reaction proved to be resistant in 14 of 36 cases, was reversed to negative in 4 and in 18 treatment had not been carried far enough to permit classification. It is in line with our general experience to expect the blood serologic reaction to be difficult of reversal in cases of visceral syphilis even without complications in the cardiovascular and nervous systems. We have never in gastric cases made the reversal of the blood serologic reaction a major therapeutic aim if it remained positive after the third arsphenamine course, 300 inunctions, and iodide, provided it was the only remaining evidence of active disease.

THE THERAPEUTIC TEST IN SUSPECTED GASTRIC SYPHILIS AND CARCINOMA OF THE STOMACH

The decision to carry out a therapeutic test for syphilis in the presence of an organic gastric lesion, the skilful conduct of the procedure, and the correct interpretation of the result are often a life and death matter Not infrequently

it is the only means, short of surgical exploration, of establishing a diagnosis. It must at times be insisted on by the clinician against the advice of the surgeon On the other hand there are times when the operability of the patient would be lessened by the least delay or when operability itself is actually in question when the surgeon should make an exploration before treatment is undertaken. The following tabulation (Fig. 624) summarizes the cases in this series in which the therapeutic test was of critical importance

Fig. 624

	Cases.
SUSPECTED CARCINOMA PROVED TO BE SYPHILIS	
Clinically or roentgenologically diagnosed definitely as cancer but proved to be syphilis by therapeutic test	3
Clinically or roentgenologically diagnosed definitely as cancer explored, and found t be syphilis	4
Clinically or roentgenologically diagnosed probably cancer but proved to be syphilis by therapeutic test	3
SUSPECTED SYPHILIS PROVED TO BE CARCINOMA	
Clinically diagnosed probable syphilis, but proved to be neoplasm by negative therapeutic test and exploration	1
Clinically diagnosed possible syphilis, proved to be cancer by negative therapeutic test and outcome	5
Clinically diagnosed possible syphilis with apparently positive therapeutic test, proved at operation t be cancer	2
BENIGN SIMPLE ULCER PROVED TO BE SYPHILIS	
Clinically or roentgenologically diagnosed as peptic ulcer proved to be syphilis by therapeutic test (one recovery symptomatic, three both symptomatically and by -ray)	4

Nonspecificity Factor—The question of the specificity of a therapeutic test for syphilis in a patient who may have carcinoma or other form of infiltrative or especially ulcerative lesion in which Vincent or other spirochetosis may be a factor (Singer Gorham discussing Freedberg and Barron) is one of special importance It will be noted that in 2 of 7 cases in which this question was confronted a sufficiently marked improvement in a case of carcinoma was obtained to lead to the temporary diagnosis of syphilis, later reversed by the finding at operation when the patient finally began to decline again (Figs. 634 635) Moreover in Fig 624 it will be seen that slight and fair improvement was made in 5 patients with cancer The tonic effect of the arsphenamine, which it is essential to use if a rapid effect is to be obtained before operation, may evidently therefore give rise to confusing improvement in some cases, especially in slow-growing scirrhous carcinoma and in other types of cancer in patients who also have syphilis. In view of this element of uncertainty in the therapeutic test, when used for differentiating gastric syphilis and gastric cancer we have been led to advise the preoperative administration in operable cases of 2 injections of arsphenamine 0.3 Gm. each with a three-day interval. If improvement within seven days is not very pronounced and if the operability of the patient may be decreased by further delay an exploration should be performed Complete disappearance of most symptoms will often occur within from seven to ten days after this amount of treatment for a gastric syphilid In critical cases mere slight improvement should not be accepted as a positive therapeutic test

The Issue of Operability—The use of a therapeutic test to differentiate

syphilis from carcinoma of the stomach is, then, conditioned by the issue of operability of the possible cancer If the lesion is inoperable and syphilis present or presumptive, arsphenamine treatment should always be given and as Bockus and Bank emphasize, carried through an almost indefinite period. But clinical improvement does not clinch the diagnosis until enough time has

A

B

C

Fig. 623.—Roentgenograms of syphilis of the stomach, showing successively the condition before treatment, the improvement produced by six weeks of treatment for syphilis, and complete recovery with normal stomach outlines one year later (Case reported by Eusterman, Med. Clin. N Amer November 1919 p. 609)

elapsed for carcinoma to prove fatal or unless clinical relief is supported by roentgenological evidence of cure of the lesion. The weight curve is often helpful and a patient whose weight continues to drop under treatment, even though his symptoms are somewhat relieved, probably has carcinoma. Failure to relieve pain, although the patient may gain weight and appetite, is again in favor of cancer

Fig. 628.

PREOPERATIVE BLOOD WASSERMANN TEST IN GASTRIC DIAGNOSIS. PREOPERATIVE DIAGNOSIS OF ULCER WITH OBSTRUCTION FOUND TO BE MULTIPLE SYPHILITIC GASTRIC ULCERS

Male, aged thirty-seven, brakeman.

Chief Complaint Food distress after meals, duration nine months. Fulness nd heaviness in epigastrium.
Pain Not Relieved by Food or Soda. N colic. N nausea or vomiting. Takes milk only
Denies Syphilis Possible primary on lip eight years ago.
Examination Epigastric tenderness, no mass. Test-meal Free HCl 0, total 18. Food remnants.
x **Ray** **Lesion at Outlet.** Moderat retention.
N Blood Wassermann Test Taken.

Clinical Diagnosis: Gastric ulcer at pylorus with obstruction. Operation advised.
Operative Findings: Multiple Ulcers of the stomach.
Punctured with Cautery and specimen removed for diagnosis. Chronic appendicitis, slight pancreatitis.
Pathologic Report Very inflammatory ulcer
Surgeon Advises Further Examination for possibility of syphilis.
Postoperative Blood Wassermann: Repeatedly strong positive.
Treatment Begun.
Excellent Therapeuti Result.

DISCUSSION

1 Low acids in young man with ulcer might arouse suspicion of syphilis. In any event, routine preoperative Wassermann is never amiss.
2 Multiple gastric ulcers, also, should arouse suspicion of syphilis.
3 Judging merely from experience in the treatment of gastric syphilis, this type of operation, where possible, is much preferable to the extensive resections often considered necessary on exploration.
4. Inflammatory infiltratio found in such cases will often subside with excellent functional result under treatment for syphilis.

Fig 629

SYPHILITIC GASTRIC ULCER. OPERATION ADVISED HEALED BY TREATMENT

Woman, aged sixty-four married.

Chief Complaint Dull aching pain (t tacks) upper epigastrium and belching of gas, thirty years
Onset two t four hours after meals. Vomiting and soda relief
T years remission ended 1918.
Weight Loss 35 pounds in si months. Extensive itching eruption, wrists, palms, ankles, eighteen years
Examination Eruption as above. Slight arteriosclerosis. Systolic mitral murmur
Palpable Nodule in Abdomen, small, hard, tender below ensiform.
Blood and Urine Normal.

Blood Wassermann Reaction: Strong positive
Stomach Examination: Free HCl 12, total 20
Ray of Stomach fter belladonna.
Small Ulcer on Lesser Curvature.
Diagnosis: Gastric ulcer Mitral regurgitation, simple goiter latent or cutaneous syphilis.
Operation Advised Refused.
Treatment for Syphilis 6 injections arsphenamil 0 ⅓ t 0.6 gm.
Results: Complete Disappearance of All Gastric Symptoms.
-**Ray Report** Ulcer healed.

DISCUSSION

1 The entire complex apparently due t syphilis. The eruption vanished, there was marked eight gain, the W ssermann remained positive for time later negative.
2. There was no hange in gastric chemistry Low acids w th an ulcer in syphilis may justify therapeutic test before operation.
3. On account of patient age treatment w not pushed. She has been ell three years, with no recurrence of gastric symptoms.

Clinical Knowledge of Syphilitic Gastric Ulcer Can Be Extended by Less Operation and More Therapeutic Test in Pati nts with Combination of Syphilis and Ulcer

Fig. 630.

GASTRIC SYPHILID WITH EXTREME CACHEXIA AND AMAZING RESPONSE. DILATATION OF STRICTURED HOUR-GLASS WITH EXCELLENT RESULT

Male, aged thirty-seven, farmer

Chief Complaint: Vomiting, four years duration.
Penile Lesion: Fifteen years ago. Two courses injections at the time.
Examination *Extreme emaciation.* Height, 6 feet, 3 inches; weight, 100 pounds.
Pain and cramps constant.
Takes liquids only
Severe diarrhea.
Much reduced gastric capacity
No Palpable Mass. Free HCl 0, total 8.
Stomach x Ray Hour-glass, syphilitic type.
Almost Complete Obstruction shown by beefsteak meal.
Urine Many hyaline and granular casts, albumin.
Blood Wassermann Strong positive.
Treatment 4 injections neo-arsphenamin, 0.3 to 0.6 gm.
Amazing Transformation Gained 22½ pounds in twenty-one days. Nephritis disappeared. Still cannot eat solid food. Vomits immediately with pain.
Strictured Hour-glass Dilated to 30 F
After 7 Arsphenamin Injections
Weight gain 63 pounds. Urine normal. Eats everything but meat.
Blood Wassermann Persistently positive.
Patient Died of Influenza at the end of his second arsphenamin course after Complete Restoration to Physical Health. Total weight gain 85 pounds.
Autopsy Large stomach with lead-pencil sized stricture of pars media, 10 cm. long. Marked dilatation of cardia and lower esophagus, and of duodenum.

Discussion

1. An example of the treatment of gastric syphilids at its best.
2. Dilatation of the strictured hour-glass was an effective substitute for operative intervention. Resection of two-thirds of the stomach would have impaired the result. Function was excellent in spite of the marked deformity
3. The nephrosis was not unfavorably influenced by treatment.

Fig. 631

CLINICAL AND ROENTGENOLOGIC DIAGNOSIS, OPERABLE CARCINOMA OF THE STOMACH. SYPHILIS PRESENT. SYMPTOMATIC RECOVERY WITH THIRD ARSPHENAMIN INJECTION. SUBSEQUENT STRUCTURAL IMPROVEMENT

Male, aged thirty-two, nurse.

Examined 5/1/16.
Chief Complaint Stomach trouble. Penile sores. Scrotal ulceration, sores on lips ten years ago.
Duration of Stomach Symptoms T years. Stiffness in shoulders and neck. Gradual loss of weight. Dull gnawing epigastric pain began five years ago. Onset two or three hours p. c. Food relief Pain disappeared after two months. Very little since. One month later vomiting began. No solids seem to pass from stomach. Typical retention vomiting. Home doctor said ulcer at the pylorus with healing obstruction.
Examination Thin, slightly anemic. Weight loss 34 pounds. Scars of nodulo-ulcerative syphilid, scrotum, and lips. Hemoglobin 61 per cent. Test-meal Free HCl acid 0, combined HCl 70 total quantity 600 c.c. Food remnants present.
Roentgenologic Examination Operable carcinoma of the stomach, residue 3. Palpable ridge corresponding to filling defect.
Stool Examination: No parasites, no occult blood.
Blood Wassermann Reaction Strongly positive (2 tests) taken after x-ray examination.
Clinician's Diagnosis Pyloric carcinoma with obstruction 75 per cent., loss 25 per cent. Give salvarsan and send to hospital as soon as sterilized.
Treatment One week after first arsphenamin injection vomiting has disappeared. Diarrhea gone. Weight gain 6 pounds after third arsphenamin injection. All symptoms gone, eats everything Weight gained 10 pounds. After sixth arsphenamin injection no symptoms. X-Ray shows no change in stomach. Retention disappeared. Five months later, weight gained 47 pounds. No symptoms, gastric, x-ray unchanged. No retention. Eighteen months later condition excellent, gastric x-ray now shows improvement. Total period of observation two and one-half years.
Blood Wassermann Reaction Fixed positive Cardiovascular examination negative.

Fig. 632.

CLINICAL DIAGNOSIS, INOPERABLE CARCINOMA OF THE STOMACH. PALPABLE MASS. POSITIVE WASSERMANN. DELAYED THERAPEUTIC EFFECT LEADS TO EXPLORATION WITH CONFIRMATION OF DIAGNOSIS OF GASTRIC SYPHILIS. CLINICAL PICTURE OF SYPHILITIC LINITIS PLASTICA

Female, aged twenty-nine, single, stenographer

Examined 6/20/21.
Chief Complaint: Gastric distress.
Duration of Symptoms Nine months. Sharp cutting pain N relation to meals or food. Symptoms continuously progressive. Pains of late sharp and stabbing
Examination Thin girl, 23 pounds underweight. Physical examination: Tenderness epigastrium and right lower quadrant. Right kidney palpable. Movable mass in epigastrium on standing Hemoglobin 70 per cent. Test-meal: Free HCl acid 0, total acidity 12.
x Ray Diagnosis Inoperable carcinoma of the stomach. Advise W ssermann. Chest negative.
Blood Wassermann Reaction: Strongly positive.
Surgeon Opinion Short treatment for syphilis Explore unless response is immediate.
Treatment Three injection arsphenamin, 3 decigrams each.
N Definite Therapeutic Response Reconsideration of operability, exploration advised.
Operative Findings Slightly enlarged stomach general thickening of both walls to within 3 or 4 inches of the esophagus, obstruction near pylorus. N signs of metastasis. Spleen three times normal size, with perisplenitis and dhesion to the transverse mesocolon.
Diagnosis: Leather-bottle stomach, probably beginning syphilitic hour-glass contracture. Pathologic specimen Multiple small ulcers. Thickened fibrous walls. No malignancy Few giant-cells. A partial gastrectomy with posterior colic, end-to-side anastomosis.

DISCUSSION

With the multiple ulcers and pathologic picture in patient with syphilis there is practically no doubt that this is case of gastric syphilid with the diffuse inflammatory fibrotic changes of syphilitic linitis plastica.

The delayed therapeutic response is to be expected in cases in which there is very extensive fibrous change in the stomach. The change in surgical opinion regarding operability explains the exploration. The resection was necessitated by the probability that this stomach would ultimately have an obstructing degree of hour-glass contraction. No further treatment for syphilis was carried on in the clinic. The spinal fluid was negative. The fact that extensive gastric fibrosis will delay or minimize therapeutic effects must be borne in mind in interpreting therapeutic tests for syphilis on gastric lesions.

Fig. 633.

"INOPERABLE CARCINOMA AT THE CARDIA" PROVED TO BE SYPHILIS BY TREATMENT

Male, aged forty-three, married, laborer

Examined 9/14/17
Chief Complaint Gastric distress and vomiting
Duration of Symptoms: One and half years Began with gastric distress now vomits all food except milk and bread immediately after eating No tarry stools. No hematemesis.
Examination No palpable mass. Test-meal Free HCl 0, total acidity 10.
-Ray Inoperable carcinoma t the cardia. Hemoglobin 79 per cent.
Blood Wassermann Reaction Strongly positive.
Treatment Six arsphenamin injections, inunctions. Result All symptoms disappeared. All food except pork agrees. Weight gain 25 pounds. Period of observation four months.

DISCUSSION

Recalling the possibilities of error in the therapeutic test on carcinoma of the stomach associated with syphilis we cannot regard the diagnosis of gastric syphilid in this case as fully established without longer observation

Fig. 634.

THE FALSE THERAPEUTIC TEST FOR SYPHILIS IN GASTRIC CARCINOMA. ROENTGENOLOGIC DIAGNOSIS, GASTRIC SYPHILIS. MARKED IMPROVEMENT UNDER TREATMENT. DEATH FROM CARCINOMA

Male, aged forty-nine.

Chief Complaint: Carcinoma of Stomach, based on exploration one year before. Thickened, inflamed tissue. N definite growth found.

A Gland Had Been Removed and Diagnosed "Carcinoma.

Present Symptoms Five years duration, intermittent heavy feeling in epigastrium. Limited stomach capacity

Blood Wassermann Reaction Negative.

Provocative Procedure Negative

History of Chancroid twenty-five years ago.

Physical Findings Epigastrium slightly tender Mass adherent to scar Test meal Free HCl 8, total 18.

Ray of Stomach Luetic.

Spinal Fluid Negative.

Neurologic and Eye Examinations: Negative.

Therapeuti Test Elsewhere.

Given 9 injections of arsphenamin.

Gained 30 Pounds. Much General Improvement. Board-like Rigidity Relieved Can now eat moderately

Fatal Termination. Autopsy refused.

Discussion

1 Examination of the mesenteric gland t operation showed carcinoma in the opinion of competent laboratory

2. The case may combine both pictures, with secondary carcinomatous degeneration of gastric syphilid. This might explain the inflammatory changes t operation.

3. Be cautious in ruling out carcinoma by transient improvement obtained in therapeutic tests for syphilis in patients who present reasonable suspicion of carcinoma. Exploration is usually safer provided the lesion appears operable.

Fig. 635.

GASTRIC CARCINOMA IN A PATIENT WITH SYPHILIS. FALSE THERAPEUTIC TEST. IMPORTANCE OF REPEATED ROENTGENOLOGIC EXAMINATION AND OF HEMORRHAGE, OCCULT BLOOD, AND PERSISTENT ANEMIA

Male, aged forty-eight, single.

Chief Complaint Upper bdominal pain; food relief nocturnal exacerbation. Periodic, later continuous.

Hematemesis three months ago.

Soft Chancre eleven years go. Bubo twenty years ago.

Examination Marked Pallor Systolic blowing murmur t apex. Glands of axilla and upper arm. Abdominal tenderness both lower quadrants.

V *palpable mass or ridge.* Free HCl 0, total 8. Hgb. 45 per cent. Color index 0 6.

Blood present in Rehfuss meal. Guaiac negative, *benzidine positive*

Stomach Ray negative.

Blood Wassermann Reaction Strong positive.

Diagnosis Syphilis, probably visceral.

Treatment 2 arsphenamin injections.

Pain Not Relieved. Hemoglobin Dropping.

Transfusion. Arsphenamin continued.

Weight gain, 10 pounds. But pain persists.

Re-examination Six weeks interval. Now has palpable ridge.

Ray Now Shows Lesion of Body of Stomach. (Six weeks ago negative.)

Test-meal Free HCl 34 total 46.

Hemoglobin 55 per cent total eight gain 24 pounds.

Still Has Nocturnal Pain. Food and soda relief

Severe Gastric Hemorrhage t eeks after last arsphenamin injection.

Second Hemorrhage. Death Following Third Hemorrhage two weeks later

Autopsy: Carcinoma involving one-third of pyloric end of stomach, anterior surface. Metastasis to retroperitoneal nodes. Chronic valvular endocarditis.

Discussion

1. Improvement obscured the situation until mass and -ray findings developed.
2. Blood suggests carcinoma—hematemesis, occult blood, marked anemia.
3 Failure to relieve pain under treatment suggests carcinoma.
4. Improvement in gastric chemistry may follow treatment in syphilis.
5 The first negative -ray probably prevented possibly life-saving exploratory operation.

Fig. 636.

PERFORATING GASTRIC ULCER WASSERMANN STRONG POSITIVE. TREATED FOR SYPHILIS. CURE WITHOUT OPERATION

Male, aged forty-eight, divorced, farmer

Chief Complaint Dull pain in the stomach.

Duration of Symptoms: One year Gradually increasing weakness. Belching of gas. Distress after meals. Constant gnawing pain Regurgitation of food. No tarry stool.

History of Syphilis Chancre twenty years ago. Left-sided facial paralysis. Small amount of treatment by mouth.

Examination: Pupils irregular Slight general adenopathy Tenderness in the epigastrium. No mass felt.

Ray of the chest negative. Test meal Free HCl acid 10 to 22. Total acidity 20 to 42. Ray of the stomach Perforating gastric ulcer Grade 2 retention.

Blood Wassermann: Strongly positive.

Medical Opinion Perforating gastric ulcer Luetic history Positive Wassermann. Luetic ulcer (?) Atypical ulcer history Low acids. No intermissions; short duration.

Surgical Opinion Explore gastric ulcer May have preliminary treatment (antisyphilitic) but surgery should not be deferred too long

Treatment: Arsphenamin 0 3 gm. After this injection, gastric distress and other symptoms had practically disappeared. Arsphenamin 0 4 gm. The end of the second week of treatment patient had gained 15 pounds. Third week, 20 pounds. All symptoms disappeared. Re-ray of stomach after fourth arsphenamin injection showed small nitch on lesser curvature. Retention improved. One year later stomach negative. Test meal Free HCl acid 34, total acidity 48. Râles in the right per arouse suspicion of tuberculosis. Sputum examinations repeatedly negative. Blood Wassermann reaction fixed positive Spinal fluid negative.

DISCUSSION

The picking out of the high points of suspicion by the clinician permitted the syphilologist to make this successful therapeutic demonstration of syphilitic gastric ulcer in a patient who would otherwise roentgenologically have been typical surgical case, and in fact, in view of the perforating feature, an emergency case. The high points on which the differentiations were based were (1) history of syphilis, (2) positive Wassermann reaction, (3) short duration and continuous character of symptoms (no remissions), (4) low acids. It should be recalled, however, that some typical cases of gastric syphilis in our series had normal and in one instance high stomach acids.

Fig. 637

GASTRIC ULCER, NORMAL ACIDS. THOUGHT TO BE NON-SYPHILITIC. PROVED SYPHILITIC BY TREATMENT PREPARATORY TO OPERATION

Male, aged fifty-three married, farmer

Chief Complaint Five years of epigastric pain one-half t one hour p. c. Sour eructations. Much gas. Food and soda relief Typical periods of intermission as long as tw months. N change in character of symptoms. Made worse by pickles, sauerkraut, nd pples. Dyspepsia wakes him early in A. M. Exaggerated by hard work and worry No vomiting Very slight weight loss.

Examination Slight systolic murmur at the pex, otherwise negative. Hemoglobin 78. Test meal Free HCl 40 total cidity 52. Clinical diagnosis, duodenal or gastric ulcer

Ray Diagnosis Gastric ulcer Blood Wassermann reaction repeatedly strong positive.

Medical Consultant's Opinion History more of gastric tha of duodenal type. Do not think gastric ulcer is luetic. Advise operation and antispecific treatment.

Surgical Opinion Explore but gi antisyphilitic treatment first.

Tre tment Complet disappearance of all symptoms following 6 arsphenamin injections. Re-ray of stomach fter fifth arsphenamin injection Ulcer healed, completely negati

DISCUSSION

The caution of the surgeon in recommending antisyphilitic treatment before operating for gastric ulcer in patient with syphilis resulted in the cure of this ulcer without operation. N dietetic or other measures were employed. Note that the history is in practically every respect typical of that of gastric or duodenal ulcer and that the stomach acids were normal or above.

most careful treatment. Their condition presents a marked contrast to the rapid progress of the patients whose stomachs, with apparently an equally *extensive pathologic change*, have been allowed to recover under treatment for syphilis. This caution, of course, does not apply too literally to those cases of gastric syphilis in which exploration and operation must be performed to relieve severe symptoms of retention from pyloric stenosis and low hour-glass strictures. On the other hand, slight retention, especially in cases of syphilitic

Fig. 638.

RECURRENT GASTRIC HEMORRHAGE. *x*-RAY DIAGNOSIS DUODENAL ULCER. OPERATIVE FINDINGS, SPLENOMEGALY SPLENIC ADHESIONS TO STOMACH, MASSIVE GUMMATOUS HEPATITIS. NO GASTRIC OR DUODENAL LESION FOUND

Female, aged forty-two, housewife.

Chief Complaint: Six severe gastric hemorrhages in three years

Onset Five years ago. Gas and bloating of lower abdomen. Distress relieved by appendectomy Hemorrhages severe, prostrating Twice required transfusion. None for past year

Ray Diagnosis One year ago Ulcer near pylorus.

Examination: No thoracic or abdominal physical signs. T enty-three pounds over weight. Hemoglobin 60 per cent. Test-meal Free HCl acid 16, total acidity 50.

Ray of the Stomach (Three successive examination with belladonna) Final diagnosis Duodenal ulcer

Blood Wassermann Reaction: Repeatedly strongly positive. Spinal fluid examination negative.

Preoperative Antisyphilitic Treatment No distinctive response.

Clinical Diagnosis Bleeding duodenal ulcer

Operation: N ulcers found. Stomach very large Duodenum enlarged and thickened. Large gummatous mass in liver Spleen five times normal size. Adherent and pressing stomach in the middle. Splenectomy performed. Pathologic report: Diffuse chronic splenitis. Good recovery

DISCUSSION

In at least two instances I have seen the roentgenologic picture produced by splenic adhesions lead to report of duodenal ulcer

ulcer at the pylorus, is promptly and usually completely relieved by treatment, and should not be made the occasion for operative intervention until after at least one and perhaps two courses of treatment.

SYPHILIS OF THE INTESTINE AND COLON

Like other aspects of syphilis of the gastro-intestinal tract, syphilitic lesions of the small and large bowel are gradually being dragged from an obscurity which places them among the rarest manifestations of the disease. Fränkel, ith an experience of 19,000 necropsies, could identify only 3 cases. Gatewood and Kolodny identified 2 cases in 117,000 hospital patients. Goyena, Bianchi and Cachro (1936) found 6 cases in 810 cases of disease of the colon. The most complete study of late syphilitic lesions of the intestine in the recent literature is that of Nishikawa from the Anatomico-Pathologic Institute of the Rudolf Virchow Hospital in Berlin. This critical résumé of the literature, reinforced by 6 authenticated cases, the largest series ever collected, forms the basis for the following summary Riggs and De la Guardia have reported authenticated cases, citing Rieder and Gutmann criteria for diagnosis. Gigon summary in the Jadassohn Handbuch also gives an excellent résumé.

Clinically two forms of intestinal syphilis are described, the syphilitic enteritis present during the acute stage of the disease and resistant to all but medication for syphilis, and the late destructive and deforming local lesions, gummatous infiltrations of the intestinal walls, and syphilitic ulcers. The clinical study of diseases of the intestinal tract discloses so many conditions, such as endemic amebiasis, idiopathic chronic ulcerative colitis, for example, whose influence in intestinal pathology is not yet fully evaluated, that one is compelled t distrust the older statistical estimates and t accept with caution the etiologic significance of a mere coincidence of intestinal disease with systemic syphilis. The nonspecific effect of modern treatment for syphilis on enteritis of various types is not as yet understood, and the response of diarrhea to arsphenamine or even mercury may mean no more than an unrecognized intestinal parasitism, such as endamoeba or lamblia infection. Exceptional caution, therefore, must be exercised in attaching a diagnosis of syphilis to diarrheas occurring in the course of syphilitic infection, even though they respond to treatment. Particularly unreliable will be of course, the responses to arsphenamine therapy for arsphenamine is now well known as an effective intestinal antiparasitic, particularly in Lamblia and Amoeba infections. It is into these categories that some of our own cases, viewed at first as instances of intestinal syphilis, have resolved themselves. In the meanwhile it may be said that Wile at the time of publication of his monographic review of the subject had never seen an authentic case and from the large surgical material at the Mayo Clinic Stokes can recall only 2 cases which presented residua and concomitant circumstances suggestive of true syphilis of the intestines. Syphilitic appendicitis rather enthusiastically sponsored by Gaucher has never appeared in our experience, and only 2 cases by Trinkler have had histologic investigation.

The essential points in the clinical picture of late intestinal syphilis are well summarized by Nishikawa. The familiar dictum that syphilis of the intestines tends to affect the jejunum more than other portions of the tract is negated by Nishikawa findings, for lesions may occur at any point. Nishikawa ttaches major importance both from his own experience and the literature to the multiplicity of the lesions, the annular character of the infiltration which almost invariably forms localized constricting ring, and the hard, flat, nonulcerative plaques characteristic of the condition which differentiat it rather sharply from the tumor formations of carcinoma, the undermining lesions of tuberculosis, and the sharply marginated typhoid lesions with infiltrated borders. This preservation, practically intact, of the gummatous infiltrated plaques contrasts particularly with and is most important in the differentiation of the irregular broken-down lesions of carcinoma. Grouping and arrangement of lesions, suggested by some uthors as of differential importance, are shown by Gutmann, and Nishikawa to be without significance. The final criterion is the tendency to stenosis produced by the syphilitic lesions. Histologically the demonstration of *Spirochaeta pallida* is difficult, if not impossible. The characteristic histopathology of the process begins with the involvement of the vascular cone with tendency to segmental distribution of the lesions and to typical endarteritic pictures seen in section. The infiltration begins in the submucosa, and its character varies with the age and stage of the process, consisting t the start largely of small lymphocytes and plasma cells, with an increasing proportion of fibroblastic change in the older lesions. Sharply circumscribed gummatous nodules are recognized, and diffuse gummatous connective tissue form, akin to the diffuse infiltration of gastric syphilis.

T these criteria, applicable to the lesion when exposed t view would be inclined to add the following points.

1 The presence of syphilis should be demonstrated in the patient by collateral signs, particularly inasmuch as seronegative intestinal syphilis can be presumed to exist, especially in prenatal syphilitic patients.

2. The absence of parasitic infection should be demonstrated by repeated examinations.

3. Pancreatic function should be normal, in so far as this can be ascertained, for a supposed syphilitic diarrhea may be traceable, not to intestinal syphilis but t syphilitic pancreatitis.

4. There must be demonstrable absence of pulmonary oral or laryngeal tuberculosis and stool repeatedly negative for tuberculosis bacilli. Therapeutic tests should be conducted preferably with bismuth or mercury t reduce nonspecific effects to a minimum. The mercury should not be given by mouth and iodide may of course be used concurrently

5. Lymphogranuloma venereum must be eliminated by skin tests, history etc. The present tendency to include a form of ulcerative colitis among the lesions of the virus disease must be recalled.

Where the question of the differentiation of late intestinal syphilis with localized lues from carcinoma arises, we would be inclined to advocate exploratory confirmation of the diagnosis, unless the condition is inoperable—a view essentially in harmony with our experience with the same problem in gastric syphilis.

SYPHILIS OF THE RECTUM AND ANUS

The subject of syphilis of the rectum has been thrown into complete confusion by the rapid expansion of knowledge of lymphogranuloma venereum. Foreshadowed in the last edition the work of Frei, Grace and others has made it clear that most if not all of what has passed as syphilis, is in reality the newly identified virus infection in this region. It will probably require years, and the painstaking exclusion of lymphogranuloma venereum from each suspected case of syphilis before a new clinical picture of the anorectal syphiloma for example, can be built up. This will be made doubly difficult by doubts of the *specificity of the serologic tests for syphilis in lymphogranuloma venereum.* It is clear that present day differentiation of the anorectal manifestations of the two diseases resolves itself not into a differential morphology of lesions but a differentiation of the two diseases as such. The observer must of course familiarize himself with the clinical descriptions of lymphogranuloma venereum as contained in the basic monographs and papers (references given by Beerman, Ingraham and Stokes, Am. J Med Sc. 197 575 1939) These are briefly summarized on page 510 With the understanding that it will not tell the reader which disease he is looking at when confronted by the individual case, the following description from the second edition of this text is still adequate for what is known of syphilis of the rectum. It may be added that Buse has observed extensive leukoplakia of the rectum in a syphilitic

Syphilis of the sigmoid and rectum, like other types of syphilis of the intestinal tract, is conventionally described as early or late in its characteristics. The process associated with early syphilis is essentially proctitis with occasional papular infiltrations, thickening of the mucosa with hyperemia, and ulcerative processes. The onset is insidious, the symptoms essentially those of proctitis, including sense of heat and itching, and pain, blood, and pus with the evacuation. Unquestionably the frequency of these lesions is entangled with the problem of rectal gonorrhea and the traumatisms associated with sodomy Where syphilis is an etiologic factor, the response to treatment is said to be good and no stenosis occurs.

The later lesions of the rectum are usually described as conforming to one of three types, rectal gumma, rectal masses or tumors with their sequelae, and the anorectal syphiloma of Fournier All types are markedly more common in women than in men, although Bensaude, Masard, and Godard, in their large series found these conditions to be equally divided between the sexes. Zimmermann has called attention to the much greater frequency of rectal stricture and anorectal syphiloma in colored women.

Gummatous infiltration of the rectum is said to be extremely rare. Bensaude et al. described examples of anorectal gumma, proliferative proctitis, and rectal infiltrations simulating carcinoma. They describe type of rugous infiltration with multiple scattered superficial ulcerative lesions covered with whitish membrane in which marked nocturnal exacerbations of pain and diarrhea occurred with very prompt response to treatment for syphilis. Perirectal gummatous infiltration may lead to fistula formation and *even to rectovaginal fistula.*

The anorectal syphiloma of Fournier described below is the probable origin of such rectal strictures as can be ascribed to syphilis. The infiltration takes place about the ampulla, extending upward for 3 to 7 cm., and encircles the rectum, as in the case of upper intestinal infiltration. The chronic fibrous changes ensuing lead to high degree of stricture in the course of years.

Anorectal Syphiloma.—According to the observations of Koch and Jadassohn and of Bandler, this is an elephantiasic lesion of the perineum and vulva with secondary ulcerative manifestations resulting from lymphatic stasis secondary to chronic inflammatory changes in the inguinal lymph nodes. The earliest symptom is chronic obstipation. The conception of the exclusive or even principal etiologic influence of syphilis in this condition has been discounted by the studies of lymphogranuloma above mentioned.

Symptomatology of Rectal Syphilis.—The symptomatology associated with late syphilitic infiltrations of the rectum with stricture is, of course, quite nonspecific. Apart from the emphasis placed by certain observers on nocturnal exacerbation, the sense of heat and tension, tenesmus, pain with the bowel movement, gradually increasing obstipation, decrease in the caliber of the stool, plus mucus and blood, may be common to variety of granulomatous and even malignant conditions, as well as syphilis.

Gigon, while emphasizing the nonspecific character of the symptomatology and the wide range of clinical pictures on examination, states that the appearance of soft, easily bleeding vegetations in the rectum is suggestive of syphilis. The picture of rectal stricture he rates as much more characteristic. On palpation ringlike elevation of the mucous membrane is detectable or the cruciate stricture form may be recognized. With the proctoscope funnel-shaped narrowing 3 or 4 cm. deep is recognizable covered by a whitish, nonulcerated mucosa. Flat condylomas may be recognizable. Biopsy is often possible, but *Spirochaeta pallida* has thus far never been identified.

Mistaken Impressions of Frequency.—Structure of the rectum has as we have indicated been more or less traditionally accepted as of syphilitic origin in a high proportion of cases. In fact, if one is to accept the opinions of number of uthors, rectal syphilids are almost as common as syphilids of other parts of the intestine are rare. Individual experience in the matter may vary under unknown conditions. For example Bensaude, Mezard and Godard in 1930 published statistics on 226 rectal strictures observed since 1910, in which they found syphilis to be indubitably present in 61 per cent of the patients. From what we have seen of the difficulty of connecting syphilis with a rectal stricture by an unbroken chain of diagnostic or therapeutic reasoning, we are convinced that mere demonstration of concomitant syphilis is insufficient to prove the syphilitic origin of rectal lesion. As in syphilis of the colon, parasitism, nonspecific ulcerative colitis and proctitis, other infections and trauma or inflammatory changes secondary to treatment for hemorrhoids, all serve as confusing elements. Sodomy seems to have been a factor in some of the Continental series. Buie has summarized the experience of the Mayo Clinic with the problem of benign stricture of the rectum due to syphilis in terms which accord more closely with our personal impressions.

In reviewing 258 cases of rectal stricture seen in the Mayo Clinic from *1918 to 1922 Buie* found 55 patients who had had syphilis. During six years of this period syphilitic cases were reviewed by the syphilologist and treatment carried out in most cases, with signally disappointing results.

In dealing with rectal stricture one is, then, studying consequence and not cause, and while ill-advised operative interference, irritants, or medication may lead to picture not distinctive of syphilis, the obscure beginnings may nevertheless have been syphilitic in character Moreover treatment for syphilis applied late as a therapeutic test can be expected to have only limited value because of the functional disability entailed by the scarring produced by the healing processes. But in spite of these modifying considerations we have found clearly demonstrable syphilis of the rectum to be comparatively rare and the demonstration of syphilis as the cause usually weakened or set aside outright by the pronounced nonspecific effects of modern treatment for syphilis on the intestinal tract. Certainly we are not able to concede validity to the "feel" of stricture or t its location *ipso facto* as proof of its syphilitic origin.

Exclusion of Other Causes Before Treatment.—When syphilis is demonstrable on collateral evidence in patient who complains of rectal symptoms, with blood or pus in the stool, or who has ribbon or lead-pencil evacuation ven with comparatively few symptoms, an effort must be made t exclude other causes of stricture before treatment for syphilis is begun. Unless this precaution is taken the effect of course of arsphenamine in concealing the existence of an endameba infection may leave the issue of syphilitic infection in the patient permanently in doubt, to say nothing of its influence as factor in the rectal condition. The striking improvement both in local symptoms and general well-being in these patients may cause one completely to lose sight of other possibilities in the case All patients with an ulcerative process in the rectum should have roentgenological examinations of the colon for the detection of the characteristic changes of nonspecific ulcerative colitis, contraction and obliteration of the normal haustrations, with the final reduction of the bowel t a contracted, straight-walled tube Treatment for syphilis in cases of nonspecific ulcerative colitis is occasionally accompanied by temporary benefit which may give the impression of a positive therapeutic test. The all-important diagnostic tests for lymphogranuloma venereum are described on page 813. Paulson has described "bowel antigen" for skin tests in these cases, claiming greater sensitivity and specificity The use of sulfonamides and antimony in therapeutic test differentiation is not trust orthy

Operative Measures After Treatment.—While relief from pain and disappearance of ulceration may follow treatment for syphilis, operative measures, ranging from dilation under anesthesia to colostomy may be necessary to deal with the obstruction produced in cases of marked severity or long duration, and to prevent the recurrence of ulceration above the stricture due to mechanical interference with the passage of the stool and consequent continuous cycle of trauma and infection. Buie, in summarizing the experience of the Mayo Clinic on this point, rated the effects of dilation under anesthesia as temporary resection of the rectum as desirable but technically difficult, and colostomy and ileostomy as the most dependable form of treatment in severe

Fig. 630

GUMMA OF THE RECTUM WITH STRICTURE. TIBIAL PERIOSTITIS. NO SEROLOGIC EVIDENCE OF SYPHILIS. CURE OF PERIOSTITIS AND STRICTURE BY ANTISYPHILITIC TREATMENT (POSITIVE THERAPEUTIC TEST.)

Female, aged forty-nine, married.

Chief Complaint Rectal trouble. History 5 or 6 miscarriages. One child died three days old.

Onset Rectal Trouble ten years ago.

Operation Much relief Little control of rectal sphincter since. Pain and blood-streaked ribbon stools. Began again three months ago. Stool will not pass unless loose.

Examination Palpable lower cervical glands. Apparently tuberculous. Twenty years standing. Hemoglobin 45 per cent. R B.C. 3,300,000. Leukocytes 11,800

Proctoscopic Examination Scarring begins at anal canal, extends upward 10 cm. Stricture not over 1 cm. in diameter Ulcerated and bleeding. Anal sphincter incontinent. Posterior vaginal wall bulged forward by infiltrate between vagina and rectum. Impossible to reach cervix. Mass soft and boggy

Syphilologic Examination Provocative procedure negative. Spinal fluid examination negative. Osteomyelitis lower end left tibia. Some years duration. Tuberculosis diagnosed by J. B. Murphy 1910. Pupillary reflexes sluggish.

Neurologic Examination Residue of old typhoid myelitis. Residue and history of hemiplegia and aphasia two years before typhoid, possibly syphilitic. Stool examination negative.

Therapeutic Test 7 injections arsphenamin 3 to 4 decigrams. Bone lesion typical Herxheimer reaction, followed by complete recovery

Rectal Lesion Rapid Therapeutic Response 90 Per Cent. Improvement. Ulceration practically healed. Stricture no longer seriously obstructs. Period of observation one year

Blood Wassermann Reaction Never Positive. Spinal fluid examination negative. Symptoms of chronic bronchitis. Relieved by change of climate. No recurrence of rectal symptoms. Dilatation not necessary

DISCUSSION

Evidence for syphilis consists of suspicious history possible syphilitic hemiplegia and aphasia. Tibial periostitis and osteomyelitis with Herxheimer reaction under treatment followed by cure. Disappearance of ulceration and infiltration under arsphenamin and mercury N relapse during one year The continuously negative serology in this patient inevitably arouses the suspicion of non-specific therapeutic effect on low-grade tuberculosis. This is reinforced by the history of tuberculosis with glands of twenty years duration. On the whole however the evidence for syphilis much outweighs that for tuberculosis.

Note that the stricture is of the typical funicular type. For some of the possibilities of non-specific therapeutic effects on supposed syphilis of the rectum and intestine see above. Note also that as is commonly the case in syphilis of the rectum, no symptoms developed to attract the patient attention until stricture had developed.

cases. I colostomy cases through-and-through irrigation and local medication by proctoscope are invaluable. W have been much impressed with the comfort which these unfortunate, severely obstructed patients obtain from colostomy and their satisfaction with the operative result. Control of the diet to avoid flatulence and certain regularity of evacuation seem to be obtainable, and to do away with many of the theoretic objections to the procedure.

T all intents and purposes, then, the differentiation of the enteritis and enterocolitis of syphilis from other types of intestinal lesions depends on the elimination of tuberculosis, parasitism, and chronic ulcerative colitis and the differentiation of late lesions (gumma, and so forth) involves the elimination of carcinoma, tuberculosis, and actinomycosis, which, in practically all cases at outset, will require operative exploration for the good of the patient. The possibility of confusing actinomycosis of the cecum with syphilis on account of the occasional marked response of actinomycosis to arsphenamine and, of course, to the iodides may need to be recalled. Any pus obtained in the course of investigation or exploration should be promptly searched for sulphur bodies. The fallibility of arsenical therapeutic tests in all aspects of intestinal lesions must be constantly borne in mind.

Anal syphilids are considered in conjunction with cutaneous landmarks, Chapters XI and XII.

CHAPTER XVIII

SYPHILIS OF THE LIVER AND SPLEEN

Syphilis of the liver and spleen should be common. Both structures have enormous capillary sieves which strain out and dispose of large amounts of toxic and infectious circulating material with a minimum of symptomatic protest. As in the nervous system, so also in the liver and spleen, there is probably a high incidence of early reaction, taking the form of congestion with enlargement of the organ, and followed by recovery as the spirochetemia subsides. Only a relatively small proportion of patients who, at the onset, have a visceral reaction, will have symptoms directing attention to it, and a much smaller proportion will be likely to develop chronic reactions or late manifestations. The lowly estate of syphilis of the liver from the standpoint of clinical recognition, is well represented by McCrae's finding of only 56 cases (0.2 per cent) in 27 000 medical examinations, as contrasted with an incidence of 1.5 per cent in 3300 postmortems. Thus 1 case in 7 of syphilis of the liver was recognized clinically in the pre-Wassermann days, to which McCrae's figures are largely referable. Figure 642 presents our observations on the simple physical criterion of enlargement of liver or spleen in 419 patients with various forms of syphilis including preponderantly latent and late phases of the disease but excluding hepatosplenic syphilis as such. This checks fairly well against current estimates of the prevalence of syphilis (10 to 15 per cent) for if 1.5 per cent of necropsies in general disclose syphilis of the liver and if 10 per cent, clinically of those persons who have syphilis, have involvement of the liver there should be an incidence of all forms of syphilis approximating 15 per cent in all persons who come to necropsy. Hahn (1943) has recently reviewed the problem of hepatic syphilis.

A close association exists clinically between pathologic changes in the liver and spleen. As Rolleston says, the presence of an enlarged spleen with an upper abdominal mass should suggest cirrhosis. The widest range of combinations appears in any considerable group of syphilitic livers and spleens, from enormous livers with almost normal spleens, to extraordinary splenomegaly with no abnormalities detectable in the liver. It is experience with this range and variability which leads the clinical syphilologist to look with suspicion on such pictures as Banti's disease and even to insist that there are no features of splenic anemia which syphilis cannot reproduce. It is apparent, however from any considerable study that syphilis of the liver is much more common, or at least is much more commonly recognizable, than is syphilis of the spleen. Part of the reason lies in the silent character of the spleen, and in the fact that it must become considerably enlarged before it is detected as abnormal on physical examination. The liver on the other hand is more accessible to physical examination and operative inspection and being equipped with more ways of expressing pathologic change in symptoms through the biliary and portal mechanism more frequently forces itself on clinical attention.

Syphilis of the liver may be discussed clinically at the present time under the following heads (1) early acute benign hepatitis (2) syphilitic destructive hepatitis or acute yellow atrophy (3) subthreshold hepatic syphilis detected

by functional tests (4) hepatorecurrence (5) mild chronic hepatitis of latency; (6) diffuse and localized gummatous hepatitis (7) chronic interstitial pericellular cirrhosis of heredosyphilis (Chapter XXI) and (8) perihepatitis. The following summary will prepare for the discussion of the diagnosis as illustrated by our own material

Early Acute Benign Hepatitis.—This is rare complication of the florid eruptive stage of syphilis, first described by Gubler in 1853. Estimates of its frequency in syphilis range from 0.37 per cent (Werner) to 3 per cent (Reimer) Wile rates the incidence below 1 per cent. Stokes saw only one undoubted case in survey of 800 patients with early syphilis. Waugh (1937) saw four cases in 4,890 cases of early syphilis (0.08 per cent). The chief symptom is jaundice, the chief sign enlargement of the liver Weight loss to the point of emaciation may occur The condition is distinguished with difficulty from intercurrent catarrhal jaundice of nonspecific origin and from hepatorecurrence, and, in fact, the differentiation must rest entirely on: (1) The presence of chancre or secondary syphilitic eruption (usually roseola) (2) Herxheimer flare-up if treatment is begun with arsphenamine and (3) prompt cure as treatment is continued. Two to five weeks should complete the recovery of patient with early hepatitis, except for residual enlargement of the liver which may persist for some time, indicating that there is possibly diffuse inflammatory factor and proliferative element in the pathology A roseola of the bile ducts, condylomas of the ampulla, and pressure from enlarged nodes in the portal fissure are among the hypotheses as to etiologic mechanism. Reimer demonstrated the influence of local adenopathy as cause of obstructive pressure in 3 cases.

Elliott and Todd have reported particularly interesting case in which the hepatitis followed two months after the appearance of the primary lesion, and the functional injury to the liver could be followed by the icterus index together with the flare-up (Herxheimer effect) on the institution of bismuth treatment. Successive readings beginning with the first examination were 65, 116 (after first Bi injection), 214 (after second Bi injection) 62 (nine days later), 24, 13.6 (three weeks after treatment begun), 8 (fifth week). This was an effective demonstration both of therapeutic flare-up, the ability of bismuth to induce it, and proof of the syphilitic nature of the hepatitis by therapeutic test. Waugh saw no clinical signs of Herxheimer reaction in his four cases, treated, one with bismuth and three with an arsenical.

Syphilitic Destructive Hepatitis or Acute Yellow Atrophy (Icterus Gravis).—Among the various causes of fulminating destruction of the liver syphilis takes an undoubted, though rarely occupied, place. The complication is so rare that no one has been able to record personal experience of more than 3 cases (Richter); most syphilologists, including ourselves, can record one each. As conventionally described, the complication is an associate of the early period of the syphilitic infection, at times even preceding the secondary eruption (Michael) as in the case of acute syphilitic nephritis. It is sometimes seen in association with the mild or benign form of icterus, coming on without warning in cases apparently running an uneventful course. The incidence of 10 per cent grave icterus in cases of mild early syphilitic hepatitis indicates the rarity of the complication. As factor in acute yellow atrophy in general the instrumentality of syphilis may be inferred from Lebert figures in 1854, in which 7 of 72 patients had syphilis. Umber in 1911 brought the total of reported cases of grave icterus in the literature ascribed to syphilis to 50.

The investigations of Buschke and Zeroik in 1911 seem to have established grave icterus to the satisfaction of most observers, as syphilotoxic parenchymatous destructive hepatitis, with jaundice of nonobstructive type. According to Bursecinski, Fischer Bendig, and others no spirochetes are found in the liver O'Leary however states that Warthin has found the organisms in large numbers, and believes the process represents spirochetal crisis such as has been observed in the heart, and in experimental syphilis. In the days of exclusively mercurial treatment the drug was unjustly held responsible for some of the cases. The appearance of the arsphenamines in the therapeutic field with their higher hepatotoxic effect has, however, altered the etiologic background so far as drugs are concerned, as will appear in the discussion of the interpretation of jaundice in patients with syphilis. Many French authors, headed by Milian, believe that acute yellow atrophy in the patient with syphilis may be not so much the result of the primary or original infection, as of fulminating relapse, following inadequate treatment similar in its causal mechanism to the types of meningeal relapse which produce the familiar neurorecurrence. Of this Greenbaum has recently reported an excellent example, with unfortunately fatal outcome that might readily have been charged against arsphenamine had the drug been used.

The symptoms of syphilitic acute yellow trophy as described by Wile and Karshner, and confirmed in the patient Stokes has seen, are: insidious onset, with mild but steadily deepening

jaundice; malaise anorexia and vomiting, with or without fever may be an accompaniment. The patient complains of muscular aching and at times severe abdominal cramps. A toxic condition then supervenes, with emaciation and a typhoid state. Enlargement of the liver is noted at first, often an extreme degree for a short time, and, as the toxic symptoms increase, diminution in size is rapid. This shrinkage should be watched for from day to day by suitable marking. Ascites may appear early but usually develops as the liver shrinks. Hemorrhages from the bowel, hematemesis and purpura of the skin with petechial bleeding from the gums and buccal mucosa are not uncommon. As intoxication becomes more profound, psychosis with delirium, violent headache, and at times maniacal symptoms develop, or there is insomnia and depression. Apart from the deep jaundice the late symptoms suggest those of meningitis or uremia, with which latter condition those cases accompanied by severe nephritis are undoubtedly complicated. Wile notes the obstinacy of the constipation and the peculiarly offensive stool. Incontinence of urine and feces occurs just before death.

Laboratory aids to the diagnosis of acute yellow atrophy may be found in the presence of leucin and tyrosin crystals in the urine of most patients, although this finding is not invariable, and was absent in Stokes case. They may be extremely abundant and even cause precipitation. Tetrachlorphthalein tests of hepatic function show rapid decline, although this has no differential value since it occurs in all progressive changes. Bile from the duodenum may contain urobilin and urobilinogen in the hematogenous jaundice of the epidemic infectious type (p. 250). Urinary evidences of an accompanying nephrosis are not uncommon. A rising blood urea accompanies an unfavorably progressing case, possibly as result of the failure of the kidneys quite as much as of the liver

The treatment of early hepatitis is considered under the treatment of syphilis of the liver on page 872.

Subthreshold Hepatic Syphilis Recognized by Functional Tests.—It is of course extremely difficult to disentangle this question from the problem of injurious effects of arsenical medication on liver function. The literature as summarized by Elliott and Todd and concerned chiefly with the phenoltetrachlorphthalein and bromsulphonphthalein tests, has not revealed a particularly promising approach.

Friedenwald and Morgan found marked variations in the performance of known syphilitic livers. Brunsting pointed out that while single tests give untrustworthy results, repeated tests were more reliable. Ottenberg and Abramson had outright negatives in known syphilis of the liver. Irgang and Sala, using the icterus index and the van den Bergh test in 179 patients with active cutaneous syphilis, observed positive direct delayed reaction in 25 per cent and in 118 with secondary eruptions, positive reactions in 17 per cent. In 12 per cent of 134 cases with negative reactions t the outset, the van den Bergh test became positive during treatment but none developed clinical jaundice. Only 10 per cent of patients with positive tests at the outset, who received 4 to 8 doses of 0.9 Gm. neoarsphenamine, developed clinical jaundice. The majority returned t normal under treatment, indicating that a liver reacting to syphilis is not necessarily specially susceptible t an arsenical. They emphasize, however the necessity for prolonged observation and bismuth therapy of patients showing abnormal icterus indices and van den Bergh tests before treatment is begun. *Irgang (1937) again demonstrated the subthreshold therapeutic* shock and paradox demonstrable by functional test, to emphasize the necessity for caution and the use of bismuth in treatment. In reviewing hepatic complications in the pregnant syphilitic woman, he emphasized the importance of considering jaundice in pregnancy as due to the pregnancy and not to the syphilitic hepatic process. He believes that the pregnancy should be terminated.

There can be no question of the desirability of further development of this field with a view to detecting liver damage by syphilis in its earliest incipiency. A summary to facilitate the use of available functional tests is given in Figure 640

Hepatorecurrence.—The conception of relapse involving the liver as a more or less localized manifestation has been largely established by the energetic advocacy of Milian, who has insisted on the deleterious or activating effect of subtherapeutic dosage of the arsphenamines, and the danger of fal-

Fig. 640.

LIVER FUNCTION TESTS

(Modified from Steigmann, Popper and Meyer J.A.M.A., Vol. 12, pp. 279-285, 1943, with additions)

Test.	Normal reading.	Deviation.
1. Bilirubin in urine.	Negative.	Daily quantitative tests indicated in parenchymatous disease.
2. Urobilinogen in urine.	Trace.	
3. Van den Bergh reaction.	Negative.	
4. Icterus index.	4–6 units.	
5. Galactose tolerance test.	Over [illegible] Gm. in urine indicates decreased function.	Abnormal intestinal absorption modifies results.
6. Oral hippurate excretion test.	Equivalent of less than 3 Gm. of sodium benzoate in the urine indicates decreased function.	Intestinal absorption does not interfere. Liver damage roughly inversely proportional to hippuric acid excreted.
7. Blood proteins.	7 Gm./ml.	Decreased in some cases of chronic liver disease.
8. Albumin-globulin ratio.	2 : 1	Decreased in some cases of chronic liver disease.
9. Prothrombin response to vitamin K.	Normal prothrombin time 18–20 seconds (Quick).	In many cases of liver disease prothrombin level low and response to administration of vitamin K slow or incomplete.
10. Cephalin-cholesterol flocculation.	Normal standard.	Density of flocculation roughly proportional to liver damage.
11. Colloidal gold test.		
12. Takata-Ara test.		
13. Alkaline phosphatase test.	2.5–5 units.	Increase indicates roughly degree of biliary obstruction. Should be used in conjunction with cephalin-cholesterol flocculation test.
14. Azorubin-S test.	Dye appears in 30 minutes in duodenal drainage.	
15. Nonprotein nitrogen.	[illegible] mg %.	Rise indicates liver failure. May be due to associated renal damage.
16. Millon test.	Negative.	Tyrosine appears in urine in severe liver damage (acute yellow atrophy).
17. Cholesterol-cholesterol ester ratio.	2.	Abnormal 1 : 1 or less roughly proportional to liver damage.
18. Daily urinary output.		Diuresis indicates recovery.
19. Graham-Cole test.	Radiopaque concentration of dye in gallbladder.	
20. Bromsulphalein test.	Less than 5 mg. in serum after 30 minutes.	

Tests to Be Performed in Early Cirrhosis

1. Icterus index.
2. Urobilinogen in urine.
3. Bromsulphalein test.

Tests to Be Performed When Administering Hepatotoxic Drugs:

1. Icterus index.
2. Urobilinogen in urine.
3. Bromsulphalein test.
4. Cephalin-cholesterol flocculation test.
5. Hippuric acid excretion test.

Signs of Alarm (Liver Failure)

1. Rise of icterus index.
2. Millon test becomes positive.
3. Drop in prothrombin level, only partly relieved by administration of vitamin K.
4. Drop in cholesterol esters.
5. Rise in nonprotein nitrogen.

minating flare-up in patients who lapse after such treatment. While Milian's insistence on continued and larger dosage of the arsphenamines is not shared by other French observers such as Ravaut, Lortat-Jacob, Sézary and Simon, hepatorecurrence as a clinical conception akin to neurorecurrence for example is established. The essence of a hepatorecurrence is its onset, some weeks or even months after the suspension of a short, small-dosage course of an arsenical, unsupported usually by heavy metal. That such an outcome can explain some of the acute yellow atrophies previously ascribed to delayed arsphenamine poisoning is suggested by Greenbaum's typical case. The difficulty of differentiating the two may be inferred from one of Irgang and Sala's cases in which the circumstances might suggest a hepatorecurrence, but partial, though not complete recovery took place under sodium thiosulphate.

The "Latent" Liver.—Latent livers and spleens are asymptomatic, and are either overlooked in physical examination or discounted as of no significance (Fig. 667). It seems possible that, as with the spleen in early syphilis, they may even disappear without attracting anyone's attention. In the series of 419 patients (Fig. 642) of 40 patients who had enlarged livers 33 had positive blood Wassermann reactions. Of the 20 patients with both hepatic and splenic enlargement, 17 had positive blood Wassermann reactions. It is justifiable to suggest, therefore, that a serologic test is a necessary part of the medical examination of all patients who have palpable livers or spleens. The wider use of this hepatosplenic guidepost and suspicion arouser, as is apparent from *many cases studied, would lead to the recognition of* an appreciable amount of syphilis during latency rather than following the appearance of symptoms due to irreparable damage.

We have found Middleton's maneuver a valuable aid in detecting hepatic enlargement in patients in whom it might easily and in fact was previously overlooked. This consists in having the patient lie on the flexed right forearm, thus elevating the thoracic spine and anterior rib margin and thrusting the liver forward, emphasizing the edge and bringing it away from the ribs. The same maneuver assists in palpating the enlarged spleen (left forearm) but is less effective. Moore (1943) discounts the conception of latent or asymptomatic hepatic syphilis on the ground of autopsy rarity of syphilitic liver disease. Hepatic enlargement alone we agree cannot be accepted as diagnostic of syphilitic hepatitis in a benign or subthreshold stage without supportive clinical and laboratory evidence. Autopsy findings years after a benign process, however, do not necessarily establish or exclude mild types of involvement many years before. The life history of certain of our syphilitic patients observed for twenty years since the onset of their infection (see Fig. 641), clearly indicates that the early warning of an ultimate hepatic cirrhosis was given by the ups and downs of hepatic enlargement otherwise completely asymptomatic in the early years of the disease, coincident at times with the appearance and disappearance of positive serologic tests on the blood.

Late Diffuse and Localized Gummatous Hepatitis.—Slow chronic inflammatory and degenerative changes and fibrosis or cirrhosis of the liver are to be expected among the clinical manifestations of syphilis, both inherited and acquired. Localized gummas vary in size from multitudes of pinhead-sized lesions to large single gummas with extensive necrosis and secondary change. Both types of lesions may develop simultaneously, the clinical behavior of the case varying with the proportion that interstitial fibrosis bears to localized gumma formation at a given moment. Part of the clinical picture in any given case will depend on the location of cirrhotic and gummatous lesions with respect to important structures within and without the hepatic and biliary systems. A large gumma projecting into the portal fissure may produce ascites by pressure on the portal vein; thousands of miliary gummas, a *diffuse inter-*

An eighteen-year relapsing and progressive history of syphilis: serologic relapses associated with [illegible] recurring hepatic enlargement; (b) re- or superinfection; (c) coronary thrombosis. Repeated response of hepatic enlargement [illegible] treatment (therapeutic test). Final appearance of splenomegaly (1941). Therapeutic response of both liver and spleen to syphilotherapy (serologic response simultaneously) plus diet and stopping of alcohol. Alcohol probable factor throughout. Clinical picture that of Laennec' cirrhosis. At no time has the patient been jaundiced there has been no recognizable ascites, and his icterus index and functional tests are recently (1941–1943) normal.

stitial fibrosis, or the contraction of a gummatous scar may be equally effective in blocking the portal circulation within the liver and bringing about ascites. Jaundice may arise from diffuse interstitial hepatitis with blocking of the finer bile ducts. It may likewise arise from the pull of a band of fibrous tissue, the distortion of a scar or the pressure of a fresh gumma which kinks or blocks the hepatic duct.

Portal cirrhosis (Laennec) nodular cirrhosis and atrophic cirrhosis of the liver include in varying degrees and in varying proportions of cases, the diffuse gummatous and gummato-fibrotic syphilitic process in the liver The studies by Schumacher (1937) of Laennec's cirrhosis, including one case of smooth hypertrophic cirrhosis of the Hanot type, well illustrate the interplay of influences involved in this group of hepatic cirrhoses. Of 45 cases of acute cirrhosis, including 44 of nodular or Laennec cirrhosis and one of Hanot cirrhosis, 28.8 per cent had presumptive evidence of syphilis, approximately one-third were known to have used alcohol in excess, or approximately one-half if those cases were excluded whose alcohol habits were unknown; and 11.1 per cent were both syphilitic and alcoholic (15 1 per cent when unknowns were excluded) Approximately three-quarters of the cases of acute cirrhosis and all of those with acute cirrhosis and syphilis were in men. Among the cases in which the duration of infection was known—that is, in less than half of them—there was no instance in which syphilis had been present for less than ten years. A control group of 45 autopsies with no cirrhosis in persons of the same age and sex as those with acute cirrhosis showed that two (4.4 per cent) had had syphilis; and two had used alcohol in excess. The two factors were combined in no instance. In a group of 21 autopsies

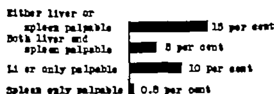

FIG. 642.—THE "LATENT" OR PALPABLE LIVER AND SPLEEN AS A GENERAL DIAGNOSTIC AID IN LATE SYPHILIS (419 CASES, RECOGNIZED SYPHILITIC HEPATITIS EXCLUDED).

of persons with syphilis, diffuse cirrhosis of the liver was found in three cases (14.3 per cent). Syphilis, therefore, long continued in association with alcoholism, and perhaps alone, may cause diffuse cirrhoses of the liver

Imitative Possibilities of Late Hepatic Syphilis.—The combination of a generalized lesion such as syphilitic interstitial hepatitis, and a localized lesion such as gumma, with inflammatory extensions (perihepatitis) to surrounding structures, can produce syphilitic imitations of every imaginable clinical entity medical and surgical in which the liver may be involved. From the standpoint of clinical pathology there may be, during the period of active infiltration, a large firm liver heavier than normal smooth, and glistening. Since the process is rarely without certain spots of localization, a few small gummas may be recognized, or there may be patches or masses of heavier unencapsulated or uncircumscribed infiltration. As time elapses, such a liver depending somewhat on the interrelation between extension and healing, as in all syphilitic lesions, may shrink and become hard and atrophic it may shrink slightly but increase in firmness or it may shrink most in those parts in which infiltration with gummatous tissue was most pronounced thus giving rise to *ridges, depressions, and irregularities not amounting to* actual lobulation, in a liver larger than normal, but not as large as in the first months or years of the involvement. Interference with the circulation may vary widely with these various changes, and a small liver does not necessarily mean an obstructed circulation, nor a large one a free portal return. If large local gum-

mas predominate over diffuse infiltration or if they are, as occasionally the only manifestations, the mass becomes the conspicuous clinical symptom. The dragging of a small lobe into the field usually occupied by another structure, the granulomatous left lobe for example, suggests to the clinician a spleen, a kidney the head of the pancreas, and so forth (Fig. 669) As gummas involute, deep clefts from scarring contracture take their places, producing two or more lobes where one was before, the so-called *hepar lobatum*. A diagnosis of *hepar lobatum* can never be regarded as excluding a collateral diagnosis of varying degrees of interstitial fibrosis or cirrhosis.

Perihepatitis.—Extensions of localized inflammatory processes from the parenchyma of the liver to the peritoneum over its surface are common in cases of syphilitic gumma. The immediate result, as in syphilis of other peritoneum-covered viscera, is adhesions to surrounding structures with varying degrees of distortion as the adhesions toughen and the original inflammatory process subsides with shrinkage. In this manner the portal fissure may be almost obliterated and the gallbladder lost in a mass of inflammatory tissue whose constricting effect and secondary inflammatory involvements become apparent in symptoms of biliary tract obstruction and cholecystitis (Figs. 661 673)

Diffuse perihepatitis may involve the entire liver with thickening of the capsule and extension to the parietal peritoneum. With these exacerbations of peritonitis, no less than with the softening of larger gummas and the waves of exacerbation in the gummatous infiltrative process, attacks of fever and pain occur which are highly deceptive to the clinician because associated in his mind only with nonsyphilitic infectious processes. Such attacks were an important feature of the symptoms in a number of our cases.

Involvement of Gallbladder and Ducts.—Involvement of the wall of the gallbladder and the ducts by an actual late syphilitic process, a gummatous cholecystitis, appears unknown. The clinical pathology in some of the cases in which operation is performed and the portal fissure is found blocked by adhesions, and the gallbladder buried, suggests the possibility that the wall of the gallbladder may have been secondarily involved in a gummatous infiltrative process beginning elsewhere, but there is as yet no support, pathologically for such a view

Involvement of the Lymphatic System.—Involvement of the lymphatic system must be borne in mind in connection with the clinical pathology of late syphilitic hepatitis. Satellite groups of inflammatory lymph nodes are often seen in the vicinity of the areas of gummatous activity in the neighborhood of the portal fissure, and may promote obstruction or suggest malignant change.

Predisposing Factors in Hepatic Syphilis.—Rolleston observed the prejudicial effect of alcohol, malaria, and previous jaundice (presumably infectious) in favoring late syphilis of the liver Warthin has emphasized the low-grade hepatitis which he observed in a large proportion of patients with syphilis to whom arsenical treatment had been administered. O'Leary has pointed out the increased likelihood of hepatic complications in the course of infections in which a jaundice has occurred whether precipitated by treatment or intercurrent. Of this we have seen what we thought were fair examples. In view however of the complexity of the factors involved, and of the fact that there does not at the moment appear to be a wholesale increase in clinical late hepatic syphilis corresponding to the second decade of the arsphenamine era,

we are inclined to doubt the great importance of the drug as predisposing to hepatic syphilis. Rather it seems to us we are dealing with syphilitic hepatic involvement dating in most cases from the early months of the disease than syphilitic hepatic involvement created out of a clear sky by the influence of a drug We have gathered from repeated examinations of patients, the impression that syphilis of the liver itself runs this lifelong course now above now below the symptomatic threshold and that only patients with an initial hepatic localization appear to make the unfortunate responses to other agents. In other words, the arsenical is not creating new hepatic syphilis it is perhaps, though not probably bringing occasional cases to the surface of clinical recognition.

The Instrumentality of Syphilis in the Production of the Banti Syndrome of Hepatic Cirrhosis with Splenomegaly and Anemia.—This subject has been critically examined by Korns. From his thoroughgoing review Korns reaches the conclusion that the Banti syndrome may be but is not necessarily always caused by syphilis. In fact, he contests outright the views, such as those of Norris, Symmers, and Shapiro to the effect that the disease is invariably syphilitic.

From 170 cases, many of them frequently cited in the literature, Korns was able to select only 36 in which the authenticity of the syphilis and the Banti syndrome was incontestable, and 30 in which it was questionable, thus discarding 104 cases in which no relationship was satisfactorily established. I the syphilitic cases the sclerogummatous form occurs most frequently The liver is reduced in size (weights as low as 700 Gm. have been recorded) and is so widely fissured and lobulated by linear and stellate cicatrices, the residua of healed gummata, that the shape of the liver may be altered out of all recognition. Rolleston ttributes the splenomegaly to amyloidosis or gummatous infiltration, but Korns believes from study of autopsy protocols that simple interstitial fibrosis is the usual picture. Cheadle statement that syphilis is the most important cause of perihepatitis is accepted by Korns as applicable to the thickening of Glisson capsule and the dense and extensive synechias to the diaphragm and adjacent viscera which are of almost universal occurrence in syphilitic Banti's syndrome. The blood picture of secondary anemia, leukopenia and relative lymphocytosis characteristic of Banti' syndrome is found in tertiary hepatic syphilis terminating in the Banti syndrome. Intermittent jaundice, usually mild, and generally obstructive in type; recurrent ascites, hemorrhage, either from the nose or stomach and pain in the upper quarters of the abdomen, are of frequent occurrence The pain is regarded as particularly important as symptom of syphilitic hepatitis.

Korns emphasizes the fact not only that all patients with Banti's syndrome in whom the presence of syphilis can be established should be treated for the disease but that all cases of Banti s syndrome without exception should be subjected to therapeutic test, prolonged and vigorous, before syphilis is finally excluded. Time and again, as he says, in the literature this consideration has been overlooked because of the absence of unequivocal physical signs or confirmatory serological tests. He emphasizes, as will be noted again later the large proportion of these cases that have done well under arsphenamine therapy

THE CLINICAL DESCRIPTION OF LATE HEPATOSPLENIC SYPHILIS AS ILLUSTRATED BY A STUDY OF 73 CASES

In order to secure a fresh impression of the problem which syphilis of the liver presents to the general diagnostician a review of 73 cases in the files of the Mayo Clinic diagnosed as syphilitic hepatitis was undertaken. The material proved to be rich in surprises, and a large proportion of the cases had taken falls out of one or another diagnostician including the syphilologist. Three

were cancers, and 2 were cirrhoses, apparently nonsyphilitic in type,* although associated in one of the cases with a positive blood Wassermann reaction and in the other with a history of syphilis and much treatment.

In accordance with the usual recorded experience in hepatic syphilis, the proportion of women affected, considering the incidence of the disease, was higher than men; 31 women to 30 men, although with the usual incidence ratio, the men should have been much more numerous. McCrae for example found 66 men to 34 women. More than half were in the fifteen-year period of middle life, thirty-five to forty-nine years. In 37 or about half the cases, the duration of the infection was known, and 75 per cent of the patients were in the first and second decades, 35 per cent in the former and 40 per cent in the latter. This makes syphilitic hepatitis one of the earlier of the late complications of syphilis. Three cases ranged in duration from two to four years, representing probably chronic extensions of mild early hepatitis, that did not come under observation.

Distinct mass felt	53 per cent
Liver enlarged much	47 per cent
Tender on pressure	32 per cent
Right-sided enlargement	18 per cent
Mesial enlargement	17 per cent
Left-sided enlargement	13 per cent
Nodular	18 per cent
Mass called right kidney	7 per cent
Mass called gall bladder	6 per cent
Mass called tumor of splenic flexure	1 per cent
Distinctly hard	25 per cent
Distinctly soft	3 per cent
Fixed	3 per cent

FIG. 643.—PHYSICAL CHARACTERISTICS OF THE SYPHILITIC LIVER.

Cachexia and Jaundice.—The appearance of the patient with a syphilitic hepatitis may vary from the most robust good health to a cachexia suggesting a malignant cause. Persistent jaundice is less suggestive of syphilis than of malignant or obstructive conditions.

Sixteen per cent of our patients were jaundiced on first sight—a small proportion. Attacks of jaundice of varying length occurred in an additional 20 per cent (total) and a few had been continuously jaundiced since onset (11 per cent). More than a third of the patients were described as undernourished or emaciated (37 per cent) and weight losses from 2 to 50 pounds were recorded. Gain in weight, stationary weight, or slight loss were frequently observed in very sick patients with marked emaciation, due to the accumulation of fluid in the abdomen and the enormous mass of the liver or spleen. Half of the weight losses ranged between 10 and 25 pounds, so that the constitutional disturbance capable of being produced by this form of syphilis can be rated as considerable.

Physical Characteristics of the Liver (Fig. 643).—The right lobe is the seat of tumefaction in about 18 per cent, and a surprising proportion of the

* J. E. Moore states (personal communication) that he has examined two patients one with syphilitic Banti syndrome and the other with acute hepatitis, jaundice, palpable liver, and fever in both of whom a loud systolic thrill and bruit could be heard over the liver. In both cases aneurysm of the hepatic artery was suspected, but the sign disappeared immediately upon the institution of treatment.

palpable change when localized occurred in the epigastrium and to the left (28 per cent) McCrae has emphasized the importance of left lobe enlargement in diagnosis (49 of 89 cases) and Friedenwald and Morrison found that gumma most often presents at the epigastrium. The fixation of the liver by perihepatitis is a point always to be borne in mind, because it deprives the clinician of the important aid of association of the tumor with respiratory excursion, and hence with liver or diaphragm.

Enlargement of the spleen will be seen to have occurred in 46 per cent of the cases McCrae found it in 50 per cent of his patients.

The nodular liver has not been conspicuous in our experience, although a distinct mass was common finding, producing irregularities in outline. Some of the minor items are of interest as indicating the sources of error the examiner apparently not seriously considering the possibility of a general involvement of the liver in certain cases, so definite was the tumor and so deceptive its characteristics. Fixation of the mass by perihepatitis was the probable cause of error in Fig 608 in which diagnosis of retroperitoneal sarcoma was made

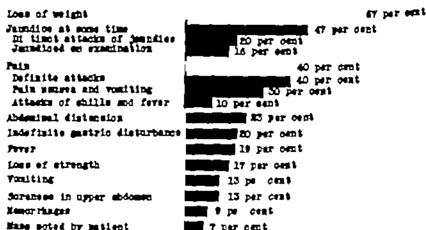

FIG. 644 —THE SYMPTOMS OF HEP TIC SYPHILIS.

Loss of weight and jaundice in 60 per cent of cases in which there is definite history of attacks, pain, nausea, vomiting, chills, and fever are more prominent than distention (field), stomach trouble, and hemorrhages, which are the earmarks of cirrhosis.

Syphilis of the liver can exist without palpable enlargement and with favorable response to treatment. The proportion of cases in which the spleen is not palpable ranges with fair impartiality through all grades of involvement of the liver from normal size to a free border at the iliac crest.

The uniformity of distribution of the splenic enlargement, so generally regarded as an accompaniment of syphilitic cirrhosis rather than of gummatous hepatitis, confirms the impression that the size of the liver of a patient with syphilis is not measure of the degree of cirrhosis which exists, and furthermore that some degree of cirrhosis is common accompaniment of cases in which gummatous masses are the chief presenting sign. The attempt to base clinical diagnosis of the type of syphilitic involvement on physical signs has a liberal margin of error owing to mixed types, although, in general, masses and lobulation are, of course more suggestive of preponderantly gummatous change.

Symptoms and Diagnosis.—Taken in the aggregate without a hypothetic distinction between cirrhosis and gumma, the symptoms of syphilis of the liver (Fig 644) bear a striking resemblance to those of infectious and malig-

nant processes, cholecystitis, cholelithiasis, and perihepatitis. On a symptomatic basis, as well as on signs, gumma is the more conspicuous type of syphilis of the liver although observers such as McCrae and Wile emphasize cirrhosis.

Unquestionably the performance of a routine blood serologic test and the taking of a careful history on all abdominal complexes will increase the apparent incidence of gumma, which has been cloaked under the symptomatic picture of acute hepatic and biliary infections, and may lead to a reduction in the relative clinical prominence of cirrhosis.

Loss of Weight.—Weight loss by untreated patients cannot be taken as having much influence in swinging the diagnosis from syphilis toward malignancy While in general the patient with a mass of syphilitic origin is likely to be in good condition, severe cachexias, with rapid improvement, are not uncommon with hepatic syphilis.

Jaundice.—A persistent, slowly deepening jaundice is suggestive of malignancy The jaundice of syphilitic hepatitis is usually mild and periodic in character It may be produced by exacerbations of hepatitis, and be nonobstructive or it may be typically obstructive with acholic stools, and be due to pressure of lymph nodes or gummas, torsion or constriction from adhesions along the course of the ducts. A persistent slight jaundice may result from interference with the patency of a large bile duct in the liver itself

Pain.—The pain of syphilitic hepatitis is often spoken of as "typical liver pain" in the right hypochondrium but the term is unsatisfactory since radiation to the shoulder seems usually to suggest disease of the gallbladder Prominence of high backache suggested duodenal ulcer twice, and low backache suggested renal colic once, in this series. Definite substernal pain with left-shoulder radiation suggested angina pectoris in a physician who had no cardiovascular lesion and who recovered immediately when his "gallbladder" was treated for syphilis. While the steady pain may be gnawing and described as gastric distress, or a sense of heaviness and weight, the possibility of occurrence of definite attacks in late hepatic syphilis should be borne home vigorously to all who have occasion to make diagnoses of upper abdominal lesions. An attack of syphilitic hepatic or perihepatic pain may be indistinguishable from that of cholecystitis or cholelithiasis. It may come on abruptly be brought on by exertion, be somewhat relieved by pressure last for hours or days, disappear abruptly and leave a tender or sore spot for hours or days. When with this typical gallbladder pain there is associated vomiting, chills, and fever it is small wonder that cholecystitis is the usual first thought, and that a mass in the right subcostal region is interpreted as a distended gallbladder and opened to the chagrin of the surgeon. It was with good reason that Rolleston made it a dictum that every patient with well-marked signs of tertiary syphilis and probable cholelithiasis should have mercury and iodides before operation. In present-day practice the well-marked signs of tertiary syphilis should include blood serological tests in all cases of upper abdominal complaints before operation, as the least measure of precaution against error

Fever —Fever occurred in only 18 per cent of the patients in the series, although it is spoken of as common. It is a probable associate of the softening of gummas, and of perihepatitis and local peritonitis. While resemblances to tuberculosis, typhoid and malaria are noted, in half of the cases there were definite attacks preceded by chills. The rise may be small and of short duration, and almost instant response follows the first administration of arsphenamine.

In one case of longstanding syphilis of the liver a striking febrile Herxheimer reaction was noted In febrile cases with an underlying breakdown of gumma, pointing of the lesion with drainage into the pleural cavity and empyema, has been observed (Rolleston)

Ascites.—Patients who accumulate fluid form a more or less distinct group symptomatically (Fig. 645) which confirms the impression that their condition is a reflection of the special pathology of syphilitic cirrhosis Ascites, especially if transient, may however be the result of perihepatitis and peritonitis, beginning at the site of a gumma, or of obstruction of the portal vein in the portal fissure by pressure. Transient obstruction of the portal circulation by an acute diffuse exacerbation of chronic interstitial hepatitis with accompanying tran-

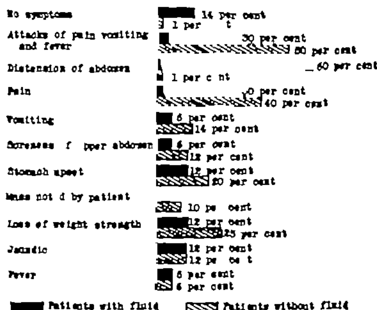

FIG. 645 —COMPARISON OF SUBJECTIVE COMPLAINTS IN P TIENTS WITH HEP TIC SYPHILIS Patients who accumulate fluid have fewer conspicuous complaints and more insidious course than those who d not.

ment jaundice may lead to the intermittent ascites, which McCrae regarded as distinctive of syphilis of the liver Comparatively small livers are commoner in the absence of ascites than with it, so that the clue to the cause is to be found not so much in the mere size of the liver as an index of cirrhosis as in the intimate pathologic condition which it is seldom possible to analyze clinically The large liver may be the seat of a diffuse obstructive process which blocks the portal return, or of an inflammatory process which sets up peritonitis or local obstruction, even more frequently than the supposedly contracted small liver

In Stokes study of ascites in the present group of cases, the observations, summarized in Figs. 645 and 646 were made. Ascites is not common complaint of syphilitic hepatic disease in the aggregate, being present in only about one third of an verage series such as ours. Normal or only slightly enlarged livers occurred in 36 per cent of cases of ascites, and large livers in 51 per cent; in the remainder the liver was medium sized (6 cm. below the costal margin). On the other hand, normal or only slightly enlarged livers occurred in 50 per cent of cases in which there was no ascites, and very large livers in only 14 per cent.

Symptomatically the patient who develops ascites is a less clamorous claimant for medical attention than is the one who does not accumulate fluid The onset is likely to be *insidious, and the first warning simply* a distention of the abdomen (Fig. 645) Attacks of various types, pain, loss of weight and strength, and gastric upsets, all seem to be more conspicuous when patients remain free from fluid. This again points to the cirrhosis as the most common cause of ascites. Localized gumma produces the more stormy symptoms, al though again the size of the liver need not be an index of the degree of cirrhosis, or at least of portal obstruction. Jaundice and ascites showed no constant relation that was detectable in this series of cases, the former occurring as often with the latter as without.

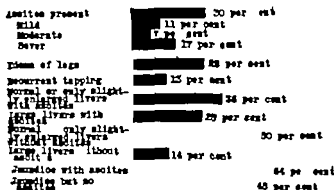

FIG. 646.—FINDINGS ASSOCIATED WITH ASCITES.

Evidently it is not the small liver that produces ascites. The proportion of large livers is higher in ascites and lower in its absence. Jaundice and ascites show no interrelation.

It has been suggested that fluid is the result of longer duration of the syphilitic involvement, with corresponding tendency to cirrhotic contracture. In the aggregate we could not find any significant difference in the duration of either infection or symptoms in the cases in which there was no fluid. The complexity of the factors involved evidently defeats generalization of this sort.

The Alcohol Factor —Chronic alcoholism long regarded as the cause of a special type of cirrhosis, and as contributory to the cirrhotic manifestations of hepatic syphilis, has lately been refused recognition by Wile and experimental reproduction of an alcoholic cirrhosis seems to have been impossible *in animals (Robertson) It is our clinical impression* however supported by cases such as Figure 641 and Schumacher's observations, that alcohol is definitely influential as a facilitator in the production of hepatic cirrhosis in syphilis. McCrae found that 62 of 70 patients used it freely but this does not, of course prove a causal relationship The examination of this point in the Mayo Clinic series, while inconclusive because of the small number of patients who used alcohol (22 of 70) suggests that while alcoholics show no distinctive effects of the drug in the size of their livers, and alcohol is not necessary to the production of a full-fledged syphilitic hepatitis, the regular and heavy drinkers are none the less definitely more often the victims of ascites (Fig. 647) and have a correspondingly worse prognosis than nonalcoholics (Fig 658) The mechanism of such an action, if it exists, is too complex for definition in a clinical study

Hemorrhage.—Hemorrhage is generally accepted as more common in cirrhotic contracted livers as the product of the rupture of the varices developing with vascular obstruction

Seven of this series of patients (10 per cent) had hemorrhages as definite feature of their course. Six vomited blood, and two passed blood by stool in recognizable amounts. The livers of all the patients were not enlarged, or only slightly enlarged, suggesting the cirrhotic factor. The spleens were variable, from normal to greatly enlarged (Banti syndrome) Three of the 7 patients had had marked ascites. The possibilities of diagnostic confusion which center around this symptom are interestingly pictured by Fig 678. A second case in which duodenal ulcer

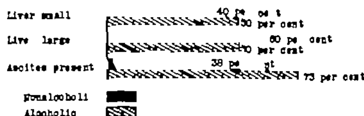

Fig. 647.—Size of Liver and Presence of Ascites in Alcoholics and Nonalcoholics

Although alcoholism does not seem to influence the size of the syphilitic liver markedly ascites is definitely more marked in alcoholics with syphilitic hepatitis.

had been diagnosed by roentgen ray was found. Dietary measures failed to give relief, and the patient died later of repeated hemorrhages following treatment for syphilis, in which it is possible that rapid shrinkage of the liver and portal obstruction combined to produce the hemorrhages without the presence of duodenal ulcer Such possibility of error in diagnosis deserves further study

The Blood Picture.—The blood picture (Figs. 648, 678) associated with the hepatosplenic complexes revealed the widest range of variation and the most interesting possibilities from the standpoint of diagnosis, but showed no

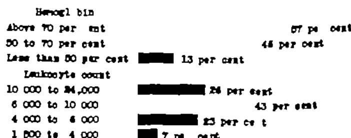

Fig. 648.—Blood Picture in Cases of Syphilitic Hepatitis.

There is no constant relation between size of liver and spleen and blood picture. There is no constant relation between leukocytosis and fever

constant relation between the blood findings and the physical findings. The simulation of Banti's cirrhosis with splenomegaly and of splenic anemia with anemia, leukopenia, and splenomegaly was illustrated by 2 cases.

In the first case a man with a hemoglobin of 36 per cent, erythrocytes 2,670,000, and leukocytes 6700, had a greatly enlarged spleen and slightly enlarged cirrhotic liver The patient had had hemorrhages. There was marked ascites, coming on two years after intensive arsphenamine treatment. The blood Wassermann reaction was positive, and the history of syphilis quite definite. No further treatment was undertaken and the patient subsequently died, without necropsy Clinically at least, he had typical Banti's disease associated with syphilis. As Rolleston remarks,

the fact that a patient in the hepatic cirrhosis group does not respond to treatment for syphilis does not disprove the ultimate syphilitic etiology since the damage to metabolism and the introduction of incidental or secondary factors due to lowered resistance may be enough in itself to tip the scale toward a bad result.

The second case, man with hemoglobin of 83 per cent, a red blood count of 3,080,000, and white cell count of 1800, had greatly enlarged spleen, but the liver was not palpable. There was no ascites and there had been no hemorrhages. Although the blood Wassermann reaction was repeatedly positive, there was no history of syphilis. Treatment was refused, and none had been given previously The patient died elsewhere, without necropsy Clinically the condition belongs rather with the splenic than with the hepatic group, and must be regarded as not proved so far as syphilitic etiology is concerned.

The possibility of deception afforded by nephritis or other extrinsic cause for anemia in a patient with syphilis and hepatitis is illustrated by woman with hemoglobin of 30 per cent, a red blood count of 3,000,000, and white blood count of 10,400, who had greatly enlarged cirrhotic liver large amount of fluid, compensated aortic lesion, and marked nephritis. A most favorable temporary response followed mixed treatment for syphilis by mouth.

Pseudopernicious anemia symptomatically at least, associated with hepatitis and splenitis, is illustrated by the case of woman with hemoglobin of 80 per cent, sore mouth, diarrhea, and achlorhydria. The liver was greatly enlarged, the spleen only palpable. The red blood cell count, however established the secondary character of the anemia (3,850,000, with a color index of 0.4) The white blood count was 6500, the blood Wassermann reaction was weakly positive in the first test and strongly positive thereafter The response to treatment was very gratifying, although, as is often the case the persistence of slightly subnormal hemoglobin and red cell count for several years was observed.

The Kidney —An early impression to the effect that the kidneys of patients with severely involved livers were unusually sensitive to treatment irritation was not borne out by this survey In fact, the normality of the renal mechanism was remarkable in a group in which, with extensive damage to the liver one should expect a high incidence of amyloid degeneration.

In only 1 case did the persistent presence of large amount of albumin with comparatively normal renal function suggest the existence of an amyloid degeneration, and this patient recovered completely with three years of treatment. The liver was greatly enlarged, but the spleen was not palpable. That the nephrosis was not entirely due to amyloid, but more probably to the effect of chronic focal infection, was suggested by the improvement which followed the extraction of number of apically infected teeth. A second patient had chronic cardiorenal complex. Only 2 other patients, besides those mentioned, disclosed definite evidence of renal irritation during treatment, an unusual showing even for young and robust persons, and not t all suggestive of marked damage to the kidney by changes associated with syphilitic hepatitis and splenitis.

SYPHILOLOGICAL FINDINGS IN SYPHILITIC HEPATITIS

The prop of clinical diagnosis in hepatic disease, so far as syphilis is concerned (Fig. 649) is the blood serologic reaction, which has reduced greatly the time requirements and exactions of the former diagnosis by therapeutic test. It has, at the same time extended equally our comprehension of the deceptive possibilities of clinical syndromes. The frequency with which in this series at least, the blood serologic reaction, routinely applied to all patients with complaints referable to the upper abdomen, would have prevented a diagnostic misinterpretation or a disappointing surgical intervention, was instructive. Nothing less than the application of the blood serologic tests before operation to every patient with a surgical lesion of the abdomen would protect the patient from error in diagnosis of syphilitic liver and biliary tract disease That the therapeutic test must follow the finding of the positive serologic reaction in certain cases in order to eliminate the possibility of mere coincidence is as true now as in the day of Rolleston s dictum. Every patient who has

repeated strong positive blood serologic reactions with a hepatosplenic syndrome or a gallbladder syndrome is entitled to a therapeutic test before operation unless he is a critical surgical emergency From the case records it will be apparent that this dictum should be extended to include patients with symptoms of pancreatitis and pancreatic tumor mesenteric tumor and so forth. The service of the blood serologic reactions in these cases is to release us from the uncertainties of palpatory diagnosis, so far as syphilis is concerned, or at least to bring syphilis constantly into the field of suspicion. As such it should be fully utilized. The reduction in incidence of diagnostic error in this group of syphilitic patients in the Mayo Clinic after the adoption of the routine blood serologic test on all surgical patients was very marked

False Negative Serologic Reactions in Syphilitic Hepatitis.—Figure 649 presents the relative importance of the various items which constitute an examination for syphilis in the hepatosplenic group of cases.

False negative serologic reactions and fluctuating returns must be expected at times, whether of intrinsic or technical origin, in syphilis of the liver

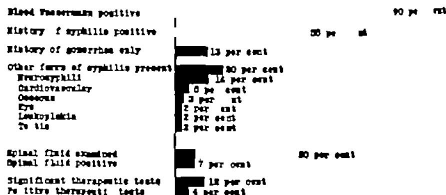

Fig. 649 —Syphilological Findings in Syphilitic Hepatitis.

McCrae found 8 negative cases in 41 of hepatic syphilis and 2 in 73 late cases appeared in this series.

The high incidence of positive blood serologic reactions is not, merely the result of serologic diagnosis, but of genuine trend to uniform positiveness with reasonably sensitive technic in a very large proportion of cases of hepatic syphilis. For some years, in watching the run of such cases through the Mayo Clinic, Stokes was almost convinced that a negative blood Wassermann reaction, repeatedly obtained, excluded syphilis of the liver outright. In studying this series of cases, however two examples of persistent Wassermann negativity one confirmed by operation as syphilitic hepatitis, the other by completely successful therapeutic test, were found. A third case that of physician who proved by therapeutic test to have syphilitic gallbladder syndrome, had negative blood Wassermann reaction repeatedly before coming to the clinic, and had received diagnoses of angina pectoris, and gallstone colic, accordingly His test was repeatedly positive with the Kolmer technic, and he had definite history of digital extragenital infection with scar The response t treatment as immediate, operation being rendered unnecessary

False Positive Serologic Reactions in Carcinoma of the Liver—The question of a false positive tendency in the blood serologic test in carcinoma of the liver is important and, so far as our experience goes, can be answered in the negative. It is, however almost impossible to prove the absence of syphilis clinically in a patient with repeatedly positive blood serologic reactions and cancer of the liver short of necropsy and, even then, because of the fact that

syphilis of the liver occupies the early middle period of the average lifetime of a patient with syphilis there may be little to clinch the diagnosis in the general pathologic findings.

In investigating the possibility of obtaining false positive blood serologic reactions in carcinomatous involvement of the liver the records of 168 patients who had come to autopsy at the Mayo Clinic with carcinomatous livers were examined. In this group 2 had strong positive blood serologic reactions, an incidence of 1 8 per cent and one a weak positive. One of the 3 patients had an incontestable syphilis of the nervous system with positive spinal fluid in addition to the positive blood (Fig 671) and the postmortem findings of the second strong positive case were incomplete. The weak positive was unsupported. In any case the incidence of definite false positives scarcely exceeds the margin of error which may ordinarily be expected of the average serologic test.

Nonspecific Effect in Nonsyphilitic Hepatitis.—We have seen nothing to lead us to suspect a nonspecific effect on hepatitis of nonsyphilitic origin from arsphenamine other than the apparent shock in Fig 671 In fact, the nonsyphilitic liver as in cases of cancer or in what appears to be a nonsyphilitic cirrhosis, responds unfavorably or the process advances at the usual rate without response.

Collateral Evidence in Diagnosis.—The examiner cannot hope to secure assistance from collateral clinical findings, excluding the blood Wassermann test, in more than 20 to 25 per cent of his cases. The conspicuous exemption of the nervous system has been a matter of comment among observers in pre-Wassermann days, and the cardiovascular system seems likewise to be protected to no small degree. The other protective" groups of structures, such as the bones and the skin are also remarkably free from involvement and may be imagined as not having been drawn on for physiologic defence because of the efficiency of the liver and spleen in supplying a protective mechanism. Because of the probable high incidence of Wassermann positiveness in cases of syphilis of the liver the relative value of the history of syphilis can be fairly judged, and does not greatly exceed 50 per cent, as compared with 90 per cent for the blood test. The interpretation of and methods for applying the therapeutic test in suspected cases of syphilis of the liver will be discussed under the head of treatment.

The Differential Diagnosis and Sources of Diagnostic Error in Late Syphilis of the Liver—Rolleston's monograph described seven common sources of diagnostic error in connection with late syphilis of the liver applicable to the diagnostic problems of pre-Wassermann days. These included (1) symptoms of syphilis of the liver suggestive of portal cirrhosis, or simple chronic peritonitis and perihepatitis (2) amyloid (3) tumors of the liver including malignant growths, hydatids, and enlarged gallbladder (4) hepatic suppurations and abscesses (5) symptoms suggesting cholelithiasis (6) imitations of chronic splenic anemia, and (7) cases suggesting hypertrophic biliary cirrhosis. The extension of knowledge has, of course, brought syphilitic hepatic cirrhosis to the front at the expense of other types. Amyloid, in our experience at least as a demonstrable clinical entity is of minor importance. In only 1 case did the behavior of the kidney suggest its presence We have not seen a case of syphilitic abscess of the liver and know of no clinical differential criterion other than the serological reactions and other evidence of syphilis, in a febrile patient with a nodular irregular or lobulated liver evidently the seat

of gummatous changes. Suppurative cholangitis may be deceptive if the patient has coincident syphilis, and must be surgically explored if the patient's condition is at all serious, in preference to attempting a therapeutic test. There remain, then, of Rolleston's group, the misinterpretation of tumors, mistaken diagnoses of cholelithiasis, splenic anemia, and perihepatitis, as the chief sources of diagnostic error linking the older syphilology with the new.

Figure 650 summarizes the material contained in the histories of our patients.

The diagnosis (elsewhere) prior to entering the Mayo Clinic is based on letters of introduction, and the patient's statements, and covers 37 cases. It cannot pretend to represent the actual achievement of the physician at large in the diagnosis of syphilis of the liver inasmuch as patients whose conditions have been correctly diagnosed seldom predominate in the Mayo Clinic. On the other hand, the proportion of correct diagnoses seems rather low even for special circumstances, and the almost wholesale overlooking of syphilis among the patient's ailments is much in point. By the "overlooking" of syphilis, we mean, for example, that patient who has large nodular

Fig. 650

DIAGNOSTIC ERROR IN SYPHILIS OF THE LIVER

Based on study of 73 cases.

Diagnosis.	On referral per cent.	Preliminary per cent.	Final per cent.	Surgical per cent.	Exploration per cent.	Aggregate per cent.
Correct	9	52	63	18	50	47
Partial (syphilis minimized or overlooked)	18	5	8.5	24		7
Indeterminate	9	5	12.5	12		10
Incorrect	64	38	16	46	50	36
Total syphilis overlooked	82	43	24	70		43

liver and symptoms of gallstones may receive a diagnosis of gallstones, confirmed on exploration, but the multiple gummas and lobulated liver then identified, escaped the diagnostician entirely.

Several important points should be recalled in connection with Fig. 650. Some of the cases included date back to a first examination in 1911 when the blood Wassermann reaction was anything but routine feature of medical practice although available in these cases. Many of the cases fall in the era when Wassermann tests, while available, were little utilized. Precise data on the employment of the blood Wassermann test with negative results by physicians elsewhere are not available, except in 1 case, in which three ordinary blood Wassermann tests were negative but the Kolmer technic, used after the patient entered the clinic, gave two strong positive results. In fairness to surgical diagnosis, it should be pointed out that the surgeon is not called to see the large proportion of patients in whom he quite as well as the medical consultant, could make diagnosis of syphilis of the liver on sight. He is merely called to see patients whose surgical complications are suspected by the medical man, who is supposed to have satisfied himself before calling surgeon that syphilis is not the cause of the patient's condition. On the other hand, it should give the surgeon pause to find that he has overlooked syphilis in so high proportion of cases as 70 per cent, and has an incorrect preoperative diagnosis in cases of syphilis of the liver averaging 46 per cent. Some of the errors are avoidable, especially if the surgeon will raise his index of suspicion. By 50 per cent correct explorations (in a total of 16 performed) is meant that surgically treatable condition was found in half the explorations advised (6 of biliary tract lesions and 2 splenomegalies). The 50 per cent of "incorrect" explorations yielded such

findings as are illustrated in the case summaries; gummatous livers with no signs of the expected lesion of the gallbladder; gallbladders bound down by the adhesions of perihepatitis obviously of gummatous origin, active hepatic cirrhoses of the syphilitic type; supposed malignant metastatic lesions which proved to be gummas; and pancreatic and mesenteric tumors which likewise proved to be hepatic gummas, especially of the left lobe. The aggregate accuracy of diagnosis is based on the entire series, and represents the result for the patient so far as could be ascertained, of examination by home physician, clinic medical examiner medical consultant, and surgeon, when called. The average is, of course, lower than that of medical consultants, because single known error on the part of any of the group of four puts the patient in the debit column. In way the result suggests that he who invites difference of opinion among several is less fortunate than he who is able to rely on the comprehensive work-up of one expert, such as the medical consultant.

Causes of Diagnostic Error.—Failure to make a blood serologic test, or properly to interpret it, stands as the overwhelming cause of diagnostic error (Figs. 651–653) The positive blood Wassermann reaction points to syphilis and, while it should not be uncritically accepted as explaining everything in the case (an uncritical acceptance is illustrated in Fig 671) the profession at large cannot afford to substitute its imperfect physical diagnostic acumen for this readily available protection against certain blunders in cases of upper abdominal lesions. In particular the syphilologist and the medical consultant

Failure properly to use the Wassermann
Physical findings deceptive
Supposed gallbladder symptoms
Supposed renal symptoms or signs
Malignancy suspected
Gastric ulcer diagnosed not found
Gastro-intestinal ray omitted lared

FIG 641 —PRINCIPAL SOURCES OF ERRONEOUS DIAGNOSIS IN 37 CASES OF HEPATIC SYPHILIS.

should insist that the protection of patient and surgeon from mistakes involving syphilis requires the performance routinely of a blood serologic test and reasonably careful attention to a history of syphilis in every patient who is considered for an abdominal operation. This series of cases includes 8 (21.5 per cent) of diagnostic errors, in which a Wassermann test before operation might have prevented error and 2 cases in which clear-cut histories of syphilis were overlooked until the operative findings led to further questioning.

Deceptive Physical Findings.—These (Fig. 653) are of much importance in the correct diagnosis of syphilis of the liver being factors in error to the extent of 60 per cent. It is only necessary to review the older literature to realize the immense burden of palpatory diagnosis that has been lifted from the shoulders of the physician in his effort to identify syphilis of the liver among the many possibilities suggested by the "feel." The details in the series of cases include

The mere occurrence of a mass or tenderness in the region of the gallbladder does not, of course, eliminate syphilis or justify the omission of the serologic tests. It is entirely possible for a gumma to be indistinguishable from a gallbladder and even for a cystic or enlarged gallbladder to be the product of retention, due to the adhesions of perihepatitis or enlarged nodes in the portal

specific perihepatitis or hepatitis is a puzzling question. From repeated observation of such cases, we are inclined to extend the maxim of Rolleston to the present day and to say that a patient with syphilis who has symptoms of gallbladder disease should not be operated on except in acute emergency until he has had at least one and better two courses of treatment for syphilis, and not merely a preparatory treatment or two. If symptoms recur after the patient is under complete treatment control, operation may of course be indicated, though even then only syphilis may be found.

Symptoms and Signs Suggestive of Lesions of the Kidney.—These served as a source of error in 7 cases (20 per cent) of the series. The attacks of pain in cases of gummatous hepatitis may occasionally suggest the seizures of renal colic (2 cases). The chief source of diagnostic perplexity, however, arises from the position of the gummatous tumor, or the greatly enlarged right lobe of the liver.

If the gummas are large, and obliterate the contour of the liver margin, a lobulated tumor markedly suggestive of polycystic kidney is produced (Fig. 672). The weight of the gummatous mass may be so great as to produce prolapse to the iliac crest, so that it is almost possible to get above the mass by palpation, or at least to believe it entirely below and free from the liver, and hence probably renal in origin. Gummas of the left lobe may produce excellent imitations of a prolapsed left kidney clearly distinguishable from the spleen, if it is enlarged. The possibility of diagnosing an abnormal kidney is increased by functional changes, such as occurred in a case examined by Braasch (Fig. 672) in which the right kidney had twice the functional capacity of the left, with evidence of slight infection on the right. The mass on the right was subsequently proved by treatment to be a gummatous liver, and the suggested left kidney turned out to be the spleen. A marked nephritis with ascites and edema may cover the underlying gummatous hepatitis and splenitis, and only when the renal condition improves under treatment for nephritis may the relaxed, but still fluid-containing abdomen permit a palpatory diagnosis to be made. We are opposed to the tapping of patients with hepatogenous ascites, and so do not recommend paracentesis as an aid to the differentiation of nephritic from cirrhotic ascites. In the nephrosis associated with amyloid degeneration, the large amyloid liver or spleen may be identified, but we know of no way, except by therapeutic test, to identify an amyloid degeneration associated with syphilis. The amyloid kidney retains its function, and the blood urea, water output, and phenolsulphonephthalein excretion remain within normal limits, in spite of the high albumin content. In the one case in which amyloid kidney was suspected, recovery took place in the course of three years, coincident with the return of liver and spleen to practically normal size.

Miscellaneous Sources of Error.—A variety of other diagnostic problems associated with syphilis of the liver presented themselves less conspicuously in the series as follows:

Confusion with Malignancy.—The importance of a routine examination of the stomach by roentgen-ray and test meal in disease of the liver needs no emphasis. To make a clinical diagnosis of metastatic cancer without it is obviously impossible, for the achlorhydria so common in syphilis may not be distinguishable from that of cancer, and left-sided epigastric tumor does not necessarily come from the stomach. On the other hand, in one of our cases an enormous liver supposed to be syphilitic in a patient whose Wassermann reaction was positive and who had neurosyphilis, was found to be carcinomatous, from a primary adenocarcinoma in the stomach, although the roentgenogram was reported negative (Fig. 671). It is important, in connection with the question of malignancy, to emphasize the unwisdom of making merely gross examinations of the abdominal viscera during explorations. A liver studded with nodules may be gummatous, not malignant, as was found in Figure 670, in which the surgeon, even when confronted with a pathologic report of fibrous and necrotic inflammatory tissue from an excised nodule, found it impossible to accept the finding as excluding malignancy, and roentgen-ray treatment was given without result; the patient recovered subsequently under treatment for syphilis. Surgical descriptions of undoubted gummas indicate a wide range in gross appearance in the living patient, from merely flesh tumors indistinguishable from liver tissue to the pale nodular infiltrates of the more superficial or older lesions. Another fact of great importance in connection with the question

of malignancy is that it cannot be eliminated simply by short therapeutic test. Observation over a period of two years or more is often necessary before one can be fully satisfied of the correctness and exclusive character of diagnosis of syphilis of the liver The liver should be carefully watched during treatment; the appearance of definite new masses, especially elsewhere in the abdomen, strongly supports malignancy even in the face of clinical improvement, although it does not prove it. This consideration occasionally justifies exploration before treatment is begun, in order to relieve the patient of uncertainty but we are inclined to believe that this sort of exploration should not be made routinely disregarding the risks of laparotomy

Other Errors.—An important possibility of confusion with duodenal ulcer in cases in which there is hemorrhage into the gastro-intestinal tract exists. In one such case in which the spleen could not be felt, owing to adhesions, the roentgen-ray findings were those of duodenal ulcer which could not be found t operation (Fig. 674). In another case the nocturnal backache, with epigastric pain and gastric symptoms, suggested duodenal ulcer clinically but the roentgen-ray findings were negative. It is, indeed, surprising that this error was not more common, since it is easily understandable. Tenderness at McBurney point and symptoms typical of appendicitis occur but, from the frequency with which chronic appendicitis is found at exploration, we are inclined to believe that the appendiceal symptoms are coincidental, and not part of liver syndrome due to syphilis. Right-sided pleurisy was the first diagnosis in 2 cases (Fig. 666),

Fig. 653.

MISCELLANEOUS MINOR CAUSES OF ERROR IN DIAGNOSING HEPATIC SYPHILIS BASED ON A STUDY OF 73 CASES

	Cases.

Hasty Surgery	1

evidently an expression of perihepatitis on the lateral surface of the right lobe of the liver It was followed later by typical hepatic symptoms. It is matter of some surprise to us that tuberculous peritonitis was not more frequently confused with syphilitic hepatitis, especially in patients with ascites. The absence of diarrhea in cases of syphilitic hepatitis (though sometimes present in pancreatitis), and the doughy masses of adherent gut and glands assist in distinguishing the late cases. The stools should be examined for fat and for tubercle bacilli.

One patient in the series illustrated a very trying possibility of error the confusion of the attacks of pain in cases of syphilis of the liver with anginal seizures. Hepatic attacks are seldom short enough for the average anginal picture, but they may be agonizing and radiate up into the chest, and even to the left arm, if the left lobe is involved. It is important in all suspected diseases of the liver due to syphilis to roentgen-ray the thorax and abdomen for aneurysmal dilatation of the aorta; this occurred in one of the cases, and was an important element in symptoms and prognosis.

Attacks of gastric crisis in tabes dorsalis, if associated with enlargement of the liver may provide most puzzling picture, as attested by the number of patients with crises who have upper abdominal scars, although this group contains no cases in point. (See Chapter XX.) The recognition of the tabetic type of neurosyphilis, the prominence of gastric symptoms as compared ith hepatic, the obstinate and conspicuous vomiting element, and the superficial or skin

tenderness, as contrasted with the deep soreness of the syphilitic hepatic or gallbladder attack, serve to distinguish most cases. The liver subsides promptly under treatment, although the crises recur periodically for a much longer time.

To summarize the outstanding points, then, the routine use of the serologic tests may be urged on all physicians as an aid in the interpretation of abdominal lesions with reference to the syphilitic liver. In our experience, at least, there is more danger of its underuse than its overuse, although uncritical interpretation of the findings in patients with positive serologic reactions is *always to be avoided. There is a serologic negative syphilis of the liver* but it is, so far as our present experience goes, uncommon. The average diagnostician should accustom himself to think of syphilis as able to reproduce every feature of biliary tract and hepatic disease, and to raise his threshold of suspicion to the point where he can cope with it. The more reliance he places on physical findings and history, as contrasted with serology and therapeutic test, the larger, in all probability, will be his error with respect to syphilitic hepatitis.

THE TREATMENT OF SYPHILIS OF THE LIVER AND SPLEEN

Modern methods, instead of simplifying the problem of treatment of syphilis of the liver, have increased its complexity, albeit, with proper application of fundamental principles, these methods have likewise improved the outlook of the patient for a permanent result and restoration *to functional* normality. The successful treatment of hepatic syphilis is a problem as special as the treatment of syphilis of the cardiovascular system, and much more difficult than the management of gastric syphilis.

The Rationale of Treatment.—Certain general considerations must be constantly kept in mind in the management of hepatic syphilis. In the first place, the liver is sensitive to heavy metals, and in any system of treatment in which arsenic plays an important part, it may be expected to sustain a certain amount of damage, which may or may not lead to embarrassing complications. In the second place, both liver and spleen are storage depots for arsenic and they act as accumulators of the drug whenever arsphenamines are used, whether in the treatment of general syphilis or of syphilis of the liver and spleen as such. It is to be expected, therefore, that the structurally damaged liver and spleen will have a reduced storage capacity and show symptoms of irritation earlier than the normal organs whose parenchymatous reserve has not been cut down by disease. They will likewise presumably throw a heavier burden on other structures in which the drug may accumulate, such as the skin. In the third place, fortunately for patient and therapist, the liver especially has a large parenchymatous reserve, and much of its substance can be replaced by gummatous infiltration or fibrous scar *with good recovery*. In the fourth place, the liver contains a vulnerable vascular mechanism in the form of the portal system, which must be kept intact as far as possible. If this mechanism is too extensively damaged, the influence on the general nutrition of the patient is such that while he might survive his mechanical defect, he cannot survive it in combination with undernutrition and damaged metabolism. Mechanically, blockage of the portal system, whether of its capillary branches by diffuse fibrosis, or of its larger radicals by pressure from gummas, or distortion by scar contraction, must be compensated for. Out of the foregoing considerations arises the fifth point, that the liver must be protected in every possible way, as must the myocardium, from the effects of fibrosis, whether due to the slow inflammatory processes of the disease, or the effects of rapid scarring by intensive treatment.

The Hepatosplenic Therapeutic Shock.—The liver and spleen are among the ideal sites for the Herxheimer reaction and the therapeutic paradox. They are favorite locations for *Spirochaeta pallida* and show, therefore, a pronounced flare-up in spirillicidal methods of treatment when large doses are employed at the outset. In the case of the spleen the therapeutic shock is of little consequence. *In the liver, however, the effects of a severe Herxheimer flare-up* may be prolonged and serious, and even precipitate a toxic reaction that may be fatal. Since the liver and spleen

are storage depots for spirochetes as well as arsenic, it should follow that incomplete destruction of the organisms by treatment will result in a correspondingly rapid and serious relapse. The exact status of this hepatorecurrence on which the French writers and especially Milian have laid so much stress, is not as yet worked out, but it undoubtedly exists, and may be the explanation of certain supposed toxic jaundices from arsphenamine. It follows, therefore, that any treatment of the liver for syphilis must be carried through to prevent relapse and a state of affairs worse than at the outset. Several cases in this series illustrate this point.

Therapeutic Paradox.—The therapeutic paradox in syphilis of the liver differs in no essential particular, so far as its mechanism is concerned, from that in the cardiovascular system. In the spleen, because of its relative unimportance the therapeutic paradox is usually of small moment. The presumption is that the earlier in the course of syphilis involvement of the liver can be detected, the better the outlook for escaping the therapeutic paradox. This most important consideration calls again for an increasing application of the routine serologic test to all patients, and special regard on the part of the physician for the possibility of syphilis in those of his patients who present palpable livers and spleens. Figure 657 is an excellent example of the penalties which the patient must pay for the failure of the clinician to appreciate the import of an enlarged liver. Escape from therapeutic paradox by way of the older less intensive method of treatment is not as simple as it seems at times. Another patient was recognized as having syphilis of the liver in 1911. Six years of mixed treatment by mouth, while it retarded the course of her disease, in all probability failed to produce a curative result, and in 1917 she was seen again with an advanced aortitis, the liver about as large as formerly but evidently now cirrhotic, and an ascites of extreme grade associated with a nephrosis. Treatment for syphilis of the liver, moreover, while taking account of the peculiarities of the structure mainly involved, should, none the less, be also effective treatment for syphilis, and should not, while holding a relatively benign process in check, permit

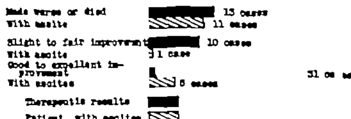

Fig. 656.—Therapeutic Results in 45 Patients with Ascites.

the development of a grave syphilitic complication such as aortitis. This is, of course, not a reflection on the management of cases seen in the first decade of this century when arsphenamine, if it had been applied at all, would probably have brought about disaster through relapse.

The three types of hepatic and splenic lesions with which one is called on to deal in syphilis require different types of therapeutic management. Early syphilis of the liver and spleen is an acute parenchymatous inflammation, recovering easily under ordinary treatment in most cases and leaving few or no residua, but prone to relapse (Fig. 641) if not sufficiently treated, and disposed to sharp reaction if given a severe therapeutic shock (Fig. 676). Late syphilis of the liver usually combines two types of lesion, the local gumma and the diffuse infiltration, which have radically different prognoses under treatment. The solitary gumma resolves readily under any intelligent management, seldom leaving a scar which has any ill effects, and often healing spontaneously even to the resolution of the perihepatitis and adhesions over the involved surface. Relief from pressure phenomena and the secondary effects of peritonitis, including transient jaundice and ascites, is usually prompt and there are no late by-effects. On the other hand, general damage to the liver with extensive fibrosis is the earmark of cirrhotic hepatitis and of those cases in which the cirrhotic phase is uppermost. Intensive treatment in such patients gives rise within a short time, varying from a few days to several months, to the therapeutic paradox (Fig. 677). Herxheimer reactions, with transient swelling and further obstruction in these seriously damaged livers, are often grave, and it is the usual thing for the patient to get distinctly worse, especially as regards ascites and jaundice if present, during the first few weeks of almost any treatment regimen. The rest period in which the patient reestablishes his functional equilibrium becomes, at times, more important than the treatment phase of his management.

It is apparent, then, that one of the most important questions the therapist is called on to answer when he assumes charge of a patient with syphilis of the liver concerns the relative proportion of localized gumma formation, and of diffuse inflammatory infiltration which the given

case presents. It is rarely possible to answer this question with the satisfying definiteness that would make one feel safe in boldly giving a patient with pure gumma liberal doses of arsphenamine, while giving a long iodide course to the cirrhotic patient. The processes are usually so intermingled that some disagreeable surprises inevitably await the overenergetic therapist. Inasmuch as prognosis is involved in the decision there are, however, certain guides which assist in determining the outlook. The age of the infection is, of course, of value in "latent livers," but untrustworthy in fully established cases. Intermittent symptoms and a stormy course of chills, fever, and the accompaniments of localized perihepatitis suggest gumma rather than cirrhosis, and these patients usually tolerate the more vigorous treatment and rapid approach (Fig. 661). Insidious onset, with fluid accumulation as the first sign, and gradually progressive distention, point to cirrhosis. The presence of ascites, then, is a distinctly unfavorable feature in the aggregate, and a definite warning to proceed slowly, although there may be exceptions due to obstructive action of gummas, enlarged glands, or perihepatitis in the portal fissure. Patients with syphilis of the liver with abdominal fluid require the most skillful management, and can seldom be promised the best results unless they can devote weeks and even months to proper preparation and to the establishment of their compensatory mechanism. Figure 656 illustrates the difference in prognosis of patients with ascites, as compared with the aggregate.

The physical characteristics of the lesion of the liver are of some assistance in deciding on the type of treatment, although by no means always trustworthy. The sharply defined, rapidly developing tumor with acute symptoms is usually a gumma, and if the antecedent process is not of too long duration, the patient will probably require less preparation than the patient with the cirrhotic type of disease. Diffuse enlargement of the liver, late in the disease, with few symptoms, should be thought of as probably fibrotic, the size or consistency of the liver not being trustworthy as a decisive point between acute diffuse gummatous hepatitis and old cirrhosis. *Hepar lobatum* is not always amenable to vigorous treatment. The damage to such a liver may also be diffuse, and its further distortion by rapid healing of multiple gummatous foci may bring on a therapeutic paradox.

While pathologists may hesitate to accept the instrumentality of alcoholism in the production of hepatic cirrhosis, my experience at least indicates that the fate of the drinker with hepatic syphilis is distinctly less favorable (Fig. 656) than that of the nondrinker. The prognostic relation corresponds quite closely to the relation between alcoholism and the incidence of ascites as previously shown.

Treatment of Early Acute Hepatitis.—The advent of bismuth has simplified the situation here, making it possible to treat these patients vigorously and at the same time fairly effectively so far as response of surface infectious lesions if present is concerned, until the return of the icterus index to normal as in Elliott and Todd's case. Personally we believe it entirely safe at this point to resume or institute the use of an arsenical in moderate doses in the effort to secure a curative effect in early syphilis.

Grave icterus should be watched for in all patients with syphilis who present jaundice early, as well as in others in whom it may occur without warning, for an early diagnosis is essential if the patient is to be saved. Here again, bismuth, vigorously employed, may be expected to be superior to mercury, the first choice in the past, and preferable to the theoretically objectionable arsphenamine. Wile's case responded to calomel intramuscularly and iodide by mouth. Some of the problems which a grave icterus may present are well illustrated by Fig. 676.

Etiologic Differentiation and Treatment of Various Types of Jaundice.—The decision of the syphilotherapist as to whether he is dealing with a toxic icterus from arsphenamine, a syphilitic icterus, an intercurrent infectious, catarrhal jaundice, a hepatorecurrence following inadequate previous treatment, or an icterus associated with gallstones or cholecystitis, is often important and beset with many difficulties.

Acute toxic icterus usually comes on in fulminating fashion, often in association with an exfoliative dermatitis during an arsphenamine course. If very low dosages of arsphenamine

have been used, it is perhaps permissible to suspect hepatorecurrence at this time, but, as rule, the hepatorecurrence is an interval manifestation, begins between courses, and comes on while the patient is on mercurials or iodide, or during rest period. It is, therefore, particularly confusable with the so-called "late arsphenamine icterus" which has usurped so much attention since the war This complication, in turn, at the present time at least is inextricably interwoven with a form of catarrhal infectious jaundice which has been responsible for an epidemic that has covered the entire world in sporadic outbreaks during the last fifteen years.

Infectious epidemic catarrhal jaundice is in our experience is the commonest hepatic disturbance encountered in treating syphilis at the present day T ose having any considerable experience with it, the prodromes become so easily recognizable that it is possible to predict, often as much as month in advance, that patient will have jaundice. Urticaria and arthritic pains, often of great severity are quite common, and may last for week or two, with gradually increasing anorexia, discomfort in the epigastrium or right upper quadrant, and loss of weight, before jaundice ppears. The liver is usually large, the jaundice moderate, the urine bile-stained, the stool acholic. In severe cases the loss of weight may be rapid, the jaundice deepens, and if the liver begins to shrink and toxic delirium sets in, death from acute yellow atrophy impends. Treatment for syphilis has no effect on the process, thus eliminating hepatorecurrence. There is usually no arsenic found in the urine, nor was there any in the liver of several reported cases coming to necropsy The gradual onset and obstructive signs have led to explorations for common duct stone, but with no other findings than those of cholangitis. True gallstone attacks are usually more acute in onset and short in duration. Edema of the papilla of Vater associated with duodenitis is suggested in some cases. In one of our cases at necropsy pus was found in the ampulla and common duct and there were signs of duodenitis. Relapse may occasionally be noted irrespective of treatment for syphilis. In the more prolonged cases ascites may develop and evidence of considerable though temporary functional impairment of the liver be found. Edema of the legs without detectable ascites is pending manifestation in some cases, but usually responds to bandaging and rest. The verage duration in number of cases observed by us was from thirty-five to forty-five days.

Differential Summary of Jaundice in Syphilis.—The average physician confronted with the duty of deciding just what he is dealing with when a patient with syphilis appears with jaundice may adopt the following course of reasoning suggested by the parallel column analysis of Fig 657 If arsphenamine has been given within a week or two, and there are signs of itching skin and beginning dermatitis, sodium thiosulphate intravenously may be employed in doses of from 0 5 to 1 Gm. every other day for several doses, and the effect watched. Glucose intravenously and similar measures are described in Chapter IX. The condition is probably an arsphenamine toxic jaundice, and the patient is likely to develop an exfoliative reaction. If the patient has not been treated for syphilis, the condition is more likely to be syphilitic, and a decision must be made as to whether the process is early or late. If it is early (patient with a secondary eruption or its residua) treatment with neoarsphenamine may be begun after a week of mercurial preparation with the succinimide or bichloride or bismuth may be used from the start. On the other hand, if the infection is not recent, all the factors which enter into the diagnosis of hepatic injury must be considered and painstakingly eliminated If the decision is in favor of syphilis as the cause, treatment should be begun as will presently be described under late hepatitis. If the patient has had treatment for syphilis in the past few weeks, months, or years, it should not be too readily concluded that he is suffering from a toxic arsphenamine icterus. He should be placed on the regimen for epidemic infectious jaundice, his symptoms from the right hypochondrium should be interpreted with reserve, and operation should be resorted to only after two or three months of persistent jaundice has failed to respond to the catarrhal regimen, or to later treatment for syphilis. In fact, several experiences suggest that it is a serious matter to explore these epidemic cases, and that a fatality may be precipitated in this way

Fig. 637

A DIFFERENTIAL SUMMARY OF JAUNDICE AND HEPATITIS IN THE SYPHILITIC PATIENT

Early acute syphilitic hepatitis (benign)	Acute yellow atrophy	Hepatorecurrence.	Acute arsenical hepatitis.	Infectious catarrhal jaundice.	Late hepatitis (cirrhotic and gummatous)
Rare	Rarest.	Probably not uncommon.	Uncommon.	Probably commonest form.	Uncommon.
Occurs primary or secondary stage only	Occurs in primary or secondary stage.	Occurs in previously inadequately treated early and latent cases.	Occurs in previously treated patients at any stage, not necessarily overtreated.	Occurs in previously treated or untreated, or even in nonsyphilitic patients.	
	Rapid onset.	Onset weeks or months after lapse.		Onset during or even long after treatment.	
Severe jaundice	Severe jaundice.	Jaundice variable, usually marked.		Jaundice usually gradually progressive in onset, mild or deep.	Jaundice often insidious or fluctuating over months or years.
Liver enlarged and tender	Liver large, then small.	Liver usually enlarged.	Other concomitants of arsenical poisoning, especially dermatitis, aplastic anemia, hemorrhages, polyneuritis.	Liver variable.	Liver if palpable may show masses or lobulation.
Spleen seldom palpable	Great prostration. Diarrhea, foul stools. Spleen rarely palpable.	Symptoms resemble early acute hepatitis.		Onset insidious, 2-4 weeks prodrome of arthralgia, urticaria and gastro-intestinal symptoms.	Subjective symptoms mild and insidious, with cirrhosis; stormy (pain, fever etc.) with gumma.
Few other symptoms except those usual in jaundice (depression, itch, gastric disturbance, slow pulse)	Toxic delirium. Fluid in abdomen.	May go over rapidly to acute yellow atrophy. No response to duodenal drainage.	No response to bismuth or mercury unless made worse (nephrosis especially)	Often part of an epidemic.	Palpable spleen 50 per cent. Fluid may be present.
Hypo or acholic stools.	Rapid course to fatal outcome (4-5 days).	Rapid response to further vigorous treatment with arsphenamine or bismuth.	Symptoms of acute yellow atrophy often ensue.	May go over to acute yellow atrophy or with sudden onset as such.	Hematemesis and melena in cirrhosis.
Urine, bile only	Urine may contain casts, tyrosin, leucin crystals		Nephrosis may be present.	Marked weight loss.	Weight retained until late.
Variable weight loss.					

Fig. 657 (Continued)

A DIFFERENTIAL SUMMARY OF JAUNDICE AND HEPATITIS IN THE SYPHILITIC PATIENT (Continued)

Early acute syphilitic hepatitis (benign).	Acut yellow atrophy	Hepatorecurrence.	Acute arsenical hepatitis.	Infectious catarrhal jaundice.	Late hepatitis (cirrhotic and gummatous)
Icterus index variable, too high.					
N previous arsphenamine treatment.			Arsenic strictly contraindicated.	Arsenicals tolerated in moderate doses.	Arsenicals may give quick improvement, but paradoxic result.
Quick response to bismuth therapeutic test (2–3 weeks).	Bismuth or calomel intramuscularly may be tried, but mortality is high.		Response if at all to sodium thiosulphate and other detoxifying measures.	No response to treatment for syphilis.	
N response to duodenal drainage.				Quick response to duodenal drainage.	No duodenal drainage response.

Fulminating jaundice with toxic symptoms should be carefully searched for evidences of recent syphilitic infection since, if they can be found, the outlook by intensive treatment for syphilis is quite good, although absolutely nil without it. Other forms of acute yellow atrophy do not respond. The possibility of an early toxic pregnancy must be kept in mind in women

Treatment of Late Syphilitic Hepatitis.—It is easy to reap disaster from a too hasty or too energetic therapeutic approach in late syphilitic hepatitis. The therapist should give due heed to the art of therapeutic coddling, and restrain his desire for arsenical miracles. If there is any sign of fluid, or the case is of long standing and of insidious onset, it is well to ask for hospitalization and a period of two or three months of cautious treatment for the first course

First week or two, potassium iodide by mouth, 1 to 2 Gm. three times daily if tolerated, and mercury with chalk, 1 or 2 grains three times daily

Second to fourth week, inunctions in addition, 4 Gm., 30 grains, clean. During this period iodide may be given intravenously if the patient's condition is good or his gastro-intestinal tolerance poor As a rule however 30 grains three times daily by mouth is sufficient. The dose intravenously should be 3 to 8 Gm daily or every other day

Fourth to sixth week, if progress is slow and there are no unfavorable signs from the kidneys, succinimide intramuscularly or the bichloride may be substituted for other mercurialization, the iodide being continued.

The Use and Dangers of the Arsenicals in Late Hepatic and Splenic Syphilis.—The undoubted gravity of the therapeutic paradox and the very natural fear of using a hepatotoxic drug in a patient with a damaged liver have combined to produce a fundamental distrust, if not an absolute prohibition, of the use of the arsphenamines in late syphilis of the liver and spleen. With this point of view we are, in the main, in sympathy and our caution has only grown with experience O'Leary in surveying the proved hepatic syphilis of the Mayo Clinic in 1931 gave this question special consideration and came to the conclusion that the prognosis of patients receiving only mercury and iodide was definitely better than that of those also receiving arsphenamine. In late forms of hepatic syphilis the continued use of mercury and iodides at intermittent intervals for several years has resulted in an average life expectancy of almost three times that when arsphenamine and mercury were used intensively There is no reason to expect that mapharsen will improve the record of the arsphenamines for therapeutic shock effects. McCrae has been unsparing in his condemnation of the use of the arsphenamines and his preference for mercury and iodide in syphilis of the liver We have seen a therapeutic paradox develop in a prenatal syphilis on our own service which had apparently sustained what we at the time regarded as adequate mercurial preparation, though applied to the wrong type of case We are convinced that it is out of the question to expect of the majority of physicians called upon to treat syphilis of the liver the necessary discrimination to enable them to avoid the dangers of arsphenamine therapy For this reason we no longer allow our medical students to consider its use nor do we advocate it for the practitioner Pending the determination of the suitability of bismuth in the treatment of hepatic syphilis (and we believe it to be subject to many of the objections which apply to the arsphenamines) we recommend that all patients with late hepatic syphilis be treated with mercury and iodide.

It is impossible however to escape the fact that a very considerable pro-

portion of patients with syphilis of the liver especially of the noncirrhotic types, do extremely well on the arsphenamines. We have seen operative confirmation of the inability of mercury and iodide by ordinary methods of administration to hold some cases of progressive hepatic syphilis in check. Korns, in his critical examination of the problem of syphilitic Banti's disease, directs attention to the fact, with which our own limited experience is in accord, that a great many of the reported cases of syphilitic Banti's disease with extensive changes in the liver as well as the spleen, have done exceedingly well on one or another of the arsphenamines, as evidenced by half a dozen reports in the literature. We believe, therefore, that the exclusive use of mercury and iodide should constitute the recommended treatment for syphilitic hepatitis in all its later stages, but that given a sufficiently expert selection of the type of case, sufficient heavy metal and iodide preparation, and sufficient judgment and skill exercised in the selection and dosage of the arsphenamine employed the arsenical group of drugs may have a definite place in the management of noncirrhotic types of patients who are still in the early stages of the disease and free from any suggestion of portal obstruction or serious hepatic dysfunction. For the practitioner and the internist, we do not recommend it.

Bismuth in Hepatic Syphilis.—The ability of bismuth to produce Herxheimer effects in acute processes and the possession of definite hepatotoxic properties by the drug, is well recognized. For these reasons, if bismuth employed in the treatment of hepatic syphilis (and it may be said that as yet no clearly defined technic has been worked out) the dosage should be moderate at the start or small with short intervals or especially in the late and cirrhotic cases, the drug should only be used if mercury and iodide fail of effect, or if there is a high degree of anemia or marked nephrosis. Bismuth may like an arsphenamine, be used after prolonged mercury and iodide preparation if there are no apparent contraindications.

Subsequent Treatment.—This must depend on the patient's progress. Two or three thoroughgoing courses of mercury inunctions and iodide should be regarded as the minimum. An arsenical, if given, should be in the form of "914" mapharsen or bismuth arsphenamine sulphonate the dosage should be moderate (not higher than 0 45 Gm. "914" or 40 mgm mapharsen respectively) and the courses long rather than short to avoid stimulating a hepatorecurrence. In the recommended form of treatment without arsphenamine, measures to combat anemia may be necessary and the rest periods between inunction courses should be as long as three or four months to allow for the marked response to rest which many of these patients show Iodide, however should be continued throughout the rest period and, if necessary suspended during the inunctions. Patients who improve should be impressed with the great importance of observation and of close attention to their treatment intervals, which their sense of well-being and striking improvement may lead them to overlook. Only in this way can a certain proportion be protected from the development of serious relapse or of other manifestations of syphilis. A follow up system is as necessary in visceral as in early syphilis.

SPECIAL ASPECTS OF TREATMENT

Certain collateral factors appear in the management of patients with late syphilis, including the control of ascites; management in the face of nephritic, cardiovascular, and neurosyphilitic complications; utilization of the rest period; the problem of surgical intervention and treatment, and the performance and interpretation of the therapeutic test.

Control of Ascites.—The slow approach in the treatment of syphilis of the liver is the best preventive of an embarrassing ascites (Fig. 677). When a marked degree of ascites is already present or develops as a transient effect, it is best controlled, not by tapping, but by restriction of fluids by mouth and elimination through bowels and kidneys by catharsis and diuresis. Brisk purgation with concentrated saline can materially relieve distended abdomen and, if the patient's general condition is reasonably good, additional hydragogue catharsis with jalap (1 to 2 grains daily) has proved very satisfactory in our work. Tapping, on the other hand, has its definite dangers, and tends to perpetuate its necessity until the patient is worn out, or until some serious injury such as puncture of the intestine ensues. It should definitely be thought of as a last resort, and not the first measure to be employed when the patient enters hospital, as is too often the case. In persons over fifty years of age, or those who have had marked ascites for some time, the effect of a single tapping, especially if much fluid is removed, may be disastrous. A species of liver crisis, akin perhaps to the pleural crises of patients with effusions of the chest, ensues, diffuse abdominal pain, great prostration, and symptoms suggesting uremia develop with fatal outcome in from a few hours to several days. Stokes has seen 2 deaths from this cause and nothing can more thoroughly impress one with the propriety of relegating paracentesis to the rank of last resort. The condition of the kidney has an important influence on the degree of ascites in a hepatic case, and no relief may be obtained if there be nephrosis present, until the contributory factors to the nephrosis, such as focal infection, are removed. In fact, renal irritation from mercurial treatment appears at times to be responsible for fluid retention, which subsides when change in methods does away with the cause. The use of the mercurial diuretics novasurol and salyrgan has achieved considerable popularity and follows the same principles applicable to their administration in edema and ascites of cardiac origin as described on page 963. Overstrain and heart damage contribute to the ascites of hepatic cases. In one of our patients, previously free from fluid for many months and with no recognizable cardiac lesion, temporary distention followed a severe physical strain of several weeks' duration, but completely subsided under subsequent rest.

Collateral Circulation.—The development of a collateral circulation through the epigastric veins in cases of severe portal obstruction requires in our observation seldom less than two years. Forcing the superficial vascular system to handle its overload by reducing paracentesis to a minimum, seems to be of value and all constricting interference from clothing should be avoided. In patients who have been thrown into therapeutic paradox by too early or intensive employment of arsphenamine, the battle must be fought quadrangularly between catharsis, diuresis, paracentesis, and the maintenance of the patient's nutrition and morale. Small sallies of iodide and mercury with rest periods, are much more effective than continuous pummeling.

Management of Complications.—In patients with coincident nephritis or nephrosis associated with amyloid changes, the treatment of the nephritis must be carried on hand in hand with that for syphilis, iodide being relied on for the preparation, and arsphenamine for the later treatment, and mercury altogether omitted for the time being. Very fair results can be secured in this way. The treatment of cardiovascular syphilis so closely resembles that of hepatic syphilis that there is no conflict. Concomitant neurosyphilis will respond to the same measures, but their intensity should be increased by the later use of neoarsphenamine in 0.45 Gm. doses intravenously and Swift Ellis-Ogilvie intraspinal treatment if warranted by the spinal fluid findings. The liver seems to tolerate tryparsamide well, if there is occasion to use it in a neurosyphilitic patient.

Rest Periods.—The rest period, as we have intimated, is a vital part of the management of difficult cases. It should be made proportional, to some extent, to the depression produced by treatment. In general, not until the patient has rallied entirely from any signs of overtreatment should he take up again the systematic use of mercury or arsphenamine. On the other hand, those patients who improve at once and strikingly should be held to shorter rest periods, and effort be made to suppress their infection entirely with complete and final reversal of the Wassermann reaction. The latter should not, in general, be used as a guide to treatment in the first year or two.

Treatment of Hepatic Syphilis as Liver Disease.—This heading is intended to cover the general medical management of hepatic disease in patients with syphilis. A group of measures often neglected includes the strict prohibition of alcohol, the sharp reduction of fat intake, with increase of protein and carbohydrate in the diet; the supporting of liver function by large doses of vitamin B complex, the promotion of intestinal elimination and the avoidance of intestinal infection wherever possible, and the use of liver extract by mouth or intramuscularly. The good effect of extending such protection to the liver far back in the course of hepatic disease associated with syphilis when liver enlargement is first manifest (see Fig. 641) will probably become more apparent as the physician in charge of the case becomes more preventively minded and foresighted.

Surgical Intervention.—In general, the emphasis on gallbladder symptoms as evidence of surgically treatable disease is so great that it is difficult for the syphilologist to dissuade the surgeon from too immediate intervention. There have been evidences of ill-effect on the patient, of which Fig. 663 is an example. In general, syphilitic patients should be spared all possible resistance-lowering shocks. On the other hand, if, after two or three months of treatment with arsphenamine and mercury the patient sustains relapse of symptoms pointing to gallbladder disease, exploration may be advisable in order to treat the coincident condition, if present. Even under such circumstances, several cases illustrate the fact that relapse in the syphilis, and not concomitant gallstone factor, may be responsible for the recurrent symptoms.

Chapman, Snell and Rowntree (1933) plead strongly for the early surgical exploration for accurate diagnosis and for the consideration of the various operative measures now available to prevent the worst of the late consequences of hepatic cirrhosis. T quote certain of their conclusions, "It is apparent that the alcoholic patient ith an enlarged liver and positive bromsulphalein test has only about an even chance of surviving for three years or more, regardless of the fact that he has not reached the stage at which most clinicians would make an unqualified diagnosis of cirrhosis. It also appears that the patient with chronic or intermittent jaundice and an enlarged liver has an equally unfavorable prognosis. If syphilis is included as an etiologic factor the gravity of the situation may be somewhat decreased. Patients with Banti' disease and secondary cirrhosis who have not yet reached the stage of portal stasis and ascites have a reasonably good outlook. Since, in the whole group, surgical exploration ppears to be well tolerated, perhaps it should be considered more often, especially in view of the possible relation of splenic and cholecystic disease to cirrhosis. No doubt omentopexy or ligation of the venous channels communicating with the esophageal vein as performed by Walters, could be done with greater prospects of benefit in compensated cases. W feel that either history of hemorrhage or the finding of collateral venous circulation may constitute definite surgical indication in compensated cirrhosis of this type. If patients have an alcoholic background and history of

Fig. 672.—Therapeutic Results in Alcoholics and Nonalcoholics.

haematemesis, the question of Talma-Morrison omentopexy and ligation of collateral venous channels connecting with the esophageal plexus should be seriously considered. Excellent clinical results have been obtained by this procedure, and failures have been chiefly due to the very advanced state of the disease at the time of operation. Splenectomy may also be considered in this connection; it is performed too late in many instances, and may offer far more in the latent case of cirrhosis, particularly if there is history of haematemesis and anemia with moderate or low degrees of retention of dye. It is apparent that surgical procedures in these latent or compensated cases should be considered more seriously in the early stage than in the advanced or decompensated stage.

Splenectomy.—The operation is by no means one of negligible mortality even in the hands of an experienced operator and with inexperienced operators may well be more serious matter than the disease. The adhesions often met with due to perisplenitis increase the technical difficulties. Four of the patients in the group here reviewed had sustained splenectomies, and 2 cases, typical of the good results, are shown (Figs. 674 675) One patient died from postoperative hemorrhage. He had been making favorable progress before operation. Another patient received no benefit, although the pathologic picture suggested Banti syndrome; he died later of hepatic cirrhosis. Splenectomy for persistent anemia resulted in permanent increase in hemoglobin of about 10 per cent in third case, and definite improvement in well-being. Where definite indications, such as hemorrhages from varices exist, splenectomy is undoubtedly in order The bleeding may be exaggerated by the effects of treatment for syphilis to the point of being the cause of death. On the other hand, systematic treatment has not had all the trial it deserves in cases of hepatosplenic syphilis. Splenectomy is hardly tonic measure for general application in visceral syphilis The reversal of the Wassermann reaction in cases of syphilitic splenomegaly following removal of the organ, is desirable, but we have been able to obtain it without surgical intervention, and have also noted Wassermann relapses after splenectomy Certainly splenectomy should not be resorted to in hepatosplenic syphilis until treatment has done its best and fallen short.

This means not less than a year of effective arsenical, mercurial and iodide treatment, and of two or three years treatment in a difficult case. When all is said and done, there will remain a few cases in which persisting asthenia and anemia should be attacked by this method after systemic treatment has failed to meet the situation.

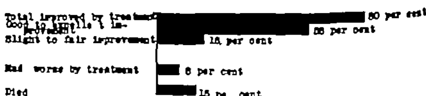
Talma-Morison Operation to Control Ascites.—Surgical treatment of persistent ascites includes the so-called "Talma Morison operation of establishing a compensating peritoneal lymphatic drainage by suturing the free border of the omentum to the parietal peritoneum. Riesman called attention to the favorable results that may ensue, and Stokes has seen one example. Riesman remarks on the species of spontaneous or accidental Talma-Morison effect which may follow repeated tappings, in one or several of which the patient may have peritoneal reaction that attaches his omentum to the abdominal wall at the site of successive punctures, with the establishment of an venous of drainage, which in time brings him relief. Chapman et al. just cited advise its earlier use if exploration justifies.

Therapeutic Test for Hepatic Syphilis.—The therapeutic test for syphilis was the court of last resort in differential diagnosis in a much larger proportion of cases in the past than at present, when the serologic reaction has so immeasurably clarified the situation for both patient and physician. On the other hand, it is till a necessity and should be well understood as the logical resolving factor for an indeterminate diagnosis. In lesions of the gallbladder the effect of treatment for syphilis may be immediate, especially if the survey of the case justifies the early use of arsphenamine. Chills, fever and pain usually subside at once, but their recurrence during subsequent mercurial course cannot always be taken as evidence that the process is not syphilitic, and that gallstones are present. Mercury and iodide can produce an effect within two to three weeks. We have seen no evidence of nonspecific action of arsenical on cholelithiasis or nonsyphilitic cholecystitis, recurrence being apparently certain if something other than syphilitic factor is present. In cirrhoses, the tendency of those who are watching therapeutic test is to expect results too soon in difficult cases. Three or four months will be needed to demonstrate favorable reaction, and test should not be adjudged failure simply because the patient is not restored to normality within that time A year and even two years, will often be needed to demonstrate that the patient has recovered from hepatosplenic syphilis with ascites.

In the therapeutic test for cancer the patient usually rapidly declines under treatment. Careful palpation of the liver is important, and if new masses are noted at the end of six weeks of treatment, or if glands can be felt by rectum or otherwise that were not there before, malignant involvement is almost certain. Inasmuch as there is little or nothing to be done for malignant invasion of the liver at the present time, the issue of delay for treatment versus exploration is of less significance medically than in operable conditions, such as suspected cancer of the stomach.

RESULTS OF TREATMENT OBTAINED IN THE MAYO CLINIC SERIES

The principles of treatment here discussed have been worked out largely on a group of 53 patients whose aggregate results are summarized graphically in Fig 659 If so good a prognosis can be established for a group of patients



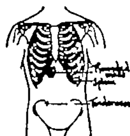


Fig 659 —Aggregate Therapeutic Results in Hepatic Syphilis.

in the pioneering stage, the results obtainable in syphilis of the liver by a *medical profession fully alert to both diagnosis* and treatment should be almost uniformly satisfactory Thirty-eight patients were placed on arsphenamine and mercury simultaneously at the outset of their treatment, without graduated preparation. Of these, 4 patients who developed therapeutic para-

doses were made definitely and permanently worse. This was in the early years of our experience. During this period we also saw several additional examples of the effect of arsphenamine overenthusiasm from outside sources. Since we have appreciated and developed the gradual approach the beginning of treatment with mercury and iodide in 15 cases followed by neoarsphenamine, has led to uniformly good results even in some unusually difficult cases. The mercurial preparation may be made ambulatory by placing the patient on inunctions and iodide for two months or more before arsphenamine is considered. Blood Wassermann reversals are much less difficult to secure than we anticipated. Failure to reverse the Wassermann reaction with routine treat

Fig. 660.

THE "GALL-STONE" ATTACK IN HEPATIC SYPHILIS—PHASE I

Woman, aged thirty-two.

Typical gall-bladder history no preoperative Wassermann taken no syphilis recognized; no gall-bladder pathology found. Syphilitic cirrhosis.

Literal Transcript of Patient's History: "March, 1918, after train trip, carrying 20-pound baby part of the time, noticed soreness below right costal margin; was told she had inflamed gall-bladder. This subsided, but had some soreness off and on since. Last August had two attacks (three weeks apart) of severe stabbing pain under the rib border deep pain, coming in paroxysms all day and associated with deep discomfort below right scapula—some upward pressure. No vomiting, no gas, no bloating. Could not get comfortable in any position. During second attack doctor was called, gave tablets (by mouth) for relief. Was quite sore for several days. No hard attacks since, but since this spring quite uncomfortable with soreness that side. Some indigestion for years—gas and discomfort—slight belching, no selective food distress. Bowels fairly regular. No urinary symptoms."

Note That This is Typical "Gall-bladder" History. The subsequent course was as follows

Physical Examination. Rounded mass which seems to be distended gall-bladder. Spleen palpable. *No Blood Wassermann Test Taken.* No history of syphilis obtained.

Clinical Diagnosis. Chronic Cystic Gall-bladder with Stones.

Operative Findings. Cirrhosis involving entire liver. (Specimen excised, reported cirrhosis.) Stomach, duodenum, pelvis negative. Gall-bladder flaccid and blue. Talma-Morison operation done. Gland from abdominal wall, inflammatory. Chronic appendicitis, moderate grade.

Blood Wassermann Test Taken After Operation. Strong positive. Now found that patient had history of lingual primary and secondaries seven or eight years before, with adenitis. *Lingual scar found.*

ment should lead to a trial of bismuth intramuscularly. Moore's (1923) recent endorsement of the gradual approach with mercury and bismuth from many years experience should be noted. The permanency of the results secured by combined treatment cannot be vouched for as yet, but in some of our most difficult cases the patients have undergone a complete restoration to normal from a condition of the most precarious invalidism. The analysis of the death and morbidity list indicates that the prognosis is even better than the chart indicates, inasmuch as 1 patient in the series died from metastatic cancer of the liver another from hemorrhage and shock following splenectomy 3 suffered relapses from neglect of treatment, 1 died of a liver crisis following para-

centesis, 2 died of cirrhoses in which syphilis was not a proved factor and 1 died of hemorrhages from supposed bleeding duodenal ulcer that did not re-

Fig. 601.

THE "GALL-STONE" ATTACK IN HEPATIC SYPHILIS—PHASE II

Typical gall-bladder attacks; syphilis recognized, but patient explored, no gall-stones; hepatic gumma pressing over gall-bladder: perihepatitis with multiple adhesions.

A Six Year History in man aged thirty-five of ttacks of right subcostal pain with jaundice at times. Duration two hours to three or four days. Soreness between times. Recent severe attack, hypodermic relief. Exercise and lifting bring on attacks.

Physical Examination Tender right subcostal region. No mass. Stomach acids low *x-ray negative, blood Wassermann positive*

Clinical Diagnosis Chronic Cholecystitis 80 Per Cent., Latent Lues.

Operative Findings: There was apparently a gumma the *right lobe* of the liver directly over the gall-bladder, with great many inflammatory adhesions between the dome of the liver and the lateral wall of the abdomen, firmly fixing liver and gall-bladder to the right so that it was impossible even to see the gall-bladder without freeing it, which was not thought advisable. No stones in gall-bladder Appendix, evidence of old trouble. Stomach, duodenum normal.

Postoperative Diagnosis Gumma of the Liver Perihepatitis.

Recovery Under Treatment for Syphilis. Observation eighteen months.

There is N Aspect of the Symptomatology of Gall-bladder Disease, Apparently Which Syphilis Cannot Imitate.

spond to diet, but which in retrospect may have been due to varices associated with splenomegaly and cirrhosis It appears, then that there can be no reason-

Fig. 602.

THE "GALL-STONE" ATTACK IN HEPATIC SYPHILIS—PHASE III

Typical gall-stone and common duct stone ttacks; syphilis recognized and treated, with indifferent results: stones, cirrhosis, perihepatitis all found t operation.

A Woman of Forty-five Became Jaundiced abruptly three months ago. Had had previous ttacks of pain in epigastrium lasting half a day brought on by drinking tea stop suddenly Attacks preceded by chill, sometimes slight fever

Physical Examination Perforated palate, moderate jaundice Mass in right hypochondrium, rounded, descends on respiration. Gall-bladder (?). *Liver palpable*

Blood Wassermann Reaction Positive.

Clinical Diagnosis Treat lues first, though gall-stones probably 75 per cent.

Treatment Inunctions and iodid. Liver reduced in size but patient is still jaundiced and has pain in right side

Operation "Thick walled gall-bladder filled with pus, mucus, and stones. Soft black stony material in common nd hepatic ducts. Liver shows marked cirrhosis with recent perihepatitis. Mild pancreatitis. Stomach and duodenum negative

Postoperative Diagnosis Cholelithiasis, hepatic cirrhosis, perihepatitis.

able ground for therapeutic pessimism in this aspect of visceral syphilis at least.

Fig 663

THE "GALL-STONE" ATTACK IN HEPATIC SYPHILIS—PHASE IV

Typical gall-bladder attacks; syphilis recognized by provocative test. No relief by treatment; operated on after recurrence, gall-stones and cirrhosis found; cholecystectomy; infectious jaundice (?) or hepatorecurrence (?) six months later

A Woman of Forty-nine Had Seven Attacks of right hypochondriac pain, two hours duration, nausea, pale stools, tenderness after attack, jaundice once No chills or fever History of labial primary lesion.

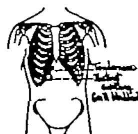
Physical Examination Tender under right costal margin, no masses.

Blood Wassermann Reaction: Negative four positives on provocative (with 3 negatives)

Clinical Diagnosis Gall-stones and syphilis. Treat first and operate if relapse.

Treatment: Three arsphenamin injections. Severe attack following.

Operation: Enlargement regional glands around gall-bladder Gall-bladder contains multiple stones. Liver shows marked hepatitis even to cirrhosis. Pancreas, stomach, duodenum normal Cholecystectomy performed.



Postoperative Diagnosis Cholelithiasis and hepatic cirrhosis.

Further Treatment with Arsphenamin and Mercury good result.

Jaundice, Severe Five Months Later, with urobilin and urobilinogen in urine. Common duct stone (?) hepatorecurrence (?); infectious catarrhal jaundice (?)

Fig. 664

THE "GALL-STONE" ATTACK IN HEPATIC SYPHILIS—PHASE V

Typical gall-stone attacks with diagnosis of gall-stones. Syphilis recognized. Surgery postponed in favor of treatment for syphilis. Immediate disappearance of all symptoms, with apparent recovery

A Woman of Thirty-seven Stated that she had been told by five physicians that she had gall-stones. She had had six years of attacks of indigestion, with pain radiating under the ribs, residual soreness, sudden onset, and relief Lying on back relieves. Pain radiates lately to shoulder (right). No jaundice or acholic stools. Chills and fever with the attacks and lately at other times. No vomiting

Physical Examination As shown in diagram. "Through-and-through abdominal mass. Stomach, subacidity x-ray negative. Shadow left kidney area. Urine negative. Leukocytes, 10,700.

Clinical Diagnosis Cholelithiasis.

Blood Wassermann Reaction Strongly positive.

Surgical Opinion: Postpone operation in favor of treatment.

Treatment: Six arsphenamin injections, 24 inunctions.

Result Mass Disappeared with Second Arsphenamin. Slight tenderness at costal margin. "Chills and fever" disappeared with first arsphenamin.

Six Months Later: Excellent health, no symptoms.

Husband Examined Also found to have syphilis.

Fig 665

THE "GALL-STONE" ATTACK IN HEPATIC SYPHILIS—PHASE VI

Typical gall-bladder ttacks syphilis recognized, treatment begun, considerable relief mercurial colic and myalgia mistaken for recurrence of ttack in rest period operation for cholecystitis gall-bladder normal but drained unf vorable effect of operation relieved by further treatment.

A Woman of Forty-eight Had Her First Attack of Right Subcostal Pain with Jaundice sixteen years ago. Since then repeated ttacks, with pain radiating to shoulder (right) nd elbow and jaundice N vomiting

Physical Examination Tender Mass, gall-bladder region. Achlorhydria. Jaundice.

Blood Wassermann Reaction Strong positive.

Clinical Diagnosis Probable gall-stones, but possible luetic cirrhosis. Treat before operation if not urgent.

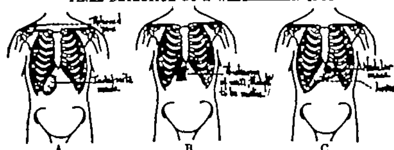
Treatment Six arsphenamin injections, 0 1 to 0.3 gm. Eleven inunctions. Much relief but very intolera t of mercury

Interim Rest and Treatment One month rest, 40 rubs; mouth became very sore, diffuse bdominal cramps, jaundice, salivation, and severe myalgia.

R turns These Symptoms, probably due to mercurial intoxication, ere misinterpreted as gall-bladder syndrome, 90 per cent., and operation done

Operative Findings A very large liver and pancreatitis. The gall-bladder was in pretty good condition, collapsible There ere enlarged glands along the ducts. In iew of the fact that the patient has specific trouble the liver enlargement and pancreatitis are no doubt due to that rather than to cholecystitis. The gall-bladder as opened for exploration Although e would consider it normal, drainage of it may help the hepatitis. Continue antispecific treatment.

Postoperative Course Jaundice became more marked, with increasing pain. Wound healed ell. Liver increasing in size Some ascites. Patient evidently orse Placed on treatment



Treatment for Syphilis Ten days small inunction and KI, then neo-arsphenamin 0 2 to 0 6 gm 6 injections.

Result J undice disappears, feels 75 per cent better

Comment This case illustrates the point made in the text as to the length of time needed for therapeutic test. Evidently not all relapses in gall-bladder yndrome in patients ith syphilis are due to gall-stones.

Fig. 886

PROGRESS OF THE HEPATOSPLENIC COMPLEX THROUGH EIGHT YEARS. FINAL DETECTION BY A WASSERMANN TEST

Male, aged thirty

First Diagnosis, 1911, *Pleurisy*. Second Diagnosis (Chart A), 1915, Cystic gall-bladder with stones. *N Wassermann Test.* Operation Performed.

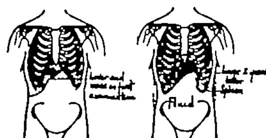
Operative Findings: Thick-walled gall-bladder buried in nest of thick adhesions. Many enlarged glands. Cholecystectomy. Note resemblance to findings in other syphilitic gall-bladder cases.

Chart B. Well for two years, then complains of pain in upper abdomen and thinks mass is reappearing. No mass found, liver not felt, but sense of resistance interpreted as highly developed rectus muscle. This was in 1917.

N Blood Wassermann Test.

Chart C. 1919. Pain in Right Shoulder, sudden, sharp. Also in old laparotomy scar. Severe, almost suffocating attacks of pain under right costal margin. Lost weight and strength. (Recall patient had had gall-bladder removed.)

Mass Felt in Left Epigastrium. Moves with respiration, enlarged liver felt.



Blood Wassermann Taken for First Time, Positive.

Exploration Advised by Diagnostician, Refused by Surgeon.

Prompt and Complete Recovery Under Treatment for Syphilis.

Fig. 887

THE "LATENT LIVER" AND THE OVERLOOKED WASSERMANN TEST

Woman, aged twenty-eight.

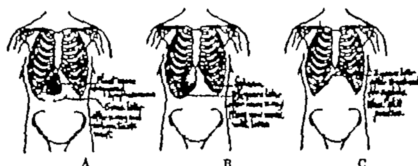
Examined 1919. Complained of nausea, weakness, and sore stomach. Intermittent attacks of pain in right hypochondriac region, with pain in right shoulder. Palpable mass moving on respiration was felt in right epigastrium, and later identified as liver. The test meal and stomach and chest x-rays were negative.

Preliminary Diagnosis. "Old pyloric ulcer with inflammatory tumor 50 per cent.; pylorospasm, 50 per cent., neurosis.

The Patient Admitted She Felt Better When Among Friends or Friendly People.

Final Diagnosis. "Palpable epigastric mass—liver. Treat for bowels. Neurosis.

N Blood Wassermann Test Taken.



Two Years Later the Patient Returned. She had had all her teeth pulled, without result. The liver was larger than before, the spleen palpable, and there was now free fluid in the abdomen. She had vomited blood once and had had fever to 103 degrees at times. All her symptoms were now referable to the hepatic cirrhosis.

Blood Wassermann Test: Strong positive. History of primary syphilis at age nineteen, overlooked in first examination, now obtained.

Look for Syphilis Early in the Examination When the Liver is Palpable.

Fig. 668.

GUMMA OF THE LIVER, FIXED IN THE EPIGASTRIUM BY ADHESIONS, MAY BE MISTAKEN FOR A RETROPERITONEAL NEOPLASM

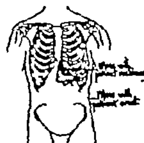
Male, aged eighteen, first examined in 1917

Nodular Mass Right Upper Abdomen: Very tender does not move with inspiration. Probable retroperitoneal lymphosarcoma. x-Ray chest negative.

N Blood Wassermann Test Taken. x-Ray Treatment Begun.

Five Months Later: Mass thought to be larger (In reality this was probably the liver edge) **Further x-Ray and Radium Treatment.**

Three Years Later: Mass as indicated at B. General health unchanged. Spleen recognized.



First Wassermann Test Taken Strongly and repeatedly positive.

Diagnosis Revised: Mass now moves with respiration. Liver identified. "Syphilitic hepatitis with gumma.

Two Years Later After Treatment for Syphilis: Liver almost normal, spleen no longer palpable, general health excellent, blood Wassermann positive.

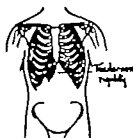
Youth, N History of Infection, Fixation of Mass and Lack of Wassermann Led to This Diagnostic Error Source of Infection Unknown.

Fig. 669.

A GUMMA OF THE LEFT LOBE OF THE LIVER MAY BY DISPLACEMENT SIMULATE A PANCREATIC OR MESENTERIC TUMOR

Woman, aged thirty-seven.

This Patient's Syphilis was Recognized before operation, but exploration wa concerred in by all consultants because of the bizarre physical findings.



A Lobulated Mass, Almost Suggesting Bunch of Grapes, could be felt and pushed about in the left upper quadrant. It did not seem to respond especially to respiratory movement.

At Operation, Saucer-like Gummatous Plaque 8 10 cm. in size, ith pie-segment divisions, was found in the left lobe of the liver The pancreas and mesentery ere normal.

The Mass Disappeared Under Treatment for Syphilis.

Almost Any Physical Finding May be Compatible with Syphilis in the Upper Abdomen. There is No More Untrustworthy Criterion.

Fig. 670.

SIMULATION OF GALL-BLADDER MALIGNANCY AND CARCINOMA OF THE LIVER BY SYPHILIS. NO PREOPERATIVE WASSERMANN TEST TAKEN

Man, aged forty-two.

Examiner's Summary "Tenderness marked in region of gall-bladder with slight rigidity Gastric -ray—three trials with belladonna—reports mass, extrinsic, stomach and duodenum negative.

Preliminary Diagnosis: Subacute cholecystitis.

Final Diagnosis: Probable malignancy of the gall passages, though possibly infected gall-bladder in anomalous position. Explore.

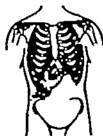
No Blood Wassermann Test Taken.

Operative Findings: "Liver filled with metastatic tumors, all sizes, having appearance of being malignant. Piece removed from one was found to be necrotic and did not show carcinoma, but clinically it is carcinoma. Gall-bladder contained no stones. Origin of carcinoma undetermined.

Pathologic Report: Necrotic Fibrous Inflammatory Tissue.

x-Ray Therapy was Ordered.

Comment on History two years later after 12 x-ray treatments with little change: "Inclined to question diagnosis.



First Blood Wassermann taken one month after above comment Strong positive.

Palpable Mass and Enlargement of Liver with All Symptoms then Disappear under treatment for syphilis (6 arsphenamin injections).

Operative Appearances May Deceive. Take Wassermann Before Exploring.

Fig. 671.

CARCINOMA OF THE LIVER IN SYPHILIS

Man, aged forty-nine.

This Patient, Apparently in Excellent Health and weighing over 200 pounds, complained of upper abdominal distress.

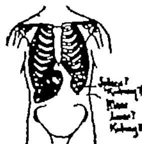
Physical Examination: Large hard rounded nodular liver containing definite masses on anterior surface. Pupils fixed to light. No jaundice or ascites.

Stomach Examination: Achlorhydria, 400 c. retention. Ray reported *negative*.

Blood Wassermann Reaction Positive.

Neurologic Examination: Tabetic neurosyphilis with positive spinal fluid.

Diagnosis Hepatic cirrhosis (?). Possibly non-specific hypertrophic cirrhosis.



Treatment: Two injections of arsphenamin intravenously 0.3, 0.4 gm.

Result Rapid development of ascites and edema of the legs. Death. Cause of death, clinical, nephrosis (?)

Autopsy: Massive *carcinomatosis of liver* from primary adenocarcinoma in pyloric ring. Pancreas, kidney etc., negative.

Comment: Had it not been for the confirmatory neurosyphilis we might have thought this an example of false positive blood Wassermann in carcinoma. Apparently arsphenamin can cause Herxheimer reaction in carcinomatous liver, for no other explanation of the ascites and fatal outcome seems vailable The excellent condition of the patient and the report of negative -ray of the stomach led to premature dismissal of the diagnosis of carcinoma, although the retention should have suggested it. The achlorhydria occurs in both syphilis and carcinoma.

Fig. 672.

THE SYPHILITIC LIVER AND SPLEEN MAY BE CONFUSED WITH DISPLACED OR PATHOLOGIC KIDNEYS

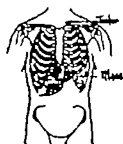
Woman, aged twenty-nine.

Medical Diagnosis before entering clinic "prolapsed kidney." Given a special corset, no relief. No Wassermann test taken. Had had attacks of right subcostal pain with fever.

Preliminary Diagnosis: Both masses appear to be kidney or extend back to kidney region.

Urologic Examination: Indeterminate renal condition, right kidney function twice that of left. Possible polycystic kidney bilateral, with slight infection right.

Blood Wassermann Reaction: Strongly and repeatedly positive.



Final Diagnosis: Mass right upper quadrant has physical characteristics of hepatic tumor. With effect of salvarsan.

Three Months Later: Hepatic mass reduced 80 per cent., spleen 20 per cent.

Good Recovery: Observation four years.

The Blood Wassermann and the Spinal Fluid Examination are Remarkable Clarifiers of Puzzling Abdominal Pictures.

Fig. 673.

DIAGNOSIS OF "PANCREATIC CYST" MADE WITHOUT PREOPERATIVE WASSERMANN TEST. GUMMA OF RIGHT LOBE OF LIVER FOUND AT OPERATION

Woman, aged fifty-three

Chief Complaint. Cancer of stomach and other tumors (*x-ray* diagnosis before entry)

1910 Operation for Gall-stones (cholecystectomy)

1911 Appendectomy

1921 *Large Nodular Hard Mass*, whole upper abdomen. Moves with inspiration.

Preliminary Diagnosis. Metastatic carcinoma (?).

Final Diagnosis: *Large pancreatic cyst.*

Operative Diagnosis. Multiple tumors of the liver, largest 8 x 8 cm. in diameter involving entire left and palpable parts of right lobe of liver. Dense adhesions from previous operations. Much perihepatitis. Gall-bladder seen but not accurately examined because of adhesions. Stomach negative, pancreas negative. One tumor 5 cm. in diameter attached by narrow pedicle removed for diagnosis. Investigate patient for syphilis.

Pathologic Report. Chronic hepatitis.

Postoperative Blood Wassermann Test. Strongly positive.

Recovery Under Treatment for Syphilis.

A Routine Wassermann Test is Surgical Forethought.

Fig. 674.

SPLENOMEGALY AS A CAUSE OF GASTRO-INTESTINAL HEMORRHAGE. X-RAY DIAGNOSIS OF DUODENAL ULCER. SPLENIC ADHESIONS TO STOMACH. NO ULCER FOUND. MASSIVE GUMMATOUS HEPATITIS

Female, aged forty-two, housewife.

Chief Complaint Six severe gastric hemorrhages in three years. Onset five years ago. Gas and bloating of lower abdomen.

Distress Relieved by Appendectomy

Hemorrhages Prostrating, twice required transfusion. None for past year

x Ray Diagnosis One Year Ago Ulcer near pylorus.

Physical Examination No thoracic or abdominal signs. Twenty-five pounds over weight. Hgb., 60 per cent. Test meal: Free HCl 16, total 30

x Ray of Stomach (three successive examinations with belladona).

Final diagnosis, Duodenal Ulcer

Blood Wassermann Reaction Repeated strong positive.

Preoperative Antisyphilitic Treatment: No distinctive response.

Clinical Diagnosis Bleeding duodenal ulcer

Operation No Ulcers Found. Stomach Very Large Duodenum Enlarged and Thickened. Large Gummatous Mass in Liver Spleen Five Times Normal Size Adherent to and Pressing Upon Stomach in the Middle.

Splenectomy Performed.

Pathologic Report Diffuse chronic splenitis.

Excellent Recovery

Discussion

1. The hemorrhages were interpreted by Dr W J Mayo as caused by the splenomegaly and may have been due to esophageal varices.

2. Some of the roentgenologic appearances suggesting duodenal or gastric ulcer were possibly due to the effect of the adhesions between spleen and stomach.

Fig. 675

EFFECT OF SPLENECTOMY ON A CHRONIC ANEMIA ASSOCIATED WITH SYPHILITIC HEPATITIS AND CHRONIC SPLENITIS

Woman, aged forty-three, married.

Chief Complaint Abdominal tumor

First symptom, fulness in epigastrium, three years ago.

Attacks of pain in right hypochondrium.

Gradually increasing sallowness, two years

Possible syphilis by previous marriage, but no definite history No miscarriages.

Examination

Marked pallor moderate emaciation.

Large liver roughened and firm.

Spleen, 8 cm. below costal margin.

Ascites moderate.

Blood findings Hemoglobin 40 per cent.

R.B.C. 2,800,000,

W.B.C. 8600

Differential negative.

Blood Wassermann reaction Strong positive.

Treatment Mercurial inunctions and iodid.

Re-examination Two years later Moderate improvement.

Hgb. 48 per cent. after 6 injections neosalvarsan.

Hgb. 64 per cent., fell to 55 per cent. after second course of arsphenamin.

Chronic slight icteric tinge, no increase in hemoglobin above 55 per cent.

Feels well.

Blood Wassermann negative.

Splenectomy 5/29/19 Spleen three times normal size, hobnailed cirrhotic liver.

Many firm adhesions.

Marked fibrosis and destruction of malpighian bodies.

Hemoglobin 66 per cent. eleven days after operation.

No Further Treatment for Syphilis.

Hemoglobin 68 per cent. one year later

R.B.C. 4,470,000,

W.B.C. 4600

Differential count normal.

Hemoglobin Three Years and Four Years Later 65 to 70 per cent.

Blood Wassermann Reaction fluctuating between positive and negative since.

Definite Improvement in General Health.

Hysterectomy and salpingectomy for salpingitis and fibroids, 5/12/20

Still Has Chronic Pallor but Good General Health.

Fig. 670.

SYPHILITIC HEPATITIS AND SPLENITIS WITH VIOLENT HERXHEIMER REACTION FOLLOWING ARSPHENAMIN RECOVERY UNDER MERCURY AND IODIDS FOLLOWED BY RECURRENCE OF JAUNDICE AND DEATH FROM ACUTE YELLOW ATROPHY. ICTERUS GRAVIS (?). HEPATORECURRENCE (?). INFECTIOUS JAUNDICE WITH ACUTE YELLOW ATROPHY (?).

A man, aged thirty-two years, laborer

Examined 1/12/1923

Chief Complaint: Jaundice of two weeks duration.

Had consulted a physician because of pallor and malaise.

Was told he had large spleen and "hemolytic jaundice

Splenectomy advised.

Apparently as preparation, was given 3 injections of neo-arsphenamin, on three successive days (Pollitzer system)

Violent Turn for the Worse. Jaundice deepened, abdomen now large and tense

History of Previous Jaundice for three days, one year before.

Pain in right hypochondrium for one month

\ attacks

Examination: Deep jaundice.

Liver down to umbilicus, hard. Spleen the same. Jaundice deep. No fluid w va, no edema of the feet. Blood-pressure 185/90.

Urine negative except for bile, urobilin, and urobilinogen.

Blood urea 16 mg per 100 c.c.

Blood Wassermann Reaction Strongly positive

Treatment Rest in bed.

Sodium iodid intravenously Mercury succinimid intramuscularly

Violent Mercurial Colic

Changed to mercury with chalk and potassium iodid

Improving Succinimid and sodium iodid resumed better tolerated

After One Month Mercurial and Iodid Preparation, given 3 arsphenamin injections without incident

One Month Later All Jaundice Disappeared.

Felt ell, weight best in years.

Resumed Mercury and Iodid for two Months because of recurrence of epigastric pain.

Treatment Discontinued One Month. Felt well.

Without Warning Jaundice Began to Return. Stools clay colored. Some diarrhea following constipation.

Returned to Clinic Six Weeks After Reappearance of Jaundice.

Liver as large as before, spleen not so large. Jaundice very deep.

Ray showed aortic calcification.

Albumin in urine moderate in amount, bile urobilin, and urobilinogen.

Free fluid present in abdomen.

Blood Wassermann Reaction Still Positive.

Treatment: Fluid reduced by free catharsis.

Mercury succinimid ½ grain daily

Iodid by mouth. (hence intravenously

Restriction of fluids.

Kidneys began to react and ascites increased.

Mercury colic reappeared. Patient howled with pain.

Paracentesis. Mercury stopped.

Patient Lost Ground Steadily: Mercury resumed in smaller doses.

Sulpharsphenamin 0.1 gm. intramuscularly

Blood Urea Going Up: Colic better

Blood urea 72 mg per 100

Emaciated and very toxic Extreme jaundice. Hemorrhage from bowel

Iodid stopped.

Blood Urea Four Days Before Death, 1?? mg.; t days before death, 184 mg.

Creatinin (blood) 3.8.

Death in Coma.

Necropsy Findings Destructive hepatitis (liver eighed 978 gm —syphilitic) intense jaundice, syphilitic splenitis (340 gm), acute diffuse nephritis, local hemorrhagic pancreatitis.

DISCUSSION

On this patient retura with his second ttack of jaundice I nalyzed his situation as follows

1 Probably combines two pictures ith the following order of events:

( ) Syphilitic hepatitis and splenitis with tremendous Herxheimer flare-up following the 3 neo-arsphenamin injections before entering the clinic

(*b*) Recovery from the Herxheimer and improvement in liver and spleen under continued mercurial and iodid treatment.

( ) Mercury colic and intolerance of iodids interfere ith treatment before and now Make intensive treatment almost impossible

(*d*) Tw months comparative good health show effect of previous treatment.

(*e*) Now has recurrent syphilitic hepatitis, hepatorecurrence (Milian), or

(*f*) Superposed infectious hepatitis hich in combination with the previous cirrhosis has produced the present extreme jaundice and ascites —

Fig. 676 (*Continued*)

2. As his case progressed, the signs of acute yellow atrophy destructive hepatitis, became apparent in the shrinkage of the liver the abdominal distress, and the deepening jaundice and emaciation. No leucin or tyrosin was recognized in the urine. The patient proved unable to carry even moderately intensive treatment, so that it was impossible to combat the condition as a syphilitic acute yellow atrophy. The nephritis and mercurial colic prevented mercurialization, bloody diarrhea followed iodids, and we hesitated at large doses of arsphenamin lest the arsenic simply hasten the process. Milian contends that arsphenamin is indicated.

3. Acute yellow atrophy may be part of the picture of late arsphenamin poisoning, a syphilitic relapse following inadequate treatment, or a complication of epidemic infectious jaundice. In this case it was impossible to identify the etiology impossible to treat the condition, and the fatal outcome was inevitable.

4. We have secured a good result in a similar case by the foregoing measures.

5. Note that the first flare-up, in which the liver was undoubtedly damaged seriously followed intensive use *of arsphenamin without mixed preparation*. The Pollitzer type of system may have disastrous results if misapplied in this way.

6. Bismuth as now used might have saved the situation for this patient.

Fig. 677

THERAPEUTIC PARADOX AND RELAPSE IN HEPATIC SYPHILIS

Case A, Male, aged forty-seven. 1921.

Syphilitic Hepatitis and Splenitis. Liver 6 cm. below costal margin. Spleen 3 cm.

Treatment. One week Hg. succinimide, 6 injections arsphenamin 0.2 to 0.3 gm.

Result: Liver and spleen subside much improvement. Home on inunctions.

Returns. Good condition, no fluid, but duodenal ulcer produces symptoms.

Diagnosis of Hepatitis Confirmed in operation for duodenal ulcer. Evidently active.

Neglects Treatment ten months. Marked ascites develops.

Hospital Care, Purgation, Iodid, slightly improved. Sent home on mercury with chalk.

Urine Contains Much Pus.

Returns After Five Months Much Improved on mixed treatment. Continued.

Returns After One Year. Sudden increase in fluid three months ago. Tap elsewhere followed by bloody and watery diarrhea.

Patient in Extremis. Sent home. Puncture of bowel (?).

Case B, Male, aged thirty-eight. 1919

Syphilitic Hepatitis. Recognized two years ago. Pain and jaundice.

Treatment. Mercurial injections and iodid. Inunctions.

Ascites Appeared one week ago.

First Arsphenamin Injection one week ago, elsewhere. Large dose (?).

Markedly Worse after Injection. Abdomen greatly distended with fluid. Immediate tapping required.

Treatment. Inunctions and iodid, the latter by mouth and rectum.

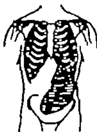
Grew Rapidly Worse. Fluid Overload, **No Catharsis, Repeated Tappings,** four times in thirty days, 7 to 12 liters each.

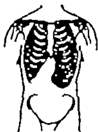
Patient Failed Rapidly. Anasarca.

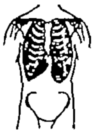
Died. Two months later.

Discussion

1. **Both These Cases Might Seem to Suggest the Ill Effects of Arsphenamin** on hepatic syphilis. Case A, however had only good results even from arsphenamin at the outset until he had neglected treatment ten months, when ascites began to develop. The operation had shown an active hepatitis, not healing, so that the ascites could hardly have been due to shrinkage and scarring.

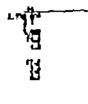






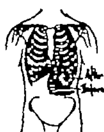
2. **Case B Illustrates the Immediate Unfavorable Effect of an Unknown but probably large dose of arsphenamin.**

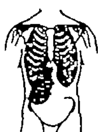
3. **Note the Contrast in the Course of the 2 Cases from the standpoint of the management of their ascites.** A was controllable by catharsis and fluid restriction. B by fluid overload, no catharsis and repeated tapping, was thrown into a vicious cycle.

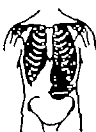


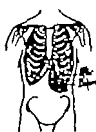
4. **Case A Might Have Been Saved by Persistence in Arsphenamin, Mercury and Iodid treatment.**

5. **Case B Might Have Been Saved by Our Present Knowledge of the Management** of ascites in syphilitic hepatitis.









6. **Note the Pus in the Urine of Case A.** Perhaps a failing kidney contributed to his relapse of ascites. Such points should be watched.

D

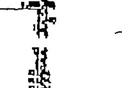


Fig. 678.—A group of cases illustrating various aspects of the hepato-splenic complex from the standpoint of blood picture, clinical diagnosis, and therapeutic response. Note syphilitic Banti complex.

CHAPTER XIX

SYPHILIS OF THE CARDIOVASCULAR SYSTEM

General Considerations.—The successful diagnosis and treatment of all special aspects of late syphilis lie in the detection and effective treatment of early syphilis in general. In no field has this apparent truism greater need of appreciation than in that of cardiovascular syphilis. Brunsgaard's clear-cut demonstration that cardiovascular disease, even more than neurosyphilis, is the Nemesis of the infection and the outcome of more than a third of fatal syphilis, cannot be too constantly borne in mind or too frequently impressed upon the medical student and upon the practitioner. Even our earliest clinical recognition of vascular involvement in this disease is unhappily comparatively late. The reason is obvious: there exists no rubric for its early detection, no sign manual like the abnormal spinal fluid to serve as a warning. Even the blood serological tests fail more often in the detection of this particular aspect of the disease. The teaching in this field, both by internists and syphilologists, has been anything but preventive. Generations of bowing at the shrine of the spectacular in physical diagnosis have led inevitably only to the identification of consequences. The demonstrator's voice rings out in triumph: the medical students crowd around the *cor bovinum* and the hat-box aneurysm: they observe with enthusiasm the thrill, the buzzing and whirring, the heave, the sound of the pistol shot. Seldom indeed does one find an equal degree of absorption or an equal frequency of demonstration of the still, small signs and symptoms of the preventable onsets of syphilitic cardiovascular disease. Until teacher and textbook turn from the parading of consequences in the amphitheatre to devote themselves to anticipatory watching in the office and consultation room, to habitual suspiciousness in observation, and to an acute analysis and ferretting out of veiled beginnings, syphilis of the heart and aorta will remain the great burying ground of the disease and the clinician's perpetual Waterloo at the hands of the postmortem pathologist.

The high points of syphilis of the cardiovascular system may be touched in three words: ubiquitous, insidious, disastrous. Vascular distribution of the infecting agent and injury to the blood vessels form the groundwork of the pathology of syphilis. It follows, then, that in almost any clinical aspect of the disease and in any method of classifying its morbid phenomena, a vascular element will be apparent. Vascular change underlies the necrosis of gumma, the absence of hemorrhage from the syphilitic gastric ulcer, the smooth, serum-discharging surface of the chancre with its hemorrhagic border. It may underlie the hemiplegia that follows rupture or thrombosis of the lenticulostriate artery in the internal capsule, or the anginal syndrome that follows syphilitic sclerosis of the coronary vessels. It is apparent, then, that no small part of syphilis of the vascular system will appear in the consulting room under the clinical mask of disease of other structures and may even fail to present any distinctive symptomatic earmarks whatever. This is particularly well illustrated by the longstanding controversy over rheumatic aortic valve disease and the differences of opinion as to a specific symptomatology for uncom

plicated syphilitic aortitis which has run the gamut from itemized tables of signs to the blanket assertion that uncomplicated syphilitic aortitis cannot be *diagnosed in life until complications appear Certain groups of vascular* phenomena may be recognizable as in syphilis of the nervous system, by certain symptoms and signs, but it may nearly always be assumed that when one tenth of the process is causing symptoms which come to clinical recognition, nine tenths with its antecedents and consequences, lie below the threshold of clinical recognition. It is this submerged nine tenths of disease of the vascular system which so frequently brings the clinician to chagrin at the hands of the pathologist, who discovers postmortem the real extent of the vascular change which syphilis produced with this minimum of symptomatic expression. Following the often mistaken or irrelevant lead of the chief complaint, the clinician is too often led astray by the prospective victim of syphilis of the cardiovascular system who, if he consults the physician at all in the early years of his disease, seeks treatment for some obvious or painful lesion such as gummatous osteomyelitis, late cutaneous recurrence, iritis, or tabetic neurosyphilis Even with every consideration for the difficulties that must confront the diagnostician in dealing with cardiovascular syphilis, there is no escaping the disconcerting demonstration recently brought forward by Moore, Danglade and Reisinger that the "index of suspicion even of a highly trained medical group toward syphilitic aortic disease is much lower than the circumstances warrant. Moore (1943) points with justifiable pride in a recent revision of his text to the fact that overemphasis, if it can be called such on a categorical list of symptoms and signs, some of which have even been proved not to be specific, has raised the percentage of the preautopsy diagnosis of uncomplicated syphilitic aortitis in the Johns Hopkins Hospital from 0.2 per cent to 26.3 per cent. Thus, indeed, is almost the crux of the matter Hypersuspicion has its place and will raise the index of suspicion of a medical group to the point where a search for collateral evidence and therapeutic tests will confirm many diagnoses and save a number of lives.

I 105 necropsy cases of uncomplicated syphilitic aortitis, the clinical diagnosis as correctly made in only 4 during life and in 13 more it was suspected that something was wrong with the aorta. On the basis of the symptoms and physical signs recorded the diagnosis might have been correctly made in 35 additional patients. Thirty-four patients died with hearts and aortas thought clinically to be normal.

It may be said with emphasis, then, that only by the most habitual and painstaking examination of the patient as a whole are the early signs of cardiovascular degeneration to be detected Not only must the signs be recognized, but they must be correctly interpreted The more one looks for cardiovascular syphilis in clinical material of whatever type the more one finds. The better one knows the earlier and the concomitant signs of syphilis as a disease the more cardiovascular syphilis he may detect at a time when its detection means some hope of recovery and not merely a veiled death sentence. It is, in fact, the examination of the well patient rather than the ill one which is the preventive crux in cardiovascular syphilis, as in all disease.

Historical Considerations and Literature.—Lancisi is credited with associating aneurysm with syphilis clinically in 1728. Wagner while still confusing the disease with atheroma, made an accurate macroscopical study and Döhle description connected the pathologic picture with syphilis in young man suffering undoubtedly from the infection. For a time the disease was known as the Döhle-Hellerschen form of aortitis. Welch, the British observer is credited by

Allbutt with the full establishment of clinical knowledge of the disease by his publication in 1873 of study of 117 cases of "fibroid aortitis, in 46 per cent of which syphilis was definitely present. The finding of *Spirochaeta pallida* in the aortic wall was first accomplished by Reuter in 1906, by Benda in the same year by Schmorl in 1907 and by Wright and Richardson in this country in 1909 The aortitis of congenital syphilis, discussed elsewhere, has been recognized since the observations of Wiesner in 1905, and the abundance of the organisms in the involved tissues in spite of the relative paucity of clinical findings has been confirmed by Rach and Wiesner and Warthin. Typical lesions have been described by Klotz.

Both on the clinical and the pathologic side, American contributions have been numerous and distinguished. During the past two decades in particular they have contributed greatly to the clarification of the entire field. Though, as he modestly asserted, Virchow foreshadowed from gross pathologic lesions some of the most striking aspects of syphilitic cardiovascular disease, it has been Warthin s technical mastery of the problem and his unrivalled persistence and patience as an investigator which have brought conviction of the ubiquity of vascular syphilis home to the medical profession at large. His insistence that microscopical findings, rather than gross path ologic changes in aorta and myocardium, are the crucial point in postmortem diagnosis, has been chief factor in broadening our conceptions of this aspect of the disease. Though they have inevitably aroused controversy and have accentuated lines of cleavage between the gross pathologic and the microscopical pathologic schools, as well illustrated, for example, in the writings of Symmers and Martland, Warthin communications have the justifiable finality of statement which only the presence of *Spirochaeta pallida* with waxed moustaches" in his microphotographs and sections can give. Klotz has clearly defined the lymphatic and periaortitic factors in the pathology of syphilitic aortitis. Reid has done much to connect pathologic findings, pathologic physiology and clinical observation in the field.

On the clinical side the American student should read particularly Allbutt' monograph, the volume by Hirschfelder the important publications of Osler Brooks, Longcope, Elliott, Pardee, Reid, Hoover Willius, Stroud, Henrichsen, Kampmeier Blackford and Smith. Most recent and extremely important are the symposium on cardiovascular syphilis before the American Heart Association in 1930, the report of the CCG (1930), the papers of Wile on therapeutic paradox, and the direct examination of treatment results by Carter and Baker and by Moore, Danglade and Reisinger containing, in addition to their own results, critical summaries of the entire diag nostic and therapeutic fields. The Continental and especially the German contributions are massively presented in the sections by Herxheimer Evelbauer and by Schlesinger in the Jadassohn Handbuch. The observations of Langer on the incidence of aortitis, and of Hubert, Frandel, Horder Kotlsey-Möller-Doham, Schottmüller and Schlesinger, have had great influence in the development of current treatment conceptions.

Among the authors contributing evidence for and against the possibility of diagnosis of uncomplicated syphilitic aortitis are: Kampmeier Glass and Fleming (1942)· Nichols (1940); Hearn (1946); Dressler and Silverman (1945) Bekaras, Hollander Goldsmith (1941); Maynard (1948); White and Wise (1937); Howles (1943); Maynard, Curran, Rosen, Williamson and Lingg (1935)

The Frequency of Syphilitic Cardiovascular Disease.—The current estimates of the incidence of cardiovascular syphilis vary with the age group, the race, the sex, and the degree of emphasis placed on microscopical as compared with macroscopical criteria. Aortic syphilis at autopsy is, of course, enormously more frequent than clinically recognized syphilis of the cardiovascular mechanism Cardiovascular syphilis constitutes from 10 to 15 per cent of all cardiovascular disease, according to the estimates of the Metropolitan Life Insurance Company (cases over fifty), Wykoff Lingg (1001 cases) and Carter and Baker (5323 Johns Hopkins cases of cardiac disease) From these various figures Moore, Danglade and Reisinger estimate that about 240 000 persons in the United States at any one time have cardiovascular syphilis, and 20 000 of these die each year

In study of 6000 patients with untreated late syphilis Turner reported that approximately 10 per cent showed definite clinical evidence of cardiovascular damage. Clawson and Bell, in 4877 necropsies, found that 126 cases (2.6 per cent) were syphilitic aortitis. Martland, from Newark City Hospital and Essex County New Jersey coroner material, found among 6067

cases investigated 1590 cases of sudden death or 18 per cent were due to heart disease. Three hundred or 18 per cent were autopsied, of these 60 were rheumatic hearts, 101 were syphilis of heart and aorta and 139 were arteriosclerotic heart disease. In 6233 patients with late or latent syphilis studied by the CCG (1936) 619 patients, or 9.9 per cent, had evidence of syphilitic cardiovascular disease, of which 4.9 per cent had uncomplicated syphilitic aortitis, 4.1 per cent syphilitic aortic regurgitation, 1.2 per cent syphilitic aortitis with saccular aneurysm, and 0.3 per cent syphilitic myocarditis. Gelperin (1940) in a study of autopsies performed at the Cincinnati General Hospital from 1926–1937 found an average incidence of 9.1 per cent of syphilitic aortitis. McDermott, Tompsett, and Webster (1942) found an incidence of 3.4 per cent of aortic regurgitation among 2718 syphilitic patients.

Langer in the enormous material of the Rudolph Virchow Krankenhaus in Berlin (43,106 autopsies), found 70 to 80 per cent of the syphilitic patients to have cardiovascular involvement. Warthin in the decade from 1909 to 1919 found cardiovascular syphilis, using both gross and microscopical criteria, in 97.6 per cent of syphilitic patients; and in the decade from 1919 to 1929, in 86.3 per cent.

The contrast of pathologic with clinical diagnostic figures is illuminating. Of Langer's material, 39.3 per cent of cases of syphilitic cardiovascular disease were diagnosed in life. Lucke and Rea found 43 per cent clinically diagnosed in life. Moore, Danglade and Reisinger found 16.2 per cent diagnosed in life.

Cardiovascular syphilis is from two to four times as common in males as in females, the higher proportion applying especially to white patients, as in Stokes's experience with Mayo Clinic material.

In 6420 cases in Baltimore, Turner found 13.9 per cent of males and 6.7 per cent of females to have cardiovascular disease; one and one-half to two times as many Negroes as whites have cardiovascular disease. Paullin, in 600 cases of heart disease in Negroes, found 38.8 per cent to be syphilitic. Of 619 patients with cardiovascular syphilis reported by the CCG (1936) 441 were males, 178 females. Of the 6233 patients with late or latent syphilis studied, 8.1 per cent of the white males, 31.0 per cent of the colored males, 6.1 per cent of the white females and 12.8 per cent of the colored females presented evidence of cardiovascular syphilis. In a study of 633 cases of syphilitic aortic aneurysm, Kampmeier (1938) reported an incidence of 3.7 males to 1 female among the colored, and 7.9 males to 1 female in white patients. Of the 633 cases 76 per cent were Negroes, 24 per cent white.

The question as to whether cardiovascular syphilis is on the increase or not is, of course, an important one both for diagnosis and treatment. Langer believes that the steady rise in the proportion of cardiovascular syphilis among syphilitics from approximately 35 per cent in 1907 to approximately 65 per cent in 1922 to 1925 is the product of modern treatment methods, particularly the use of the arsphenamines. On the other hand, Moore, Danglade and Robinson, examining Langer's figures, reached the conclusion that the apparent increase is the result of added pathologic experience, particularly in microscopical diagnosis. In a study of 3641 cases of syphilis treated during the early stages of the disease, the CCG (1930) reported only 26 cases (less than 1 per cent) which subsequently developed cardiovascular syphilis. Of 103 cases followed for ten to twenty years, 6.7 per cent developed cardiovascular disease but in none did syphilitic aortic regurgitation or aneurysm develop.

The Age of Onset.—Cardiovascular syphilis is recognized in middle life, by far the larger number of patients coming to diagnosis between the ages of thirty five and fifty five.

In 406 cases of syphilitic aortic disease at the Buffalo City Hospital Levitt and Levy (1940) found 78.9 per cent were between thirty-one and sixty years of age. Nichols (1946) reported the average age of patients in whom aortic insufficiency was diagnosed to be 48.0 years, with 73.6 per cent diagnosed between the ages of forty-one and sixty years. In 843 Negroes with syphilitic

aortic insufficiency Blackford and Smith (1938) found an average age of thirty-seven years. Of 926 patients with uncomplicated syphilitic aortitis, the CCG (1936) reported 9 per cent developed before the age of thirty years, the highest incidence (39 per cent) diagnosed in the thirty-five–forty-five age group.

The role of cardiovascular syphilis as Nemesis, its trick of taking toll of the years of mature achievement, the best of middle life, is very apparent and indicates at the same moment its enormous costliness to the community and the danger of social criteria in its diagnosis. Many young man without footbold in the world when he acquires his primary lesion at twenty is member of the substantial business or professional community when his vascular degeneration overtakes him. He is then, to his own detriment perhaps, too respectable in the eyes of his medical advisor or his life insurance examiner to have syphilis seriously considered, or he has forgotten its obscure beginnings (Fig. 679).

Duration of Infection at the Time Patients Seek Advice.—Very little cardiovascular involvement is recognized in the first decade of the disease. Forty five per cent is recognized in the second decade, 30 per cent in the third. Improvement in the present state of diagnosis must, then, be made by setting our clocks ahead a decade or two, so to speak, and studying the patient in his first five to ten years after infection, if we hope to anticipate irremediable damage.

Maynard, Curran, Rosen, Williamson, and Lingg (1933) reported that in 100 patients with syphilitic cardiovascular disease in which the duration of the infection was known, 25 per cent showed evidence of cardiovascular syphilis within ten years after the occurrence of chancre, although the mean interval was twenty years. In 170 cases of cardiovascular syphilis reported by Wile and Snow (1936), the duration of the disease was over fifteen years in 90 per cent of the cases. Of 196 patients with uncomplicated syphilitic aortitis in which the duration of the disease was known, the CCG (1936) noted 10 per cent were diagnosed less than five years after onset of the disease, 3 cases diagnosed in the second year of infection. Kampmeier (1938) reporting on 243 patients with aneurysm found the peak at sixteen to twenty years, approximately half of the patients being in the eleven to twenty year post-infection group.

There are, of course, number of well-authenticated instances of precocious involvement of the cardiovascular system with early clearly recognizable clinical signs. Among these should be, of course, included the hemiplegic accident of neurorecurrence. Reid records case in which young man infected in June had definite evidence of aortic involvement by August and enough signs for positive diagnosis in September three months after infection. Harlow Brooks observed case in which death resulted from perforation of the aorta just above the valves before the secondary eruption was fully developed. Osler noted an aneurysm of cerebral artery eighteen months after the chancre. Osler also describes in the Schorstein lecture (1909) the case of "a young man aged nineteen in the early secondary stages of syphilis who as shoving up side of beef but it came back on him so that he had to let it down. He tried again and again and at last succeeded. He was faint and tired, and soon felt severe pain in the abdomen. Shortly afterward he developed large aneurysm of the abdominal aorta. Blackford and Smith (1938) reported that eight months after dark-field examination had revealed the treponema, boy of eighteen years of age who had received no antisyphilitic treatment experienced sudden, excruciating chest pain. Cardiac failure followed promptly with signs of aortic insufficiency when examined by us. H died three weeks after onset. Autopsy revealed rupture of gummatous aortic cusp. Additional case material is reviewed on page 904. From the pathologic physiology of syphilis it is difficult to understand how the heart and great vessels can ever escape involvement, and the remarkable clinical fact is not that they are involved, but that the involvemen is comparatively benign in the early stages.

Effect of Occupation.—In a study of occupation of 1000 syphilitic patients, Cochems and Kemp (1937) conclude that physical exertion seems to contribute toward the graver forms of syphilitic cardiovascular disease. Osler said that Venus, Mars, and Vulcan were the triad responsible for aneurysm In 633 cases of aneurysm reported by Kampmeier (1938) approximately 60 per cent were laborers. In 210 cases of cardiovascular syphilis studied by Wile

Fig. 879.

CARDIOVASCULAR SYPHILIS (ANEURYSM) UNDER TREATMENT. SYMPTOMATIC IMPROVEMENT. REDUCTION IN SIZE OF ANEURYSM. PROGRESSION OF ELECTROCARDIOGRAPHIC SIGNS OF MYOCARDIAL DEGENERATION IN SPITE OF TREATMENT

Salesman, aged fifty-three years, married.

Examined 7/6/1920.

Chief Complaint: Hoarseness and suspected aneurysm (home physician). Below par for three years. Woke up hoarse six weeks before coming to Clinic.

Lit Insurance Examination Seven Years Before. Aortic Murmur Recognized, but Apparently Ignored. Went on about his business and played golf.

General Health Good, though thin and of poor color for years.

Denies Venereal Infection. On Close Questioning Recalls Penile Abrasion Thirty-five Years Ago.

Blood Wassermann Reaction. Negative at home. **Strong Positive now.**

Has Been Taking Mercury and Iodid.

First Examination

Heart much enlarged. Double murmur all over chest, loudest at first and second interspaces.

No thrill.

Dulness over manubrium 8 cm. wide.

Slight diastolic shock.

Tracheal tug.

Blood-pressure 210/70.

Paralysis of right vocal cord.

x Ray, Small Aneurysm of Arch. Heart enlarged.

Diagnosis. Aortic aneurysm with aortic regurgitation.

Treatment. Rest in Bed, sodium iodid by mouth, mercury succinimid intramuscularly.

Blood-pressure in Bed drops to 165/90.

Two Months Mercury and Iodid Preparation, 6 injections neo-arsphenamin 0.2 to 0.4 gram.

Hoarseness Disappears, general condition much improved.

Second Examination. No change in objective findings.

Electrocardiogram. Rate 83, sinus rhythm. Left ventricular preponderance.

x Ray of Chest. Small aneurysm of the arch, no change.

Two Months' Rest at Home on Inunctions.

Third Examination: Hoarseness and chest discomfort gone. Introspective.

Electrocardiogram. Rate 88, sinus rhythm, notched QRS complex, Lead II, left ventricular preponderance.

x-Ray of Chest: No change.

Fourth Examination: Complaints as on third examination.

Electrocardiogram. Rate 75, sinus rhythm, inverted T wave, Lead I, left ventricular preponderance.

x Ray of Chest. No change.

"The development of T wave negativity in Derivation I unfavorable (Willius).

Treatment: Rest, small doses neo-arsphenamin 0.05 to 0.4 gm. 6 injections. Quinidin 3 gr. three times daily before and after injection. Bromids.

Sixty Inunctions at Home. Returns year and three months later.

Fifth Examination: Symptoms as on third examination.

Electrocardiogram. Rate 75 sinus rhythm, aberrant QRS; Lead II slurred, Lead III notched. T wave negative. Leads I and II. Progressive myocardial degeneration.

x Ray reported negative.

Inunctions and Iodid at Home. Returns in seven months for re-examination. Has restricted his activities markedly.

Sixth Examination: Condition fair as usual.

Electrocardiogram. Rate 82, sinus rhythm. Slurred QRS II, notched QRS III. T wave negative in Leads I and II and P wave negative in Lead III. Progressive myocardial involvement. (Coronary sclerosis?) x Ray of chest. Slight dilatation aortic arch. Heart enlarged.

Fig. 679 (*Continued*).

DISCUSSION

1 In this case again, we have an illustration of the effect of ignoring an aortic murmur Had the clue been followed up and treatment pushed at the time the life insurance examiner identified the lesion, the patient life expectancy might have been greatly prolonged.

2. Note that only with considerable effort, and after negative blood Wassermann reaction had been rechecked with positive, was it possible to obtain history of syphilis, the landmark to which the practitioner too often clings in his effort to identify the underlying cause.

3. Negative and fluctuating positive blood Wassermann reactions are not rare in syphilitic vascular disease.

4. Considering this patient's condition his treatment was fairly intensive. In view of the disastrous results that may attend therapeutic overenthusiasm, especially in the too early use of arsphenamin (Fig. 706), it was vigorous treatment.

5 *Treatment was worth while from the standpoint of the patient's comfort, for it* relieved him of his hoarseness and chest pain, greatly reduced his dyspnea, and increased his sense of well-being. In physical appearance and ability to carry on some kind of remunerative work he was very much improved.

6. From the standpoint of his aneurysm it resulted in reduction in size of the sac, an unusual occurrence. In three years the lesion retrograded from the point where it was readily identified by x-ray to the point where one x-ray was reported negative, and second some months later slight dilatation of the aorta. T this extent therapy was undoubtedly of value.

7 The valuable series of successive observations by Willius, showing progressive evidence of myocardial damage as evidenced by the electrocardiogram, raises the question as to whether the myocardium can be reached by treatment, whether progressive coronary sclerosis occurs as the result of, or in spite of, treatment, and whether the myocardial damage is the result of actual progress of syphilitic lesion, or the result of fibrosis in the process of healing. The grave electrocardiographic signs, as Willius has shown, are the appearance of T wave negativity first in Lead I and later in Leads I and II; and the development of aberrant QRS complexes.

8. It is as yet too early to evaluate exactly the influence of treatment in the development or retardation of these myocardial lesions. I another case (Fig 781) under observation for similar period, minimal treatment to arrest mild tabes with unrecognized myocardial lesion, was later found to be associated with progressive signs of myocardial degeneration, which have not yet, however terminated fatally Just what progress an untreated case could make under similar circumstances remains to be determined. There is little doubt that overzealous treatment t the outset, by inducing rapid uncompensated changes in the vascular tissues and sudden shrinkage of the coronary circulation, does harm.

and Snow (1938) at the Univ of Michigan Hospital, there were 34 per cent laborers, 22 per cent tradesmen, 15 per cent officeworkers, 26 per cent housewives or domestics, and 2 per cent professional workers.

THE PATHOLOGIC FINDINGS AND PHYSIOLOGY

The pathologic changes induced by syphilis in the vascular mechanism have been to some extent discussed in other chapters, but a review of their specific application to the heart and aorta is especially necessary to a compre-

hension of the pathologic physiology of syphilitic cardiovascular disease In the interpretation of the various changes observed the views expressed depend to some extent on the relative weight given to gross and to microscopical appearances. Thus Warthin, using the microscopical group of lymphocytes and plasma cells as a guide, stressed the enormous extent and variety of vascular involvement and gave the myocardial phase perhaps greater weight than have some clinicians and pathologists Martland for example, in the American Heart Association symposium strongly opposed Warthin's views of the importance of myocardial change in cardiovascular syphilis, stressing particularly supravalvular aortitis as the one most common and most characteristic lesion of cardiovascular syphilis. The difficulty experienced by some investigators, such as Clawson and Bell in finding spirochetes in lesions described by Warthin as spirochete-containing, has formed the basis for much argument. Personally from a number of experiences in spirochete staining and through Warthin's courtesy in allowing us to see a number of his preparations, we believe that we must yield to him as our master in the matter and ascribe to technical difficulties many of the reported failures to confirm his findings.

General Vascular Pathology.—*Spirochaeta pallida* invades larger vessel walls by way of the vasa vasorum. The endarteritic process which they set up in the blood supply of the vessel walls and the effect of the lymphocyte-plasma cell invasion is to cause patchy destruction of the elastica with crinkling, fibrotic weakening of the vessel wall and aneurysmal changes. In the finer capillaries of the peripheral circulation, as in the brain, endarteritis leads to thrombosis and ischemic injury of the affected tissue. While much emphasis has been placed on the mesaortitis associated with the involvement of the vasa vasorum, there is strong ground for the belief that an adventitiitis, or even a periarteritis, may furnish the primary source of damage, particularly in the case of the aorta and the great vessels in the mediastinum.

Pathologic Changes in the Aorta.—The bulb and lower portion of the ascending aorta is the theater for the most striking and characteristic pathologic changes in syphilis of the vascular system. Here the perivascular invasion assumes considerable importance. Klotz has pointed out that there is good reason for suspecting that the distribution of spirochetes in aortic disease is lymphatic from without, rather than hematogenous from within. The important lymph node groups in the mediastinum lie around the base of the aorta and the bifurcation of the trachea, and lymph nodes are also numerous in the mediastinal tissues. The inflammatory processes which underlie aortitis and aneurysm, therefore, are in part periaortitis and mediastinitis by extension from the lymphatic reservoirs of spirochetes in these regions as well as a mesaortitis from invasion by way of the vasa vasorum. Clinically there seems to be much to support Klotz' view of an extra-aortic factor in aortitis. The symptoms of aneurysm, for example, judging especially by their response to treatment without change in physical signs, are clinically in part those of mediastinitis and not merely those of pressure from dilated vessel whose walls have been weakened by arteritis. The symptoms may disappear without visible change in the caliber of the vessel. The pain lacks the pulsating character to be expected in mere pressure phenomena. Moreover the expansile impulse is frequently lacking in an aneurysm until after treatment has produced resolution of the incarcerating mediastinitis. Such late appearance of pulsation with relief of symptoms in spite of frequently apparent enlargement of the aneurysmal sac seems due more probably to resolving inflammatory infiltrate than to resolution of clot or of changes intrinsic to the vessel walls. The presence of enlarged lymph nodes around the ascending portion of the arch and evidence of thickening, shown by the roentgen-ray are too common observations to be entirely without significance Increase in definition of the margin of an aneurysmal sac and decrease in density which we have several times observed after treatment, seem to confirm our impression (Fig. 707) that treatment relieves symptoms in part by resolving an external inflammatory process.

The localization of the syphilitic invasive and degenerative process to the region of the aortic bulb and sinuses of Valsalva presents double menace. Infiltration with subsequent fibrotic replacement of elastica results in weakening of the aortic ring and destruction of the mobility and competence of the valve flaps. The development of nodules and infiltrates contributes to the insufficiency Martland places the site of onset of the characteristic syphilitic supravalvular sclerosis in the portion of the aorta above base line drawn through the upper limits of the attach-

ments of the aortic cusps. Utilizing the observation of Von Glahn on high-placed coronaries as frequent congenital anomaly Martland thinks that the sinuses of Valsalva are less often involved than has been believed, much of the atresia and stenosis of coronary orifices arising in the case of congenital upward displacement of the openings. There is general agreement that most of the injury done to the coronary arteries by syphilis is secondary to the aortic change about the orifices rather than in the walls of the coronaries themselves.

The Mediastinal Factor in Early Aortic Physical Signs.—The mechanism of the earliest physical signs of aortitis (accentuation and change in timbre of the second sound at the aortic area, and aortic systolic murmurs) may be interpreted as a function of the perivasculitis and mediastinitis described as early features of the pathologic process.

The experiments of Reid in the production of murmurs in tubes in which change in material or density takes place at given point bear out the possibility of murmur arising simply from change in the structure of the aortic wall and its surroundings. The fact that even a tremendous

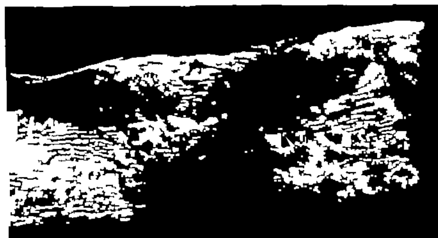

Fig. 690.—A typical syphilitic aorta. Note the criss-cross striation or wrinkling This aorta was found in patient aged sixty-five, ho was known to have had neurosyphilis during life, but in whom there had not been the slightest clinical sign of aortitis. He had been under observation and repeated examination for years.

roughening and distortion of the inner surface of the aorta from syphilitic atheroma, as shown in Fig. 690, may never produce signs marked enough to attract clinical attention, is apparent from the cases which are not recognized before necropsy These cases seem to bear out Reid' experimental observation that mere roughening of the inner surface of the tube without change in its material, rigidity or caliber does not give rise to murmurs. Leiby Callaway and Fleming (1940) suggest that the murmur is in part due to venturi effect producing eddies t the periphery of the central column of ejected blood in the dilated aorta, and the tympanitic sound to water-hammer effect from the larger volume of blood in the dilated inelastic aorta. The early signs of aortic syphilis, then, are conceivably due to the recoil of the valve and vibrations in the wall of tube whose behavior under moving column of fluid has been altered by changes in its rigidity and caliber, due to surrounding inflammatory process, periaortitis as well as an arteritis. If the periaortitis has progressed beyond certain point, damage has been done to the vessel wall and its supports which will never permit the tube to regain its normal elasticity or caliber

Treatment, with healing sclerosis exaggerates (Fig 719) rather than reduces the signs. On the other hand, if the process is extremely early function

may be completely restored and the murmur at least will completely disappear

The Mechanism of Development of Aneurysm.—The important part played by perivasculitis and mediastinitis in the development of aneurysms, especially in the thorax, is suggested by the fact that two lesions of the arch of the aorta in many respects similar as judged by clinical signs, give rise to two widely different groups of symptoms, one of which suggests a marked and severe grade of mediastinal pressure and extensive involvement, though little or nothing can be seen with the roentgen-ray while the other with a practically asymptomatic course, has a lesion easily visible by roentgen-ray. The smaller sacculations or "finger" aneurysms (Fig. 893) are of course, the results of localized bulging at weak spots due to the fibrosis resulting from inflammatory changes around the vasa vasorum, but clinically the behavior of the wholesale bulge of the whole side of the vessel as in aneurysm impresses one as more suggestive of a perivascular than an intramural lesion. This impression is deepened by observing the way in which the subjective symptoms and some of the signs of aneurysm may disappear completely under treatment, without any detectable change in the size or pressure-producing capacity of the lesion.

Study of the relations between the blood pressures of patients with aneurysm and those with aortitis alone in the Mayo Clinic material strongly indicated that the production of aneurysmal dilatation in the diseased aorta is not the direct result of the sharp, repeated pounding of a powerful hypertrophied left ventricle, producing a high but transient systolic pressure against a weakened vessel wall. The tendency of systolic blood pressure in both aortitis and aneurysm, as Martland has also observed, is to be low and especially low in aneurysm. On the other hand, diastolic pressure, presumably maintained in part by the integrity of the aortic valve, tends to be low in aortitis without aneurysm and high in aneurysm. It appears, therefore that the integrity of the valve, by making possible the maintenance of a constant, even though lower pressure on the aortic wall, is the more probable factor in deciding whether a diseased aorta will tend to develop aneurysmal dilatation or not. If aortic valvulitis is the principal feature of the picture, the patient tends to escape aneurysm by the development of regurgitation. He reaps little benefit thereby however for he is only precipitated then on to the less kindly lap of myocardial failure from atresia of the coronary orifices, coronary sclerosis, and the ultimate decompensation of a hypertrophied but inadequate or fibroid myocardium. These considerations are of some use in interpreting the treatment and prognostic outlook of the two principal types of syphilitic aortic disease.

The Myocardium.—Myocardial direct invasion by *Spirochaeta pallida* is logically a feature of all aspects of cardiovascular syphilis. Nowhere is the difference between invasion and reaction better illustrated than in the vast numbers of organisms that may be present in the heart muscle of the prenatally syphilitic child without the slightest sign of tissue reaction. But when it comes to the interpretation of the visible changes of chronic fibrotic myocarditis, the logical sequel of reaction to *Spirochaeta pallida*, discordant opinion at once becomes manifest. The inability of many in fact most pathologists, to demonstrate the organisms in heart tissue in association with myocarditis plus syphilis, has thrown much doubt about the statistical prevalence, not to say the actual existence of such an entity as syphilitic myocarditis. For an excellent critical review of the whole problem since Warthin's publications, see Saphir O Arch. Path. 16 00–15? 1933 with a bibliography of approximately 400 titles. For excellent microphotographs, see Warthin, J C J A.M A. 108 109 1937 The gist of the matter would appear to be this. Did Warthin see *Spirochaeta pallida* or artefact? Are there not reasons for suspecting that the form of the organism may be altered under conditions prevailing in heart muscle? Are the observed changes, especially the degenerative ones observed in the heart muscle of the syphilitic not equally well explained by the ischemia produced by disease at the coronary orifices, where as in the aorta, it is much easier to find acceptable *Spirochaeta pallida*? That there is a true syphilitic myocarditis seems reasonably established, in the form of an acute or subacute process, relatively uncommon in the opinion of many clinicians and pathologists. It is the ubiquity of syphilitic myocarditis that is questioned, and the specificity of changes which can be explained without the presence of spirochetes, as expressions of general myocardial injury of nutritional origin. As we have already said, our experience with the staining of *Spirochaeta pallida* in the nervous system and our observation of the striking effect of direct instruction by Warthin, on those who have had difficulty with his methods, as well as our study of Warthin's own slides, lead us to accept his belief that true syphilitic myocarditis of chronic type organism present, does exist. As the methods for the detection of conduction defect for example improve (Wolferth, Edeiken, Margolies) they indicate an increased frequency in syphilitics, but whether this increase is due to lesions or disturbances produced by ischemic fibrosis or active spirochete-containing foci, is still "over the horizon

Ischemic fibrosis of the myocardium from coronary obliteration appeared in Carr series in less than 10 per cent of 127 cases. Warthin found active syphilitic lesions of the larger coronary vessels to be infrequent. On the other hand, in contrast to the rarity of thrombosis, sclerotic changes are more frequent.

Syphilis and Arteriosclerosis, Especially Coronary Sclerosis.—Herxheimer in his discussion of syphilitic aortitis, points out how rapidly especially with advancing years, the characteristic picture of aortic syphilis is cloaked by an advancing arteriosclerosis, leading to marked fatty changes, atheroma and calcification. Scott has pointed out that syphilis gives rise t the smooth plaques which rarely ulcerate, while ulceration is common occurrence in arteriosclerosis and atheroma. Elliott has emphasized on the other hand, the comparative rarity of calcification in the syphilitic aorta. Herxheimer emphasizes the importance of comparing the root with the peripheral portions of the aorta, for in the latter the pure atheromatous changes can be identified as basis of comparison with the mixed picture presented at the root. The practical importance of arteriosclerotic change is greatest with reference to the coronaries. Clinicians, including Levine, have been disposed to assign syphilis minor role in the production of coronary sclerosis. Warthin, however in one of his last papers, reviewed this question from the standpoint of the microscopical lesions and large autopsy experience. His findings show clearly that whereas coronary sclerosis occurred in 24 and 38 per cent respectively of two groups of nonsyphilitic autopsies, it occurred in 31 and 54 per cent of the tw corresponding groups of autopsies on syphilitic patients. Angina pectoris, myocardial infarction, and coronary thrombosis likewise occurred more frequently in syphilitic than in nonsyphilitic patients.

Saphir (1933) summarized the subject of coronary embolism. Norris (1937) described in detail narrowings, puckerings, corrugations, swellings, small sacculations interspersed with yellow deposits in the first five cm. of the length of the coronary arteries, one sometimes involved without the other. *Arteriosclerosis seems to begin at the terminals, syphilis at the ostia*, but the two processes are often associated. Porter and Vaughan (1940) bring the literature of coronary embolism as complication of syphilitic aortitis up to date (30 cases, 3 new) Burch and Winsor (1942) identified myocardial infarction in 1.5 per cent of 21,618 cases of heart disease (369 cases) of which only 3 could be ascribed to syphilitic coronary stenosis. Of 103 patients with syphilitic aortitis however 40 (40 7 per cent) had narrowing of one or both coronary arteries. Strassmann and Goldstein (1942) review literature and opinion on aortic-coronary involvement.

Syphilis of Peripheral Vessels.—Clinically speaking, the circle of Willis at the base of the brain probably follows the ascending aorta in frequency as site of syphilitic vascular changes. Syphilis of the arteries of the extremities is comparatively uncommon and syphilitic thromboses and endarteritic changes in the arterioles rarer still. These processes, when they affect the larger vessels, give rise to isolated massive gangrene, and when they involve the smaller arterioles produce the remarkable picture recently described by Warthin and Wile in the form of multiple punched-out *gangrenous ulcers of the skin and subcutaneous tissue. Peripheral capillary endarteritis* gives rise to clinical pictures suggestive of Raynaud' disease and arteriosclerotic gangrene (Fig. 700). None of these pictures has, clinically at least, high degree of specificity Aneurysmal changes in the larger vessels of the extremities are well recognized, but are not always syphilitic. Saphir pointed out, from study of 80 cases of syphilitic disease of the larger vessels that the branches of the aortic arch and the common iliac, because of their excess elastic tissue, more frequently show injury and interruption of continuity of the media than do the muscular vessels such as the femoral, in which button-like fibrosis with little medial change occurs. Syphilitic phlebitis, both an acute form associated with early syphilis and more chronic type in the later stages, is well recognized, tends to involve the saphenous veins and may also affect the superficial arm veins. The literature including the earlier important contributions of E. Hoffmann, and an American case reported by Morrow and Epstein is reviewed by Evelbauer (Jadassohn Handbuch)

Gumma in the Vascular System.—Typical changes of the gummatous type occur in syphilitic infiltrates of the heart muscle (Warthin) Harlow Brooks found true gumma in 5 of 80 cases. The frequency in the case of gumma of the heart ranges according to material from 1 in 600 to 6 in 20,000 autopsies, according to Schlesinger summary (Handbuch). Spain and Johanssen (1942) summarize the experience of the Bellevue Hospital, N Y in three cases of heart gumma in which conduction defects were explained by the location of the lesion. Gordon, Parker and Soma Weiss (1942) in reporting gummatous aortitis, gave the percentage of microscopic gummas recognized in chronic syphilitic aortitis as 2.2 per cent.

Syphilis of the Pulmonary Vessels.—Syphilis of the pulmonary artery is extremely rare. According to Laubry and Marcel Thomas it may take the form of specific primary arteritis, secondary arteritis accompanying the so-called Ayerza disease (see p. 1172), and thirdly sclerotic changes. The proliferative type of arteritis with gummatous changes leads to sclerosis,

scarring and pulmonary valvular stenosis or aneurysm. (See Allan and McCracken 1940.) Warthin and Peck (1927) have discussed the pathology. McPhedran and MacKenzie have described a case of massive hemorrhagic infarction of the lung due to pulmonary endarteritis and thrombosis. Segal (1940) has reported pulmonary (gummatous) arteritis with rupture into the bronchial tree. The syphilitic character of the Ayerza syndrome is regarded by a number of observers as not completely established (Herxheimer Handbuch).

THE CLINICAL COURSE OF CARDIO-AORTIC SYPHILIS

It is customary to discuss the cardio-aortic manifestations of syphilis in terms of the structure involved. We believe, however, that a touch of vividness and a little closer contact with the examining and consulting room will be established by a chronological discussion carrying the patient from the period of syphilitic secondary manifestations through latency and the years of observational control or lapse to the actual development of clinically recognizable lesions.

The Silent Period.—We have already emphasized in previous discussions the silent invasion of the cardiovascular mechanism by *Spirochaeta pallida* and the latency ranging from several months to twenty-five or more years, when even the most thoroughgoing search fails to disclose a single abnormality. As we have already pointed out in the discussion of the treatment of early syphilis, there is a certain inevitability about the advance of cardiovascular disease during this silent period, and there are certain predisposing influences (*e. g.* physical exertion). Even under fairly thorough modern treatment for syphilis and with practically continuously negative serological tests, patients will develop the signs of the second or warning period. Relapsing serological tests, including occasional faint positives, and the fixed or irreversible positive, both should direct attention to the possibility that the silent period may terminate in definite evidence of cardiac or aortic disease.

Harlow Brooks and Carroll have observed 24 cases in which the cardiac involvement occurred during the secondary period of the disease. In 2, autopsy confirmation was obtained, the remaining 22 recovering under specific treatment. One of his patients died of acute myocardial failure, another of perforation of one of the aortic sinuses. Arrhythmia and tachycardia were observed in several instances, there were 2 cases of acute pericarditis and several of apparent early endocarditis of the aortic valve which rapidly and completely cleared up under specific treatment and no other measures. Stroud reports a case of syphilitic aortitis nine months after infection. Grassmann's study is no longer acceptable in the light of present more refined methods of study. Turner and White, in a thoroughgoing cardiovascular examination of 50 cases of secondary syphilis, including roentgenograms and electrocardiographic studies, found practically no sequelae cardiovascular changes attributable to syphilis. F. N. Wilson made physical and electrocardiographic examinations of 40 patients with secondary syphilis, with negative results. Arnett found no organic cardiovascular disease demonstrable in 25 cases of secondary syphilis, 10 with electrocardiograms by Wolferth. Arnett's study was of particular interest because it bridges the gap between the silent phase and the period of clear-cut early signs. He worked with women, in whom the incidence of cardiovascular disease is statistically less than in men, and used a control series of 70 cases which clearly brought to light the fact that until definite signs of aortitis appear (3.6 per cent of his cases, with regurgitation in 2 per cent) only a tendency to tachycardia more marked in both the early and late syphilitic patients, and an increased incidence of T-wave defects in the electrocardiogram pointed toward abnormality of the cardiovascular mechanism in the syphilitic group. Aortic systolic murmurs were no more frequent in the two syphilitic groups considered than among the controls. Lukomski found cardiac enlargement in 13.5 per cent of his cases. In contrast also with Arnett, Lukomski found definite hypertension in the younger patients, in contrast with hypotension found by Arnett. In the C.C.O. (1936) material only 10 per cent of

The Mayo Clinic series referred to in this chapter is more fully reported in the first edition of this work, and consists of 190 patients.

patients had developed detection signs before the fifth year and there was none in which the duration of the syphilitic infection was less than one year

Pericarditis and endocarditis, the former with friction rubs, has been reported (Schlesinger, Handbuch) but valvular changes with the endocarditis are skeptically regarded (Price)

The Prodromal Period.—First Warnings, Subjective and Objective.—Paradoxically speaking, of the warnings, the first may be sudden death.

Fatal Exacerbations of Myocarditis.—In 1928, Warthin, still further to confound his clinical opponents on the frequency and significance of syphilitic myocarditis, reported 8 coroner's cases of sudden death due to an exacerbation or "spirochaetal crisis" in the course of latent syphilitic myocarditis. The individual patients ranged in age from twenty-five to fifty-seven years, only 3 were definitely known to be syphilitic, in 1 there was clinical suspicion of rheumatic fever and 4 presented no clinical or historical evidence of syphilis. All were apparently in good health, the fatal accident being brought on apparently by overexertion and heat. Death occurred within few hours to two days with symptoms of dyspnea, cyanosis, vague precordial distress and dizziness, radiating pains, burning sensations, and palpitation and collapse. *Spirochaeta pallida* was demonstrated in the heart muscle of all 8 cases.

In the discussion of these cases, Warthin brought out in classic fashion his conceptions of the mechanism of cardiac death in the syphilitic patient, including: (1) Myocardial atrophy and fibrosis due to slowly progressive mild syphilitic lesions in the myocardium terminating in acute dilatation, (2) syphilitic lesions of the coronaries, resulting in infarction and fibrosis; (3) combinations of these two processes; (4) true aortic valvular syphilis with decompensation, (5) combinations of myocardial syphilis and syphilitic mesaortitis, and (6) acute myocardial death of the type just described, the frequency of which remains to be determined.

In his subsequent examination of the question of sudden cardiac death in the syphilitic patient in particular connection with coronary sclerosis, Warthin found that sudden death due to cardiac decompensation and dilatation is five times as frequent in latent syphilitics as in nonsyphilitic persons.

Prodromal Period.—First Signs of Aortic Disease.—Moore Danglade and Reisinger's effort (1932) coordinated with the work of Carter and Baker (1931) to place a well-defined symptomatology of uncomplicated syphilitic aortitis at the disposal of the physician, has resulted, first, let us say as syphilologists, in a valuable rise in the index of suspicion as applied to the diagnosis of syphilitic aortitis, and secondly in a critical and at times controversial reexamination of the entire question of diagnosis in aortitis at large, and syphilitic aortitis in particular The reexaminations have compelled substantial modification of the Moore, Danglade and Reisinger diagnostic criteria, and cannot be regarded as yet as settled In other words, there do not exist absolute criteria for diagnosis, but rather suspicion-arousers which will, and have already led to a substantial reduction in the rather discreditable gap between clinically diagnosed aortic syphilis and the prevalence of the condition at autopsy Fig 681 undertakes to summarize these suspicion-arousers under the categories of signs and symptoms, following a categorical statement of the question at issue. The individual signs and symptoms merit additional comment, as follows

The Altered Aortic Component of the Second Sound.—Agreement seems so far general that this is the most important of the early signs of syphilitic, as distinguished from general, aortitis, that every physician called upon to check the course of the disease in patients over a period of years should familiarize himself with it. It should be emphasized that altered tonal quality rather than mere accentuation is the essence of the matter The words used to describe the musical quality of the sound vary from the hollow tap of an Arab drum to the German "clang" "Amphoric" is often used, and "tambour

is to our minds the best term Age, and the absence of hypertension are essential considerations when this sound is recognized but notwithstanding this qualification, the tonal quality described gives support to a diagnosis of syphilitic aortitis. Some cases of hypertension arteriosclerosis without hypertension and some normals may give an identical tambour type of sound according to Wolferth *et al.* (personal communication)

Fluoroscopic and Teleroentgenologic Criteria.—These have grown steadily in importance under the evaluative process, and fluoroscopy seems largely to have displaced dependence on the teleroentgenogram at the hands of the most experienced observers. Maynard (1942) and Moore particularly maintain, that routine postero-anterior teleroentgenograms and the Vaquez Bordet measurements of aortic width cannot be trusted unless extreme values are noted In fluoroscopy oblique positions must be used and where the apparatus permits, plates should be timed to meet the movements of the heart. In all interpretations, experience on the part of the examiner is of great importance and particularly so in estimating the effects of age and of structural types and relations involving the thorax, the diaphragm and so forth. It is believed therefore that the most expert cardiologic assistance possible should be obtained for this work, and that *such items as the measurement* of the true diameter of the aortic knob should not be employed by those whose personal experience does not fit them to interpret such work as that of Roesler (1943) and publications such as those of Maynard (1942) Boharns, Hollander and Goldsmith (1942) and others A localized bulging of some part of the aortic arch particularly the ascending portion, is almost pathognomonic of syphilitic aortitis (Wolferth *et al*)

Aortic-Systolic Murmur—As in the interpretation of aortic density caliber and so forth age is of critical importance, so also with the aortic systolic murmur Physiologic systolic murmurs at the base of the heart are notable traps for the inexperienced and were found to be particularly common in women with syphilis and patients under stress (Arnett, 1920) a point which our experience confirms Variability from time to time during the examination or in successive examinations, particularly after the patient has been at rest, disappearance on change of posture, particularly on sitting up evidence of a nervously over-acting heart, are particular reasons for distrusting this sign. In persons under forty without hypertension, when the murmur meets the qualifications described under 4c in Fig 681 further detailed study is justified rather than a diagnosis of aortitis or a confirmed suspicion of syphilitic aortitis.

The Serologic Reaction.—Opinion on this point varies from a categorical insistence on an invariable one or two strong positives to establish the presence of syphilis, to the Cooperative Clinical Group s (1936) finding of only 73 per cent positives (including weak positives) and a reduction to 52 per cent in patients who had had preceding treatment and Willius s (1931) 10 to 15 per cent seronegatives in the Mayo Clinic experience. Blumgart (1930) estimated that 20 to 30 per cent of patients with syphilitic aortitis and complications have a negative serologic reaction. The interpretation of serologic tests in these cases is being increasingly complicated by the recognition of biologic false positives rather than negatives, so that clinical evidence and spinal fluid examination must often be invoked for assistance (see below)

Clinical Evidence of Syphilis.—This includes first scars and late syphilids (CCG 4 per cent skin, 5 per cent bone, 2 per cent visceral) (Figs. 702–703),

a reliable history of diagnosis rather than merely treatment, and above all, clinical and spinal fluid evidence of neurosyphilis which is present in from 50 to 70 per cent of patients with cardiovascular syphilis. Willius (1941) using Mayo Clinic experience, found 70 per cent of aortic syphilis to have abnormal spinal fluids. Other figures CCG (1936) 49 per cent, Wile and Snow (1938) 31 per cent, Levitt and Levy (1940) 28 per cent, Strond (1943) 50 per cent.

Minor Signs.—Pulsation in the first and second interspaces to the right of the sternum at the cricoid cartilage and in the suprasternal notch have been specifically mentioned by Strond (1943) and Willius (1941). Pulsations in the suprasternal notch are extremely common in hypertension with elongation of the aortic arch and are usually seen late in syphilitic heart disease (Wolferth, Margolies and Edeiken). Relative widening of retromanubrial percussion dulness has been sharply criticized since its proposal by Moore, Danglade and Reisinger (1932) and is now generally accepted as a late sign of aortic dilatation, pointing towards beginning aneurysm rather than towards uncomplicated syphilitic aortitis.

The Earliest Symptoms—Retrosternal Pain.—This rates easily as the most important complaint in patients with early aortitis. In the earliest cases it is more often paroxysmal than continuous and much influenced by exertion, but as the disease progresses, the continuous burning ache beneath the sternum becomes the more clearly defined symptom, and one almost immediately relieved when treatment for syphilis is instituted. Other causes of substernal pain or ache should be considered, such as hypertension, esophageal spasm, etc. Precordial anxiety dependent largely on exertion, is a much less trustworthy and suggestive symptom. Paroxysmal nocturnal dyspnea we place second, in deference to the prominent names in the literature attached to its emphasis, for in our experience it is rare. The onset of the dyspneic attack is dramatic, and in fact must be so to be distinctive the picture being that of a pseudo-asthmatic or cardiac asthmatic storm waking the patient who hastens to a window to get air and suffers acutely from a few minutes to a half an hour with abrupt subsidence of the symptoms followed by exhaustion. While Keefer and Resnik (1926) Carter and Baker (1931) and Moore and associates (1932) emphasize this symptom Kampmeier Glass and Fleming apparently found it to be almost as common (47 versus 50 per cent) in syphilitic patients without, as with pathologic evidence of uncomplicated aortitis (1942). Paroxysmal dyspnea, unless it be a nervous phenomenon, is produced by left ventricular failure or paroxysmal tachycardia of some form. It is nearly always a late manifestation of cardiovascular syphilis and is rarely present unless aortic regurgitation has developed. It is not an "anginal equivalent. Symptoms of diminishing cardiac reserve coming on abruptly in relatively young persons in whom other obvious cardiovascular disease can be excluded justifiably arouse suspicion, but are certainly not a definitive group of symptoms. Somewhat the same thing can be said of coronary paroxysmal pain with characteristic radiation, though again, coronary disease in relatively young persons without hypertension or premature arteriosclerosis very properly calls for confirmation or negation of the possibility of syphilis. In these hard pressed days, alcohol, coffee, tobacco, and cardiac (sympathetic?) neurosis, together with other causes enumerated under *anginal mechanisms* must be carefully weighed, and are too often overlooked.

What Makes Clinician Diagnose Rheumatic Aortic Valvular Disease as Against Syphilitic Aortitis?—The literature on this question is controversial and sometimes, within the same paper

Fig. 681

SUSPICION AROUSERS IN SYPHILITIC AORTITIS

The Close of the Latent Period

1. Existing controversy embraces the questions:
   (a) Can aortitis be definitively diagnosed before complications appear?
   (b) Can aortitis when recognized be diagnosed by direct evidence (distinctive symptoms and signs) as syphilitic aortitis.
2. The weight of opinion, broadly speaking, answers both questions with a qualified no. Uncomplicated syphilitic aortitis may be suspected rather than diagnosed
3. Among the authorities, in answer to 1a (note the "qualified" above)—
   (a) Yes: Moore (1941) Howles (1943) Stroud (1943) Hansen (1944), Maynard (1944), Carley and Reid (1942), Cooperative Clinical Group (1936), Leiby Callaway and Fleming (1940), Dressler and Silverman (1945).
   (b) No: Scott (1947), Wilson (1937) White and Wise (1937), Nichols (1940) Bedarra, Hollander Goldsmith (1942), Kampmeier Glass and Fleming (1941), Wolferth, Margolies and Edeiken (personal communication, 1943).
4. The earliest suspicion-arousing signs in order of accepted importance (more important than symptoms):
   (a) Evidence of localized aortic bulging, especially of the ascending portion of the arch; abnormal density (many uncertainties including anatomical and other variations), considering age (under forty) and medical history; abnormal or localized pulsation and bulging, especially to the right. Fluoroscopy essential, plate much less reliable (Maynard), especially Vaquez-Bordet measurements.
   (b) The altered (tympanitic, amphoric, tambour) aortic component of the second sound, in patients under forty without hypertension.
   (c) An aortic systolic murmur in persons under forty without hypertension, persistent with or accentuated by change of posture (sitting). Transmission upward into vessels of neck, occasionally heard at apex.
   (d) Clinical evidence of syphilis, including neurosyphilis, scars, reliable history etc
   (e) A confirmed positive serologic test or tests.
   (f) Pulsation first and second interspace to right of sternum or in suprasternal notch (relatively late may be due to elongation of arch as in hypertension).
   (g) Relative widening of retromanubrial dulness (late and in other conditions).
5. The suspicion-arousing symptoms (nonspecific and less significant than signs)
   (a) Retrosternal pain, precordial stress, on exertion or continuous.
   (b) Paroxysmal (nocturnal) dyspnea (rare in our experience also Wilson) Very late produced by left ventricular failure with aortic regurgitation, may be simulated by nervous phenomena (Wolferth *et al*)
   (c) Diminishing cardiac reserve: tachycardia, weakness, dyspnea and nonproductive cough on exertion, palpitation, dizziness, edema. Some late some nonspecific
   (d) Coronary (paroxysmal) pain, with characteristic radiation, etc (usually late).
   (e) Abrupt onset of above symptoms under age forty alcohol, coffee and tobacco, and rheumatic heart disease considered.
6. Electrocardiographic changes. In young persons without other explanation, may be suggestive A higher proportion of EKG abnormalities in syphilitics without physical signs of heart disease than in similar group of nonsyphilitics. Conduction disturbances (minor intraventricular defects) T wave changes, slurring or splintering of QRS complex and so forth (Wolferth, Edeiken and Margolies).
7 Suspicion-arousing calls for due weight and examination for other causes of cardiac disease painstaking examination for evidence of syphilis; willingness to use the therapeutic test with conservative interpretation of nonspecific effects; and to be a little more ready to accept the syphilitic possibility than determined to reject it.

self-contradictory for which coverage is sought by the statement that so many exceptions exist that categorical statement is impossible Even on the question as to whether syphilitic and rheumatic aortic valvular disease coexist, there is no unanimity but the studies of Liss and Chandler (1934) and Liss, Solomon and Eckstein (1942) seem clearly to indicate that coincidence of the

two diseases is not rare. Wolferth, Margolies and Edeiken have given us (personal communication) a summary of the more usable differential criteria as follows

1. Age.—Rheumatic insufficiency develops early in life, rarely after thirty years of age except in connection with an undoubted attack of rheumatic fever in an adult (the mild attacks are confined to childhood).

2. Nonprogressive lesion.—In syphilitic, untreated, a nonprogressive lesion points toward rheumatic disease.

3. Dilated Aorta (localized bulging).—Though sometimes present in young persons with rheumatic heart disease, the dilated aorta suggests syphilis, especially before regurgitation appears.

4. History of Rheumatic Fever.—If positive, suggestive of rheumatic aortic valvulitis. If negative, and with previous negative heart examination, suggests syphilis.

5. If serologic tests negative but aorta dilated, in the absence of history of rheumatic fever the process is syphilitic until proved otherwise.

6. A coincident mitral lesion tends to support diagnosis of rheumatic aortic valvular disease.

7. Aortic stenosis may develop where syphilis and rheumatic fever coexist (anatomically or clinically) but aortic stenosis swings the diagnosis toward rheumatic fever. Progression after long latency suggests but does not prove syphilis. Many provisos.

8. Aortic diastolic murmur transmitted down right side of sternum with dilated aorta, suggests syphilis.

Other informative discussion includes Nichols (1940) who mentions especially the low reserve and short life of the victim of syphilitic aortic disease after regurgitation develops, in contrast to the benignity of the rheumatic lesion. An important group of papers includes Braunstein and Townsend (1940), Rosenberg (1940) and Koletsky (1940) on the coincidence of syphilitic aortic valvular disease and bacterial endocarditis. Koletsky emphasizes the importance of using autopsy evidence alone in establishing such coincidences, point the more significant with the newer developments on biologic false positive serologic tests.

In the Mayo Clinic series, taking sixteen years as the mean duration of infection, it was evident that very much larger proportion of cases of aortic and particularly valvular damage are recognized early than of aneurysm.

The Third or Progressive Period.—The progressive period carries forward the signs and symptoms of the prodromal period and ends in the parting of the ways, so to speak, between aortic regurgitation and aneurysm (Fig. 687). From the Mayo Clinic study it was possible in this phase to differentiate the

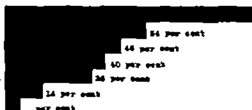

Fig. 688.—Interrelations of cardiovascular and neurosyphilis.

pain of simple aortitis with its frequently anginoid character from the more continuous aching, grinding, or neuritic pain of an aneurysm. Our survey of the diagnostic problem in this stage showed clearly how essential it will be if we are to accomplish a fundamental advance in our diagnosis of cardiovascular syphilis from the standpoint of preventive medicine to carry our conceptions of its earliest onset well back of the period of obvious physical signs described in the text-books. The first step in achieving an adequate index of suspicion is to realize that latent syphilis may be present in every patient who consults us. This implies a systematic inquiry into the history of sexual habits and possible infection, regardless of the social status or personal make-up of the patient. Yet in our cardiovascular survey this was lacking in a fifth of

the cases. It was evident that serological tests must be applied routinely in all medical examinations if they are to be of genuine service in the prevention of cardiovascular disease. A much more thorough physical examination than is often given is essential in the critical scrutiny which prevents vascular disease from emerging from the latency of an unrecognised syphilis. Attention will presently be drawn to the early signs of neurosyphilis most important in our experience and emphasized also by Moore Danglade, and Reininger in detecting syphilitic cardiovascular disease while it is still in a treatable stage. Had the knee jerk been interpreted rather than merely recorded in Fig 721 the tabes would have been considered and treated perhaps in time to forestall

Fig. 683.—*Treponema pallidum* in heart muscle. Stained by Levaditi method (× 1000) (Collection of Dr Noguchi.)

the appearance of cardiac degeneration. Had it occurred to someone that gumma and sarcoma of the testis are constantly confused treatment might have been of some help (Fig 719) Insistent and repeated warning that reliance on the patient's story and treatment based on his presenting symptoms will let early vascular syphilis slip through must be dinned into the ears of the coming generation of physicians. The moment syphilis comes above the etiologic horizon in a given case, the patient's name should be placed on a pad calendar so to speak, like that of an obstetrical patient and his vascular system should be subjected to reexamination by a competent observer at intervals throughout life

It is well, too, in this stage to comment on the influence of age in connection with the symptoms. While the age of the patient undoubtedly influences any estimate of the importance of the various clues the mere fact that a patient is more than forty five years old when signs appear should not lead to too hasty a conclusion that causes other than syphilis underlie his vascular lesion. It is well, we believe slightly to overemphasize rather than under emphasize the syphilitic possibilities in the so-called "pseudo anginas" and the "neurotic hearts," which have never really been completely evaluated from the standpoint of modern syphilology Every syphilitic patient with an irritable" heart or precordial stress and pain, even though repeatedly negative serologically can be seriously considered as a candidate for a therapeutic test or if not that, at least for thoroughgoing annual study The inclination

Fig. 694.—Aneurysm of the descending aorta. This type of lesion produces the posterior dulness in percussion along the spine.

to diagnose "neurasthenia" or "menopause" whenever the symptom complex becomes a bit baffling is entirely too easy to be safe for the patient (Fig. 693) or satisfying to the physician when subsequent events demonstrate the underlying cardiovascular syphilis.

Toward the close of the progressive period the recognition of a faint diastolic whiff appearing at A_2 marks the beginning of regurgitation, if it is to develop, while the transition into diastolic shock and the appearance of thrill marks the development of well-defined aneurysm. It is at this point that the much-debated roentgenological signs are put forward with increasing confidence by their proponents. Let it be emphasized, as Willius, Thayer Conner and others have maintained, that the diagnosis must rest upon the broad and well-coordinated interpretation of the entire case.

Cardiac failure (not terminal)	92	24	26.0

In the American Heart Association symposium Steel, Kurtz, and Eyster and Hampton, Bland, and Sprague of the Massachusetts General Hospital, summarized present views of the

problem and created much discussion among the clinicians. Steel named five changes as associated with the pathologic aorta, as follows:

1. A dense shadow often with hazy borders.
2. A high, dense, and prominent aortic knob.
3. Irregular and also general dilatation.
4. Increased pulsation.
5. Association with aortic insufficiency

Of these, he rated irregular dilatation as the most important, particularly spindle-shaped dilatation of the root. This change causes the anterior and posterior borders of the ascending aorta to run, not parallel as normally but to converge toward the high aortic knob, giving the silhouette triangular appearance with the base down. Kurtz and Eyster named as criteria for diagnosis of aortitis the following:

1. Elongation or tortuosity
2. Widening of any portion.
3. Pulsation to the right of the sternum.
4. Increased density permitting visualization of the descending aorta, especially in patients under the age of fifty years.

It was conceded that it would ordinarily not be possible to distinguish between the syphilitic *and arteriosclerotic types of aortitis by fluoroscopic examination.* The Massachusetts General Hospital group discussed interpretation on the basis of the Hampton and Jones technic of oblique teleroentgenological examination of the aorta. The interpretations depend upon careful measurements of aortic dilatation; the normal and arteriosclerotic ascending aorta without dilatation averages 5.5 cm. while the dilated ascending aorta invariably measures over 6 cm. in diameter when estimated by the method presented. None of the roentgenological methods undertakes to do more than to assist in the identification of aortitis, the etiologic factors responsible for the condition being decided by clinical, serological, and other roentgenological findings.

In the literature since 1934, the above criteria have largely been reiterated with emphasis on their inability to stand alone. The angulation of the aorta in oblique roentgenography (Nichols) and the localized bulge repeatedly stressed by Wolferth and coworkers seem important, but nihilistic views are expressed by Bohares, Hollander and Goldsmith.

The Period of Consequences.—Figure 687 is drawn to illustrate schematically the offshoots from the stage of uncomplicated syphilitic aortitis which in the form of aortic regurgitation, coronary disease, and aneurysm constitute the picture of late consequences terminating in myocardial failure or rupture, and death. It will be recalled that it is essentially the preservation of the integrity of the valve with its maintenance of aortic diastolic pressure that would *seem to furnish the force back of* the aneurysmal bulge of the weakened aortic wall. There is a tendency to low systolic and high diastolic blood pressure in aneurysm and relatively the reverse in aortic regurgitation. Figure 688 compares the subjective symptomatology of syphilitic aortitis with that of aneurysm Kampmeier's observations on 566 cases of aneurysm show relatively similar proportions. The symptoms of aortitis are distributed more evenly over the range of cardiac and circulatory embarrassment with pain, dyspnea, palpitation, and indigestion leading the list, and hoarseness, so prominent in all thoracic aneurysms, almost never occurring in aortitis. In watching cases clinically both before and during treatment, one is impressed with the great significance of precordial distress and dyspnea as early warnings of cardiac and aortic lesions in general and with the fact that they may long precede the development of signs. While this may seem a truism it by no means finds the application in practice that it should. A complaint of shortness of breath or precordial stress, even if not actual pain, should not be dismissed as due to neurasthenia or overweight.

The Signs of Aortic Regurgitation.—The progressive nature of the process is expressed in the developing signs. Both symptoms and signs are summarized in order of frequency in Nichols (1940) and Kampmeier's (1943) published

In the American Heart Association symposium Steel, Kurtz, and Eyster and Hampton, Bland, and Sprague of the Massachusetts General Hospital, summarized present views of the

experience in Fig. 689 Functional diastolic murmurs are said by Wilson to occur occasionally but as a rule they are of structural origin and according to Wilson practically indicative of syphilis.

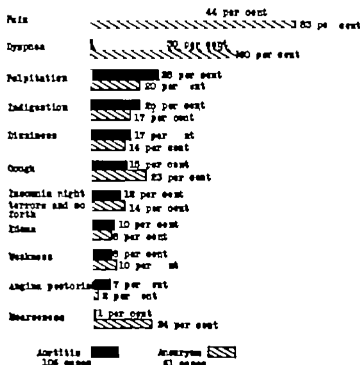

Fig. 688.—Comparative symptomatology of aortitis and aneurysm.

The loud musical diastolic murmur is due to retroversion of the right anterior valve flap (Bellet, Gouley Nichols and McMillan 1939) or rupture of leaflet. Blackford and Smith (1936) do not consider diastolic aortic murmur diagnostic of syphilitic aortitis in the Negro.

Fig. 689.

SYMPTOMS AND SIGNS OF AORTIC INSUFFICIENCY

Symptom or Sign	Nichols (1940) (70 cases) %	Kampmeier (1943) (163 cases) %
Aortic diastolic murmur	100	100
Definite cardiac enlargement	83	
T and fre murmur	87	
Dyspnea on exertion	71	74
Edema	40	47
Corrigan pulse	80	47
Cough		45
Austin-Flint murmur		15
Pain (cardiac) or substernal oppression	43	41

The insufficiency arises primarily from the widening of the commissures between the valve flaps, whether due to fibrotic weakening and dilatation of the ring or as Scott maintains, to the adhesions of the margins of the cusps

to the aortic wall, a pathologic picture which is stated by Scott to be pathognomonic of syphilitic aortitis. Cardiac enlargement and hypertrophy invariably occurs at this stage and the heave which this increase in size and effort requirement imparts to the precordium can often be recognized almost across the room as the heart attains the proportions of the *cor bovinum*. The left ventricular hypertrophy can be early recognized also in the roentgenogram. Diminution of the aortic second sound, or its complete overshadowing by the diastolic murmur, not infrequently occurs and its decreased audibility or absence in the vessels of the neck is a point in favor of aortic insufficiency (Thayer). The "blubbering" or rumbling Austin Flint murmur presystolic at the apex, was recognized by Carter and Baker in 50 per cent of their cases, and in 4 patients was associated with a palpable thrill at the apex. The differentiation of this murmur from that of mitral stenosis in the presence of a history of rheumatic disease is fully discussed by Thayer. Carter and Baker

	Sudden Death from Rupture.
	Signs of Cardiac Failure from progressive coronary sclerosis, *aortic regurgitation* or myocarditis.

were unable to confirm Herrmann's suggestion that this murmur is produced by major involvement of the posterior aortic cusps, and Gouley (1911) believes it due to the vibrations of a cupped or pouched aortic flap.

Certain symptoms and signs have negative value in that their absence strengthens the diagnosis of late syphilitic aortic disease. Carter and Baker and Nichols mention the absence of evidence of mitral *disease as* important in eliminating rheumatic fever. The absence of auricular fibrillation, commented upon by a number of writers, including Willius and *Carter* and Baker, is given by the latter almost the weight of an excluding element in diagnosis. Syphilis was present in only 3 per cent of their large series *of auricular fibrillations*, the proportion being much higher in rheumatic and arteriosclerotic heart disease (85 per cent). Fever, mentioned by Reid as *occurring in a number* of his cases, was notably absent in the Mayo Clinic series and in that of Carter and Baker.

The current literature of aneurysm includes several reports based on large material, notably the excellent study of Kampmeier (1938) and the CCG series (1938) which contain interesting statistical data but have not altered the main outlines of the subject, of which this text is representative. Kampmeier defines the pain of aneurysm as present in 60 per cent of the transverse and ascending arch groups, in 78 per cent of the descending arch and 86 per cent of the descending thoracic portion. Dysphagia, vertigo, tracheal compression and hoarseness are more common in transverse arch involvement. Another group of reports concerns itself with unusual aneurysmal localizations; Kampmeier abdominal aneurysms (1936), hepatic (Malloy and Jason, 1940),

Fig. 691.

HOARSENESS AS THE FIRST SYMPTOMATIC WARNING IN ANEURYSM OF THE ARCH. INCREASED BASAL CARDIAC DULNESS AS AN EARLY PHYSICAL SIGN. ABSENCE OF MURMURS

Locomotive engineman, aged thirty-eight years, married.

Examined July 13, 1918.
Chief Complaint: Hoarseness.
On questioning it was found that he had been short of breath and had smothering spells for eight months.
Penile Sore Twenty Years Before. N secondaries.
Treatment Mercury and potash by mouth. Fifty rubs in three courses at Hot Springs. Medication by mouth, off and on, since. Recently 4 injections of arsphenamine and further treatment by mouth.
Preventive Test Negative Five Months Before Examination.

Examination (Laryngology) Complete paralysis of left true and false cords.
Ray of Chest Mediastinal tumor aneurysm, aortic arch.
Physical Findings (Willius)
Heart 4.5 by 10, apex eighth interspace.
Increased basal and cardiac dulness, 9.5 cm. wide over upper sternum.
A arrhythmia, no murmurs.
Faint tracheal tug.
Blood-pressure 98/74, 98/72, both arms.
Electrocardiogram, rate 90, sinus tachycardia.
Blood Wassermann Reaction: Strongly positive
N Change Occurred Under Treatment.

Discussion

1 This is typical example of "too late.
2. It is also an excellent illustration of the ineffectiveness of much that has passed as treatment for syphilis in the prevention of vascular accidents. This man had had almost lifelong treatment of one sort or another, but always inadequate.
3. A negative preventive test means little or nothing in the future course of case.
4. Gummatous mediastinitis and sarcoma, substernal goiter mediastinal Hodgkin' and malignant metastasis must all be considered here.
5. There was curious traumatic history in this case that may or may not have been significant. He was beaten about the neck daily with "hammer for four minutes three times day as part of his previous treatment.
6. Involvements of the recurrent laryngeal nerv are most frequent in aneurysms of the ascending and transverse portions of the arch. A very large tumor toward the descending limb may give no symptoms.
7 A thoracic examination consisting merely of auscultation might have missed the lesion completely
8. Note that the valve (aortic) is apparently intact. There were no signs of acute dilatation.
9. Reduction in the size of an aneurysm is rare under treatment.

celiac (Lalpply 1945) Rupture of an aortic aneurysm into the pulmonary artery (Potter 1934, rated 54 reported cases as authentic) has definite syndrome including continuous and severe breathlessness; preponderance of right heart failure of early onset; slight pulmonary stasis not proportional to dyspnea, cyanosis is present; purring systolic and diastolic thrill over base; long harsh continuous murmur loudest at left 3d interspace no Austin Flint; roentgenogram shows aneurysm of ascending aorta. (Other reports include very complete summary by Nicholson, 1943.) Welty (1939) demonstrates the decline in the frequency of aneurysm from 23 per thousand autopsies to 9.5 per thousand from 1907 to 1937

The Signs of Aneurysm.—In this field the Mayo Clinic material was particularly instructive (Fig. 690) Probably the earliest clinching identification

Fig. 602.

THE SYMPTOMS OF MEDIASTINITIS AND ANEURYSM OF THE ARCH CONFUSED WITH NEURASTHENIC AND HYSTERIC SYNDROMES. UNSUPPORTED POSITIVE WASSERMANN REACTION ON PROVOCATIVE TEST. CONFIRMATION BY THERAPEUTIC TEST

Housewife, aged thirty-three years.

Examined February 17, 1918.
Chief Complaint. Flushing and choking sensations of two years' duration.
Extremely nervous.
Feels as if a string were drawn tight around her neck.
Face "bloats" on slight exertion.
Much worse on lying down.
Lips get blue at times she said.
Said also that hands and feet bloated.
No obstruction to respiration, but slightly short of breath on exertion.
Occasional slight precordial pain.
Could not raise arms over head without their getting numb.
One Miscarriage. One Healthy Child.
Tonsils Removed to relieve above symptoms.
Pustules on Face Two Months after Vaccination fifteen years before. Wound sore two months.
Examination (Preliminary).
Face pocked, right kidney palpable, uterus tellered.
Blood Wassermann reaction negative.
Blood-pressure 150/90. Hemoglobin 57 per cent.
Test-meal negative.
Examiner's Diagnosis. Neurasthenia. Secondary anemia, advise Blaud's.
This Examiner's Consultant Found the Following Additional Points of Interest in checking this opinion.

Consultant's Examination (W. A. Plummer).
Face congested. Filling of neck veins.
Left pulse nearly disappeared on raising hands above head.
Blood-pressure right arm 130/100, left, 145/100.
Orders x-Ray of Chest for Substernal or Mediastinal Growth.
x-Ray of Chest. Aneurysm of the descending portion of the aortic arch.
Syphilologist Ordered Provocative Procedure to check the negative blood Wassermann result.
One Strong Positive Test. Six negatives.
Treatment Continued. Six arsphenamin *injections.*
Felt Much Better. Could now stoop, and dress her hair without trouble with arms. Throat better, no palpitation, no edema of face.
Spinal Fluid Negative.
Took 20 Injections at Home.
Returned "In Wonderful Shape." Practically nothing left of her original symptoms except some palpitation on exertion. Sleep, nervousness, and so forth, all better.
x-Ray Showed No Change in Aneurysm.
Patient Lapsed from Observation After Three More Arsphenamin Injections. Considered herself well.
She Had Never Had but the One Positive Blood Wassermann Reaction in Eighteen Months' Observation.

DISCUSSION

1. To the hasty, snap-shot, subjectively minded physician, who eliminates syphilis by the negative blood Wassermann examination and no history, this might well sound like the story of a nervous, hysteric woman.

2. Careless and incomplete examinations, and the designation of neurasthenia on snap-shot impression pass an enormous amount of syphilis unrecognized through the clinics and hospitals of the country.

3. Flushed face and thumping neck do not always make a *diagnosis of menopause.*

4. Difference in blood-pressure and pulse between the two arms repeatedly give the clue to aneurysms of the arch that even the x-ray may overlook at first.

5. One of the earmarks of mediastinitis is the engorgement of the face on stooping or lying down, and the development of cyanosis almost to lividity.

6. Why so good a therapeutic result when there was no change in the aneurysm seen with the fluoroscope? Presumably this is due as is remarked in Fig. 107 to the resolution of the peri-aortitis and mediastinitis which seems always to precede or accompany an aneurysm. This infiltration and not the pressure of the aneurysm seems to be responsible for many of the symptoms. The rigidity which it imparts to many aneurysmal sacs leads to diagnoses of tumor before treatment is begun, which must be revised after the first course or two when expansile pulsation becomes apparent.

7. Patients with aneurysms seen at this stage and judiciously treated and watched have a good life expectancy.

of aneurysm or rather an impending aneurysm of the aorta and its branches is made by the fluoroscope in cases in which abnormal dilatation of the circumscribed portion of the aorta under *the systolic impulse of the heart* can be detected Physical diagnosticians very properly contend, however that broadening and distortion of the arch can be detected very early by careful percussion to the right of the sternum from the base of the heart upward. This broadening and extension upward of the percussion outline of the base *of the heart, especially when the dulness appears on both sides of the sternum* may be quite trustworthy but should always be supplemented by careful fluoroscopy It is worth while to emphasize that the earliest physical signs of aneurysm are obtained by percussion and palpation in contrast to the use of auscultation in the detection of early aortic disease. The accentuation and tonal change in the aortic second sound is not invariably present, or if it is it may be the only auscultatory sign if the root of the aorta and the valves are not involved It is for this reason that very careful percussion of both the front and back of the thorax is necessary It would seem to be the lack of percussion findings, or rather their obliteration by liver dulness that makes the subdiaphragmatic aneurysm so hard to identify in life. Percussion close to the vertebral column may yield a small area of dulness with obliteration of breath sounds in aneurysm of the descending aorta.

The late signs of aneurysm begin with pulsation and thrill. A soft systolic bruit may be heard early but the louder murmurs and diastolic shock are parts of the picture of aneurysms better suited for display in pathologic collections than for demonstration as hopeful therapeutic cases. Differences in blood pressure in the two arms proved to be important in identifying several of the aneurysms of the arch and its branches in our series.

The location and contour of an aortic aneurysm and the amount of periaortitis and mediastinitis involved provides for a disconcerting variety of symptoms and signs. For example, tracheal tug may appear quite early or very late according to the location of the sacculation of the arch. It is remarkable how nearly asymptomatic an aneurysm may be in its beginnings and how often signs, if present, may be of a type likely to escape a hasty examiner who merely auscultates without percussing (Fig. 691) or without comparing the pulse and blood pressure in the two arms (Fig 692) Bulging to the left may reach a large size with but few signs, whereas bulging to the right and upward from the same point in the arch may give rise to a wealth of signs. The subdiaphragmatic and abdominal aneurysms, perhaps because they are rarer seem to pass unsuspected until they reach a size which gives rise to radicular pressure pains. They may be more or less completely concealed from roentgenological observation by the overhanging liver The signs associated with various types of aneurysms are illustrated in the case histories, and certain important syphilological and fluoroscopical diagnostic points in Fig 693 The types of aneurysms in order of frequency are as shown in Fig. 694 Subclavian aneurysms in particular were important in our experience, 5 cases occurring in the series. The resemblance of the signs of a large innominate aneurysm to substernal goiter is illustrated in Fig 713

Pressure Signs.—The response of the so-called "pressure signs" of aneurysm of the arch such as cord paralysis from involvement of the recurrent laryngeal nerve and the vagus, pupillary inequality from involvement of the cervical sympathetic, and compression of the trachea, even when the mass *itself shows little apparent reduction in size* suggests that there is either a

disappearance of inflammatory reaction, or that the mass becomes more yielding or less pulsating and less capable of producing compression symptoms

Fig 693.—Forty-nine diagnoses of aneurysm, exclusive of aortic dilatation.

under treatment. It is perhaps for this reason that pressure signs may sometimes seem so conspicuous in comparatively small aneurysms (Fig. 695) and

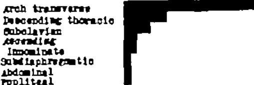

Fig. 694 —Types of aneurysms in order of frequency Kampmeier found lower proportion of transverse (32 per cent)

that large sacculations of long standing, in which the acute perivasculitis has subsided or intravascular clotting has occurred, may give rise to an amount of discomfort small in proportion to the extent of the tumor In following the

Fig. 695 — Finger type aneurysm of the aorta, perforating the trachea. Death from rupture. Symptoms those of tracheal obstruction. (Courtesy of Drs. Gabriel Tucker and Richard Kern.)

data given by patients it has often seemed that hoarseness antedated by a long period the presumptive appearance, at least, of gross signs of dilatation.

Differentiation of Mediastinal Tumor and Aneurysm—Fluoroscopic Error.—It is in the fluoroscopic differentiation of mediastinal tumor and aneurysm that the probable influence of perivascular and mediastinal incarceration of the sac in the surrounding inflammatory infiltrate reaches its greatest importance. Obviously in the roentgen-ray if any enlargement whatever is disclosed, it appears as a tumor whose location may, of course, identify it correctly. It is quite likely, however, to be indistinguishable from the lymphomatous tumors of mediastinal Hodgkin's disease or lymphosarcoma, from malignant metastasis and from substernal goiter. The crux of the roentgen-ray differentiation, therefore, rests with fluoroscopic study. But if pulsation is not apparent, the inclination is to diagnose a solid tumor (Fig. 713), occasionally allowing for the possibility of an aneurysmal sac fixed by intramural clotting (Fig. 706). Our study indicates that this point of view is distinctly fallible, and that the entire picture may be transformed by a short therapeutic test, which, by resolving the mediastinitis and perivasculitis, permits the pulsation of the "tumor" to become visible under the fluoroscope (Fig. 707).

Question of tumor cross — 19 cases

Question raised by x-ray plat — 13 case

Fluoroscope showed pulsatio on first examination — 7 cases

Fluoroscope showed no pulsati on first examination — 6 case

Total positive therapeuti tests — 6 cases

Pulsatio appeared after therapeutic test — 4 cases

Diagnosis f syphilis confirmed by disappearance f symptoms — 4 cases

Physical signs confirmed aneurysm 1 spit f negative fluoroscope — 1 case

Necropsy confirmed aneurysm — 1 case

Fig. 696.—Tumor versus aneurysm.

The technic and differential considerations when the therapeutic test is used for the recognition of aneurysm are discussed on page 937.

Enlarged Lymph Nodes May Accompany Syphilitic Mediastinitis.—It should be emphasized that the presence of palpable or even markedly enlarged lymph nodes in the supraclavicular spaces or the axilla, does not establish a diagnosis of malignant mediastinal growth or lymphoma, or render a therapeutic test for syphilis unnecessary. Gummatous local adenopathies simulating metastasis, common in the neck in association with syphilids of the throat and tonsils, must also be reckoned with (Fig. 712) in association with the mediastinitis of aortic aneurysm. At the same time it must not be forgotten that carcinoma and syphilis may be closely connected, and that examination of an accessible gland is entirely safe if treatment is begun afterward. The microscopic diagnosis on the node may indicate the uselessness of treatment except for palliation, or permit additional treatment by roentgen-ray.

Cord Paralysis.—We have been repeatedly impressed with the importance of hoarseness as a symptom for the general practitioner's attention (Fig. 691), although, especially with accompanying aortitis, pain in the chest and dyspnea were more likely to be the patient's chief complaints.

The value to the general diagnostician, working unaided, of being able to see the vocal cords, deserves emphasis, and such an examination in case of prolonged hoarseness should be made without waiting for the brassy cough. The equipment is simple; a lamp, a head mirror, large laryngeal mirror, a glass of hot water towel, and a soothing and reassuring voice may occasionally afford the physician on the frontier a most gratifying diagnostic *coup d'œil*. In fact,

Fig. 697

SYNDROME OF COMBINED TUBERCULOSIS AND SYPHILIS (?). AORTITIS WITH ANEURYSMAL (?) DILATATION IN A CHILD

Boy aged six years.

Examined March 15, 1918.

Chief Complaint: Swelling of one finger ulcer on toe, cough, tired easily Pain in back on jarring or handling

Family History Mother lost first baby from smallpox at birth. One miscarriage, two living children.

Whooping-cough two years before. Fluid in abdomen three weeks. Short of breath since influenza. Pneumonia and pleurisy Attacks of pain in abdomen.

Examination *Slight kyphos* and rigidity of fourth, fifth, and sixth dorsal vertebræ. Probably tuberculosis, but little destruction. *Proximal phalanx* left third finger spina ventosa. Sinus, great toe. Nasal bridge depressed. Liver *enlarged*, left lobe hard and nodular

Spleen palpable.

Doughy mass right iliac fossa.

Blood-pressure 98/68.

Von Pirquet tuberculin +++

Blood Wassermann reaction weak positive.

Brother's Wassermann reaction, eak positive.

x-Ray of bones, destruction of finger and toe.

x-Ray of chest, mediastinal shadow right upper

Fluoroscopic Pulsation, aortic dilatation. Spine negative.

Consultant's Opinion: "History of ascites with indurated left lobe liver may mean former tuberculous peritonitis, or ith dilatation of aorta may signify syphilis.

Treatment Put on Bradford frame and given 6 arsphenamin injections and 25 inunctions.

Response Immediate Finger and toe healed. Marked improvement in back.

Cardiovascular Examination (Willius):

Short of breath since influenza.

Heart 4 by 8 cm. N arhythmia. Systolic murmur at base, maximum at aortic area.

Increased aortic dulness.

Electrocardiogram: Rate 128 shows tachycardia.

DISCUSSION

1 Aortitis and aneurysm in children with heredosyphilis are genuine rarities in my experience. This may have been an infection acquired t birth.

2. Did the boy actually have syphilis? Without the aortitis and aneurysm the findings in the case would be thin, for the remainder of the picture including the weak positive Wassermann reaction might have been that of tuberculosis.

3. The therapeutic response was little too good for tuberculosis alone, although arsphenamin can produce marked improvement in tuberculosis.

4 The entire picture except perhaps the von Pirquet, might conceivably have been the work of syphilis, even to erosion of the vertebral bodies by aneurysm and deformity and pain simulating Pott disease. It is also easily possible that the process in the spine as syphilitic gummatous osteitis.

5. In such complexes it may be impossibl to disentangle the two diseases, but they need not interfere with treatment for syphilis. In such case it ould be inexcusable not to employ it, even had there been no aneurysm.

if the symptoms suggest aneurysm, one cord may be paralyzed without hoarseness (New). The response of pain and dyspnea, and not infrequently of hoarseness, to treatment must be the guide to improvement and is often quite convincing.

Aneurysmal Erosions.—Erosion by aneurysmal pressure may be confused with tuberculous and carcinomatous metastatic lesions of the spine (Fig 697). In aneurysms of the descending aorta from the median thorax down, and in

high abdominal aortic aneurysms, it is particularly important to keep in mind the possibility of confusion with Pott s disease which the radicular pains may suggest. In fact, in interpreting aneurysmal symptoms both within and without the thorax, it is always important to keep in mind their referred character and to recall that the pain of an aneurysm of the descending aorta may be felt in the epigastrium, while the physical signs may be found only on examination of the back. The symptoms of abdominal aneurysm may lead to surgical intervention for a supposed pancreatic lesion. Here again if the serologic test gives the clue, the response to treatment for syphilis may make the diagnosis, and afford relief.

The diagnosis of the unusual types of aneurysm is illustrated in the case sketches, and is a combination of knowledge of the anatomic position of the vessel, the pressure symptoms to which its enlargement may give rise, the identification of *expansile pulsation and bruit*, and the *signs of disturbed* arterial rather than venous circulation.

The Signs of Mediastinitis.—These, when they appear as accompaniments of thoracic aneurysm, are identical with those described for syphilitic mediastinitis in general on page 1173

The Signs and Symptoms of Coronary Sclerosis.—Angina pectoris and the general symptomatology of coronary sclerosis play a particularly important rôle in treatment decisions involving syphilitic aortitis. For this reason the symptomatology of angina pectoris is reviewed in parallel column with that of coronary thrombosis in Fig. 698, even though the rôle of syphilis in the production of coronary thrombosis particularly is not generally accepted by clinicians as especially important. It must be said, on the other hand, that this question is far from evaluated. Certainly it cannot be answered, as will presently be seen, by limiting the definition of syphilis to those patients who have positive blood serologic reactions, as in Levine s monograph. Particularly should the nervous system be carefully investigated for supportive evidence. When all is said and done, however our own experience is in accord with the literature to the effect that if a distinction is drawn between paroxysmal pain other than the distinctive Heberden anginal attack, coronary disease is, relatively speaking, the least important of the four groups of symptoms—aortitic, aneurysmal, myocardial and coronary which one encounters in clinical cardiovascular syphilis.

Even though this be true the seriousness of coronary symptoms in the course of syphilitic cardiovascular disease cannot be exaggerated. Willius and Brown found syphilis in 19 per cent of 86 patients coming to necropsy with coronary sclerosis. The history of anginal attacks or of a tendency on the part of the precordial pain of aortitis to radiate into the arm shoulder or neck, is a warning of the utmost gravity indicative of threatened injury to the blood supply of the heart, whether from the course of the disease or as a result of coronary atresia from misdirected and overstrenuous treatment of aortitis. Any increase in the severity of the pain seizure, in its frequency in the diminished exercise tolerance of the patient, is a warning of an unpropitious course. Transient difficulty however may be overcome under the continuance of treatment—but it is decidedly more probable in our experience, that the outcome will be disconcerting. An invaluable guide to the extent that the myocardium has been damaged by the coronary lesion and the degree of overload it can sustain during treatment is obtainable in advance from the electrocardiogram

The recognition of anginal symptoms in any patient should, of course, be the signal for the application to his case of all the test criteria enumerated in the discussion of early aortitis, and particularly to the roentgenological study of the aorta. In patients exhibiting atypical aortic pain marked nervous reaction during the attacks or outright evidence of psychasthenia and hysteria, the possible instrumentality of syphilis should by no means be waived and the case should be investigated to the bottom. We, even in a limited experience, have had occasion to reproach ourselves more often than otherwise for over

Fig 498.

SYMPTOMATOLOGY OF ANGINA PECTORIS AND CORONARY THROMBOSIS

Angina Pectoris	Coronary Thrombosis
1 Pain in the chest, radiating into arms, usually left; into shoulder neck, epigastrium.	1 Pain in the chest, viselike, griping or squeezing with the usual radiation.
2. Patient remains motionless, pale.	2. Patient shows agitation and shock, often restless and thrashing around, or may collapse, fall, lose consciousness.
3. Pain of short duration, paroxysmal. Increasing frequency of attacks common	3. Pain of prolonged duration, hours or days, though may have been preceded by paroxysms of angina.
4. Pain usually brought on by exertion, anger exposure to cold.	4. Onset frequently when at rest, at meal, or in sleep.
5 Vomiting less common.	5. Vomiting common ("acute indigestion").
6. Pulse little change	6. Pulse small, weak, rapid, but these changes may be delayed several hours.
7 Blood pressure often elevated or unchanged, but may be low	7 Blood pressure falls.
8 No pulmonary symptoms or dyspnea, no râles.	8. Pulmonary edema may occur. Râles usually present and dyspnea.
9 Liver no change	9 Liver tender and enlarged.
10 Abdomen usually soft.	10 Abdomen often rigid.
11 Heart sounds usually normal, no arrhythmia.	11. Heart sounds, especially the first, very weak and distant, the latter often absent, sometimes gallop rhythm.
12. Fever and leukocytosis absent.	12. Fever and leukocytosis frequent after several hours.
13. Nitrite or nitroglycerin relief	13 No nitrite relief
14 No pericardial rub.	14 Pericardial friction rub may be heard.
15 Death rare in first attack of true angina.	15. Attack prolonged over days with evidence of cardiac failure.
	16 Embolic accidents from mural thrombosis.
	17 In abdominal cases there may be signs of an acute surgical abdomen and even jaundice.

emphasizing the functional Women and physicians are too apt to have their cases lightly estimated

Cardiologists of great experience hesitate to make a sharp differentiation between true angina pectoris and those neuroses which may very closely simulate it When a cardiologist makes the latter diagnosis he usually crosses his

Wolferth et al. (personal communication) state that the characteristics of pain in angina pectoris and coronary thrombosis are about the same so far as location, distribution and type of pain are concerned The pain tends to be more severe and is greatly prolonged in coronary thrombosis. The abdomen is not actually rigid in coronary thrombosis, but distention is frequently present. The liver does not become tender until after enlargement has occurred which is exceptional in the acute stage

fingers and often waits only to see the patient develop true attacks of angina a year later or worse still, to see the poor "neurotic" die during an attack of real angina. In a goodly percentage of cases, however there are a few criteria which often help one to differentiate between the two conditions and these are given in *Fig 690*

The electrocardiographic identification of disease of the coronary arteries is growing in importance especially since Wolferth and Wood's work on the precordial leads. At the close of an excellent symposium on coronary disease (Proceedings of the Staff Meetings of the Mayo Clinic, 17 305 1944) however Barnes, after pointing out variety of abnormalities and particularly the value of the EKG in myocardial infarction, felt obliged to say that too much reliance is placed on the electrocardiogram in the identification and exclusion of disease of the coronary arteries.

Fig. 690

DIFFERENTIATION OF "TRUE" FROM "PSEUDO" ANGINA

Heberden's Angina Pectoris	"Neurotic" Angina Pectoris
1 Pain usually definitely related to exertion. (After meals—cold blustery days—physical exertion.)	1 Pain variable. (Most often emotional exertion.)
2. Location—substernal.	2. Location—most often precordial.
3. Character Deep pressure—crushing, viselike constriction. Heavy feeling—weight. Burning.	3. Character Knifelike. Sharp.
4. Pain stops the patient on the spot—walking—leaning against all—lying down—sitting up.	4. Patient runs around—causes great commotion.
5. Radiation—varies considerably Arms, chin, neck, epigastrium—gallbladder region. Appendix, thigh.	5. Radiation. Much the same.
6. Relief By stopping. By nitrites—inconstant.	6. Relief Moving about. Drugs less effective.
7 Sense of impending death questionable.	7 Sense of impending death may or may not be present.
8. Facies Awestruck; ashen sweat on forehead; quiet.	8. Flushed—Patient voluble.
9. Dyspnea absent. Quiet breathing.	9 Breathes heavily
10. Blood pressure usually rises 10 to 20 mm. May stay at normal.	10. Rises.

Sprague (1942) from Massachusetts General Hospital material pointed out the frequent association of high degrees of coronary obstruction, with bundle branch block.

The attack of abdominal angina, as described in Fig. 700 may as Willard Stone points out, be confused with reflex disturbances from chronic cholecystitis. The short duration of the typical anginal seizure differentiates this satisfactorily from the confusion elements enumerated by Levine in the abdominal symptomatology of coronary thrombosis. Stone also mentions myocardial fatigue-states in overactive patients with marked arterial hypertension as being capable of producing chest pains distinguished with *difficulty from* angina pectoris and disappearing on proper rest.

Wolferth *et al.* (personal communication) state that anginal pain is usually relieved by nitrites; in fact, failure to obtain relief brings the diagnosis into sharp question.

Anginoid pain not infrequently has to be differentiated from syphilitic angina. Among the more important causes of anginoid pain are substernal pain due to hiatus (diaphragmatic) esophageal hernia (Jones, 1941), profound anemia (Bernstein and Ginsburg, 1941), myxedema (Perl, 1943), herpes zoster (Gale and Abrahamson, 1939; Spillane and White, 1939; Parsonnet and Bernstein, 1939) cervical rib (Reid, 1939), hypertrophic spondylitis (Willius, 1938) osteoarthritis of cervical spine (Nachlas, 1934) a manifestation of male climacterium (McGavack, 1943), mediastinal tumor (Pardee, 1933, Fenn, 1936), deformities of the thoracic spine (Smith and Kountz, 1942) and cellulitis of the breast (Nell, 1932) Semmes and Murphey (1943) in particular

[illegible]

Fig 700 —Reproduction of the recorded history of patient with abdominal angina pectoris.

DISCUSSION

1 The patient specially remarked on the fact that his epigastric pain followed exertion with the arms, such as pushing a door or turning the steering wheel of an automobile

2 On examination an aortic roughening was detected, the blood Wassermann reaction was strongly positive the x-ray of the chest showed no abnormality The right lobe of the liver was enlarged and the edge tender There was an inequality in blood-pressure between the two arms that suggests an unrecognized aneurysm, though no trace of one could be found Blood-pressure right 120/50, left 90/60. There were neurologic signs suggestive of neurosyphilis, but no spinal fluid examination was performed on account of the patient's departure The electrocardiogram showed T-wave negativity in Lead I of grave prognostic significance.

3 The stomach was negative to x-ray and test-meal.

There is often resemblance in the history to that of aneurysm of the arch. Abdominal angina pectoris should always be carefully studied for signs of aneurysm.

have reported two physicians and a woman in whom rupture of the 6th cervical intervertebral disk very closely simulated repeated coronary seizures.

As a final point of emphasis Fig 701 may be used to bear home the lesson that advanced coronary sclerosis does not necessarily carry with it the warning signs of anginal seizures. We were impressed several times in our unfavorable outcomes with the very great difficulty of estimating from the clinical side the degree of actual coronary injury in patients whose markedly unfavorable re-

Fig. 701.

CARDIOVASCULAR SYPHILIS AND NEUROSYPHILIS. DEATH UNDER TREATMENT. ADVANCED CORONARY SCLEROSIS OF A GRADE NOT SUSPECTED DURING LIFE

A woman, aged thirty-five years, married, housewife.

Examined 11/22/1920.
No History of Primary or Secondary Syphilis.
One Miscarriage
Duration of Symptoms Ten years.
Onset gradual, with vomiting during the first two years.
Symptoms
Precordial pain, steady moderate, non-radiating.
Fatigue.
Dyspnea, two years duration.
Cough, nocturnal, choking
Palpitation, tachycardia, five years.
No *definite anginal attacks.*
No *edema or anasarca.*
Physical Signs
Heart greatly enlarged.
Auricular fibrillation.
Ventricular extrasystole
Murmurs, systolic, diastolic.
Thrill, aortic area.
Pistol shot, Corrigan and capillary pulse.
Blood-pressure Systolic, 140 *Diastolic not obtainable*
Urine normal.

Spinal Fluid, Wassermann reaction positive Nonne reaction negative, 48 lymphocytes.
Neurologic Signs: Pupils irregular unequal, but reacting well. Few sensory but no important reflex changes.
Treatment: Rest in bed with mercurial preparation for arsphenamin.
Mercurial preparation Ten injections mercury succinimid (1 gr daily) intramuscularly
Arsphenamin Injections 0.2 gm 0 4 gm., 0.3 gm., 0 3 gm., intravenously at weekly intervals, begun after tenth injection succinimid.
Succinimid continued to 20 injections.
Improvement Marked: Dyspnea, pain, and fibrillation disappeared, heart reduced in size.
Patient Died Suddenly in Bed six hours after fourth arsphenamin injection.
Necropsy: Far advanced aortic valvulitis; valves reduced to stubs. *Total obliteration left coronary artery* Only fibrous cord with few necrolations could be found.

DISCUSSION

1. **In advanced grades of valvular involvement the involvement of the coronaries may be expected to be severe The symptoms may not be a guide. Even in mild grades of aortitis coronary changes may be so severe as to menace life.**

2. Coronary involvement may be severe without definite anginal attacks.

3. **A careful estimation of life expectancy is a valuable element in deciding the treat**ment applicable to a given case.

4 **The combination of cardiac and neurosyphilis is not rar**

5 The risk is always great, the cardiac condition, because it limits treatment, being the more serious element. Prognosis is, to some extent, proportioned to the severity of the heart lesion. The cardiac symptoms may completely dominate the case and overshadow the neurologic symptoms.

6. **This patient was a wreck.** Cardiac dilatation, fibrillating auricles, and low diastolic pressure are warnings of the hopelessness of the case, the extent of structural damage, and the impossibility of attaining radical results.

7 **This patient was overtreated.** Mixed treatment by mouth with rest in bed for weeks might have prolonged life probably it could not have affected the neurosyphilis.

8. **Arsphenamin, because it administers a therapeutic shock (Herxheimer reaction) because of the rapidity of the healing changes it produces, and because of its vasculotoxicity is dangerous to bad hearts.**

9 **The arsphenamin dosage was too large for such a case, and neo-arsphenamin was** probably to be preferred. The first dose should not exceed 0.03 gm the last, 0 6 gm.

10. **The treatment of the neurosyphilis should have been secondary If the car**diac condition ever improved enough to warrant it, intraspinal measures should have been used.

11 **Intraspinal treatment after a long mercurial preparation or tryparsamide is the method of election in combined neurosyphilis and cardiac syphilis.**

sponse to treatment and in some cases necropsy findings proved the presence of what should be regarded as an absolutely contraindicating degree of involvement from the standpoint of intensive treatment.

Myocardial Symptomatology.—The occurrence of sudden death from an acute exacerbation of syphilitic latent myocarditis has already been discussed. The recognition of myocardial involvement in the later years of the disease, unfortunately is none too satisfactory The electrocardiograph must in all probability furnish the chief reliance. There are no specific symptoms of syphilitic myocarditis, electrocardiographic or otherwise. Shortness of breath on small provocation diminishing exercise tolerance, weakness either in the circulatory readjustments of the early morning or in a gradual shortening of the period of effectiveness during the day· slight edema of the extremities signs of dilatation weak action and distant sounds, low blood pressure, persistent well-defined tachycardia or bradycardia and the arrhythmias indicative of organic disturbance such as conduction block, are the familiar signs. The rarity of auricular fibrillation in the syphilitic heart, as contrasted with its frequency in rheumatic fever has been mentioned by Carter and Baker as a significant differential point.

SPECIAL DIAGNOSTIC PROBLEMS

The Collateral Evidence of Syphilis.—Diagnostic or confirmatory evidence of the presence of syphilis, apart from the serological tests, is even yet not sufficiently searched for in the presence of cardiovascular disease and even of aortic regurgitation itself In illuminating this aspect of the diagnostic problem, Stokes's Mayo Clinic material of 190 patients with cardiovascular syphilis was particularly serviceable. No history pointing to a syphilitic infection could be obtained in one third of the cases. A surprisingly large proportion of those in whom a venereal history was taken had had gonorrhea (81 per cent) *as compared with 60 per cent in most of the surveys*. Nearly 20 per cent could give no history of a primary lesion or other syphilitic manifestations but had had gonorrhea.

Chief reliance in diagnosis must rest upon two groups of findings the serological test and the examination of the nervous system, including that of the spinal fluid To these might well be added the therapeutic test, for reasons presently enumerated.

The Serological Tests in Cardiovascular Syphilis.—Moore, Danglade and Reisinger have reported 75.5 per cent positives in their series of cases of syphilitic aortitis. Carter and Baker reported 92.6 per cent in their first hundred cases. Miller (T H) on our service at the University of Pennsylvania, obtained 81.8 per cent positive Kahn reactions in cardiovascular syphilis, and 84.8 per cent positive Kline reactions (slide precipitation test) McIntyre and Gilman found the Kahn test to be more sensitive than the Kolmer Wassermann in cardiovascular syphilis (96 tests in 25 cases). In the literature prior to 1916, Elliott placed the margin of error of the negative blood Wassermann reaction in syphilitic vascular disease as high as 40 per cent. In 31 necropsies in cases of syphilitic disease of the aorta, Reid reports that 17 per cent were Wassermann-negative on the blood shortly before death. In Reid' American Heart Association symposium series, positive Wassermanns were obtained in 78 per cent of cases. Cannaer and Dexter obtained 73 per cent positives in 80 cases and Longcope 74.5 per cent positive in 47 cases. Levine found 30 per cent negative in 40 cases (American Heart Association symposium) and Willius in 100 selected cases of syphilitic cardiovascular disease found 65 per cent Wassermann positive in aortitis, 82 per cent in aortic insufficiency and 85 per cent positive in aneurysm. Longcope observed the same higher proportion of positives in aneurysm as compared with aortitis. Other figures including CCG (1930), White and Wise (1937) Arkin (1934) Wile and Snow (1939), Kampmeier (1938)

Levitt and Levy (1940), Nichols (1940) Willius (1941), McDermott, Tompsett, Webster (1942), Levitt and Ireland (1942) have yielded essentially similar data. Beckh (1943) has collected the recent literature bearing on the serologic reaction in cardiovascular syphilis. In study of 100 cases of cardiovascular syphilis, *diagnosed at autopsy*, in which the serologic reactions had been done by modern technic, he found of 49 cases of aortic insufficiency or aneurysm or both, in 43, or 88 per cent, there was positive Wassermann or Kahn or both on first examination. *Of 51* patients with uncomplicated aortitis, 80 per cent had positive serologic reaction. In none of the cases of aortitis was the diagnosis made clinically

Of the 49 patients with clinically diagnosable cardiovascular syphilis, i.e., aortic insufficiency or aneurysm or both, 96 per cent had either positive Wassermann or Kahn or both, or history of positive Wassermann in the past, or lastly history of previous antisyphilitic treatment.

The proportion of serologic negativity in the neurological phases of vascular disease of the nervous system is fairly high. The proportion of serologic negativity would be higher in the field of cardio-aortic disease were clinicians more alert to the possibility of negative bloods and willing to subject patients

Fig. 702.—Arciform, crescentic late nodular syphilid of the forearm. The patient and her examiner thought she had eczema. She had the aortitis described in Fig. 703.

with contestable negative serologic reactions to therapeutic tests. Of this our material gave a number of excellent examples (Figs. 702, 703)

False Positive Serologic Reactions in Cardiovascular Disease.—Any survey of an invisible aspect of syphilis is affected by the fact that it takes courage to attach the clinical diagnosis to patient with negative serologic reaction. This fact probably influences all returns on the *proportion of positive and negative blood serologic reactions in cardiovascular disease* and all clinical observations on the influence of syphilis in their production. One of the most instructive features of the case abstract is the proof they offer that the blood serologic reaction may present all grades of fluctuation, from complete and persistent negativity to complete and fixed positivism, in patients with all grades of involvement of the vascular system.

The finding of positive blood serologic reaction is most often open to question in connection with aortic valvular disease accompanying mitral lesions. Stokes has seen at least eight examples in which repeated strongly positive blood serologic reactions were obtained with endocarditic manifestations, obviously of septicemic or subacute bacterial type This is certainly *small but by no means negligible* proportion. *In several of these cases* clinical examination (Fig. 704) made the probability of syphilis extremely slight, and even at necropsy convincing evidence of syphilis was hard to find. In febrile cases, therefore, certain amount of confusion is inevitable On the other hand, so far as the acute rheumatic fever problem is concerned, w have seen no satisfactory evidence of definite tendency to false positiveness in serological tests.

Fig. 703.

CUTANEOUS SIGNS OF SYPHILIS IN THE IDENTIFICATION OF EARLY VASCULAR LESIONS. THE PRESENTING SIGNS OF EARLY AORTITIS

A farmer's wife, aged forty-two, examined 1916.

Chief Complaint Pressure in the chest. "Eczema" left forearm, desired general examination.

Her First Examiner Noted the Following:
Complaint of throbbing at the back of the neck.
Tightness in chest at times amounting to pain on exertion.
Slight headache slight *dyspnea*, cold numb arms.
Filled teeth, epigastric tenderness.
"*Many reddened areas* on left forearm.
Blood-pressure 146/78.

Heart Described as Negative: Noted, however that second sound was somewhat accentuated.

Blood Wassermann Negative.

Dermatosyphilologic Examination: Patient would not undress, saying she came only for eczema on the arm.

The Lesion on the Forearm is Indurated Arciform, and Leaves a Slight Atrophic Scar

The patient denied infection with syphilis or gonorrhea

"**The Cutaneous Lesion is None the less Almost Certainly Syphilid** in spite of the negative blood Wassermann."

Provocative Procedure Negative throughout.

The Lesion, However Vanished Within Eight Days.

On reconsideration and discussion, the patient admitted exposure at age eighteen

Internist Asked to Reconsider General Findings Consultant (Wilhus) reports *Heart not enlarged.*

Accentuated second sound, especially at aortic area.

Low reverberant systolic murmur at aortic area, not transmitted.

"**This, with the History of Retrosternal Pain, Make Aortitis Quite Definite**

Pupils reported very sluggish to light.

This Patient was Placed on Vigorous Treatment with Arsphenamin and Mercury and repeatedly studied during the next four years to watch the progress of the aortic lesion.

She Has Never Had a Positive Blood Wassermann Reaction, and the spinal fluid is normal.

The Valvular Lesion Passed Through a Stage of Accentuation (therapeutic paradox) in which the murmur became audible in the carotids, then much louder always with accented second sound.

Diastolic Murmur was First Recognized Fourteen Months After Her First Examination Pain in chest became more marked. For a short time the systolic murmur disappeared. Blood-pressure ranged from 146/80 to 160/86. Transient slight edema disappeared with tincture digitalis 10 minims t. i. d.

Then the Findings Became Stationary and have remained so for four years, with the patient in excellent health.

x Ray showed only slight enlargement. Electrocardiograms repeatedly normal

This is the Stage at Which Syphilitic Aortitis Should Be Recognized for satisfactory therapeutic results.

DISCUSSION

1 The cutaneous lesion in appearance and behavior under arsphenamin was, beyond reasonable doubt, a syphilid. Note how completely it was underestimated by the first medical examiner

2 Note that dyspnea, precordial distress, slight hypertension, and accentuation of the aortic second sound were all significant points overlooked by the examiner when it came to interpretation, though he observed most of them.

3 The definite recognition of the early systolic murmur may have been the result of the action of treatment on the aorta or valve between first and second examinations, or have been identified by more expert auscultation.

4 The later appearance of the diastolic murmur marks the development of insufficiency probably from shrinkage of the cusps in healing, for there was no subsequent evidence of an advancing process instead of a healing one

5 As the insufficiency developed transient signs of a strain on compensation appeared, but were relieved by digitalis.

6 There is no evidence to date of an advance of the process either at the valve or in the myocardium as in some of the late cases here described

7 The blood Wassermann reaction has played no part in the diagnosis. Serologic negativity in vascular syphilis is not rare In late syphilis clinical signs here take complete precedence over laboratory syphilology when they are present It needs only that the physician shall recognize and correctly interpret them.

A modern serological test may then be relied upon in suspected untreated vascular syphilis to identify the presence of the infection in from 70 to 85 per cent of cases

The Provocative Procedure.—We no longer employ this procedure when cardiovascular syphilis is suspected.

The "No History of Syphilis" and Blood Sero-negative Group.—Thoroughgoing inquiry into the history of syphilis is sometimes neglected in cardiovascular cases. In 30 of the series of 190 patients, no serious attempt had been made to elicit a history of syphilis or at least to record one.

Fig. 704.

THE BIOLOGIC FALSE POSITIVE BLOOD WASSERMANN IN SUBACUTE BACTERIAL ENDOCARDITIS

Female, aged eighteen, single.

Chief Complaint: Pain in legs and palpitation. Palpitation three years, pains five months.

Pains in Back and Legs Followed Trouble with Wisdom Tooth and Fever.

Painful Nodes Developed on both feet. Evening temperature 100 101 F Weight loss 35 pounds.

Urine Negative. Hemoglobin 85 per cent. dropped 10 per cent. in ten days.

Leukocytes 8000 to 12,400.

Physical Findings Double murmur over hole precordium. Water-hammer pulse. Femoral pistol shot. Heart enlarged to left (x-ray) Electrocardiogram, inverted T all leads.

Blood-culture Streptococcus viridans.

Blood Wassermann Reaction Strong positive.

Dermatosyphilologic Examination
Multiple petechiae.
No adenopathy
No abnormalities of any structure diagnostic or suggestive of syphilis.
Intact virgin.

Blood Wassermann Strong Positive on repetition.

Death from endocarditis and bronchopneumonia. Autopsy refused.

Diagnosis Double aortic lesion, poly valvular insufficiency subacute bacterial endocarditis, streptococcus septicemia.

Discussion

There seems no reasonable doubt, even without autopsy that this young girl did not have syphilis. The aortic lesion was apparently streptococcal, and the repeated positive blood Wassermann, as in other cases have seen, biologic f lse positive.

Of 56 patients, all presenting physical evidence of cardiovascular disease but seronegative at the outset, 12 proved after the most critical examination to have what amounted to "no case for cardiovascular syphilis. This constituted margin of 20 per cent error in seronegative cases. Of the 47 patients having no recorded history of syphilis, 43 per cent gave history of gonorrhea, 60 per cent were Wassermann-positive, 36 per cent had positive neurological signs, 30 per cent positive spinal fluids, and 24.5 per cent positive roentgen-ray signs. Of the Wassermann-negative group of 56 patients, 67 per cent had positive history of syphilis, 44 per cent positive neurological signs, 32 per cent positive spinal fluids, and 80 per cent positive roentgenographic signs.

Syphilis of the Central Nervous System in Association with Cardiovascular Disease—From this group of manifestations great assistance in diagnosis may often be had. Neurosyphilis was present in 54 per cent of the Mayo Clinic series. The value of the routine spinal fluid examination is apparent from an incidence of abnormal spinal fluids in 40 per cent, though as Reid wisely remarks, the mere presence of coincident neurosyphilis does not prove the

vascular lesion to be syphilitic. The neurological examination reveals neurosyphilis more frequently than the spinal fluid (49 per cent) which is to be expected from the well-recognized occurrence of complete serological negativity in vascular neurosyphilis. Asymptomatic neurosyphilis appeared in only 5 per cent of our series, a situation to be expected because of the long duration of the disease in this group The routine spinal fluid examination and the neurological examination must therefore be regarded as integral parts of the study of every syphilitic patient suspected of having cardiovascular disease and as part of the examination of all suspected cases, unless positively contraindicated by age or grave illness. High-grade meningeal and parenchymatous changes may be associated with vascular syphilis, and the clinical picture may range from hemiplegia with complete serological negativity to paresis with strong and irreducible positive Wassermann reactions and pleocytosis in the spinal fluid In fact, the frequency of cardiovascular syphilis in paresis and tabes has been a matter of general recognition for a number of years.

The figures in the literature show wide variation, depending on the thoroughness of the investigation for neurosyphilis and on necropsy control. A excellent review of these figures is given by Herxheimer (Jadassohn Handbuch) From 15 to 20 per cent of paretics clinically present aortic disease, the estimates based on necropsy however ranging from 62.5 per cent (Glasberg) to 87 per cent (Coppola) In tabes the clinical frequency of aortitis ranges from 11 per cent (Nonne) and 26 per cent (Musser and Bennett) to such high proportions as Kessler's 60 per cent. Musser and Bennett found that in 102 cases of vascular neurosyphilis, 88 per cent had late syphilitic aortitis, and 8.9 per cent had advanced to the stage of aneurysm. In 110 general paralytic cases, 28 per cent had syphilitic aortitis with 3 4 per cent aneurysms and 26 per cent of 20 tabetic necropsies revealed syphilitic aortitis with no aneurysm. Advanced syphilis of the aorta and resulting aneurysms were more frequent in association with the endarteritic and meningeal forms of cerebrospinal syphilis than w th the parenchymatous (tabetic and general paralytic) types. The obverse of the picture, which is more important for the diagnosis of cardiovascular syphilis, is represented by range of 16 to 33 per cent for the incidence of tabes in patients with aortitis. Hubert s finding of 23 per cent tabes in 220 patients with aortic syphilis (1919) is fairly typical. In general, the frequency of combined cardiovascular and neurosyphilis increases with advancing years.

More recent figures including CCG (1936), Wile and Snow (1938) Levitt and Levy (1940), Stroud (1945) continue to show wide variability in incidence of neurosyphilis in association with cardiovascular syphilis. In interpreting any of these figures one must remember that investigation for neurosyphilis is usually done only on suspicion and often omitted in cardiac wrecks. Therefore the actual incidence is probably greater than that reported

A number of authors have called attention to the relatively benign course of aortic syphilis coincident with neurosyphilis in the same individual Schlesinger and Wagner-Jauregg have found cardiac deaths among paralytics, for example, to be a rarity It is suggested, too, that the neurosyphilis in patients with marked syphilitic cardiovascular disease tends to run an abortive course. The rarity of aneurysm in tabetics and paretics is emphasized by Herxheimer

The more recent statistics by Willius rendered in tabular form in Fig. 45 are both a summary and a guide to the frequency of collateral evidence of syphilis in a typical thoroughly examined and well digested material on cardiovascular syphilis.

The Therapeutic Test in Early Aortic Syphilis.—The worth of this resort in diagnosis has, we believe received insufficient attention from clinicians. If the tambour second sound and the aortic systolic murmur are the earliest evidence of change in the aortic wall and its surroundings, the identification of these signs in young persons without hypertension or with suspicion arousing fluoroscopic signs in whom even a moderate degree of suspicion of

syphilis may be raised calls, we believe, for consideration of the therapeutic test. This is especially true in patients placed under modern treatment for early syphilis and carried through observation with long periods of seronegativity punctuated occasionally let us say by slight positives, or in patients returning to observation after prolonged lapse. The therapeutic test also has important applications in seropositive latent syphilis in younger persons in whom the first suspicion-arousing signs of aortic disease may appear

McDermott, Tempsett and Webster (1946) though using methods for detecting cardiovascular abnormality (vital capacity venous pressure and circulation time) in addition to roentgenoscopy which are not available to the average clinic, clearly showed the relatively long duration of the now commonly accepted asymptomatic period in syphilitic cardiovascular disease. The finding of presumptive evidence justified treatment for syphilis to prevent further involvement. In only 2.2 per cent of their patients were the serologic tests negative in the absence of history of previous antisyphilitic treatment.

Fig. 705.

100 CASES OF CARDIOVASCULAR SYPHILIS REPORTED BY WILLIUS, 1930
(The figures represent per cent positive to the nearest integer.)

Symptom or sign.	Aortitis, 17 cases.	Aortic regurgitation, 59 cases.	Aneurysm, 24 cases.
Blood Wassermann reaction	65	[illegible]	[illegible]
Abnormal spinal fluid	18	20	25
Other forms of syphilis present	24	29	21
Painful seizures	18	25	48
Significant electrocardiographic abnormalities	71	65	17

In the interpretation of such a therapeutic test it is important to understand the mechanisms involved. In very early aortic syphilis up to and including the period of early valvular sclerosis, it is entirely safe to employ a therapeutic test, unless there is definite evidence of coronary disease. A number of excellent examples of its usefulness will be found in the clinical cases. The course of a therapeutic test may follow either of two directions, as far as signs and symptoms go, depending probably on the duration of the process and the extent of permanent replacement of healthy by inflammatory or scar tissue. From our observations it is difficult to predict clinically that the valve is undamaged, even though only a tambour second sound may be identified. When the patient is placed on treatment, a succession of changes may occur which carries him through the sclerosis and increased rigidity and may form the basis of a systolic murmur and tonal changes to the diastolic murmur that marks the sclerotic distortion of the healed or healing, probably fibrous, valve flap Clinically speaking, one might conceive that such a patient, as a result of his therapeutic test, is in a last state which is worse than his first, in that for a competent valve an incompetent one has been substituted. In a sense this patient has undergone a therapeutic paradox in the process of attaining a diagnosis. On the other hand, the institution of treatment may

cause a prompt and marked remission or complete disappearance of all clinical symptoms and signs.

The Paradoxical Increase in Signs.—The paradoxical increase in signs on the institution of treatment in early aortitis, whether with diagnosis or for therapeutic test, was observed not only in the Mayo Clinic material but subsequently at the University of Pennsylvania and has had confirmation by Moore Danglade and Reisinger Observation of such patients for a period of several years, as in certain of our cases, corrects the impression above mentioned that the last state of the patient is worse than the first. It indicates clearly that the patient has in reality exchanged a progressive disability for an arrested and static one (Fig. 703) He can now proceed to compensate for a slight regurgitation in a healed lesion, instead of finding himself some years later the possessor of a broken compensation resulting from a progressive lesion, and finally an irremediably ruined aortic valve.

For example, a patient may not present a murmur at the outset, merely an accentuation of the aortic second sound. Two or three months or even three or four weeks after treatment is begun a soft blowing, systolic aortic murmur may be recognized and may grow to a rough systolic murmur and become stationary while the patient exhibits, coincidently a slight rise in blood pressure and slight but transient myocardial embarrassment. The precordial pain may on the other hand, vanish coincidently with the first stage of treatment, the dyspnea may disappear entirely or if the myocardial effect is marked may increase and then subside. Transient edema may appear In very early angina pectoris the symptoms may show improvement from the start, but if the coronary lesion is of long standing and myocardial damage is definite, there may be a very pronounced and even injurious exacerbation. For this reason it may be well to carry out therapeutic tests, even on early lesions, with the patient at rest, although in a way the alteration of the mode of life makes the subjective part of the test less clear cut. The circumstances must be adjusted to the individual case and to the information which is sought. If the systolic murmur was marked at the outset, the later appearance of diastolic murmur under treatment may be expected, probably as the physiologic expression of contraction of the healing valve flaps. In such cases compensatory myocardial hypertrophy will probably be more marked, and myocardial stress temporarily more pronounced.

The prolonged watching of the progress of a therapeutic test is obviously of the utmost importance, although the examiner should not expect rapid and immediate changes. The lapse of from six weeks to three months before the changes associated with healing become easily detectable by physical signs is not at all unusual. The symptomatic responses, while usually more rapid, may be similarly delayed The serologic tests should be repeated at the outset if the first blood serologic reaction is negative and occasional single repetitions may after a time show an undoubted swing toward the positive. The technic of the therapeutic test is discussed under treatment. The use of the therapeutic test in differentiating aneurysm from mediastinal tumor is considered on page 937 in connection with roentgenological diagnosis.

The Rheumatic Fever Question.—We have already reviewed the symptomatic and objective differentiation of syphilitic and rheumatic aortic valvular disease (see p 907)

Coincident involvement of the mitral valve points toward the septic or rheumatic origin of an aortic lesion, although, as Hirschfelder points out, systolic murmur t the apex in a syphilitic aortic lesion, due to relative mitral insufficiency is not uncommon. Warthin says that he has never found syphilitic lesion of the mitral valve.

The influence of streptococcal and rheumatic infection on the aortic valves, without a mitral complication, is as yet hardly evaluated clinically for means of detecting syphilis in the seemingly rheumatic patient are still only em-

ployed in the most rudimentary way by the majority of physicians. A negative history of syphilis and a single negative blood serologic reaction with a history of tonsillitis, pains in the joints or acute rheumatic fever in a young adult, are still accepted by many physicians as eliminating syphilis from the possible explanations of aortic systolic murmur While this uncritical attitude persists, it will often be impossible to recognize syphilis of the aorta in the first decade of the disease, when its diagnosis means the most in outlook for the patient. The more uncritically the term "rheumatism" is used the larger will be the proportion of patients to escape through this loophole and develop the late complications of cardiovascular syphilis. We have pointed out in previous chapters how well an early syphilitic infection with arthritic manifestations in which ostealgias, myalgias, hydrarthroses, and so forth are indiscriminately jumbled, can imitate "rheumatism" clinically Even to the examining eye deception is sometimes easily possible, to say nothing of the untrustworthiness of the patient's history Due allowance must, of course, be made for the clearcut picture of acute rheumatic fever which should be sharply differentiated in its historical and diagnostic value from the muddle of "rheumatism" arising from catch-basket use of the term.

Rheumatic aortitis has been discussed by Osler and cases have been reported by Klotz, Renon, Baris, P whski, and others. Bennert formulated, on the basis of 20 cases, rule which certainly deserves critical reexamination in the light of modern syphilology that aneurysm in children and in youths is result of rheumatic fever A tendency to spontaneous recovery in such cases is marked. Mamorstan and Kraus have described influenzal aortitis, Allbutt speaks of aortitis as complication of suppurative infections, erysipelas, smallpox, typhoid fever diphtheria, measles, scarlet fever pneumonia, tuberculosis, and gonorrhea, but fortunately other observers also with extended experience, such as Elliott and Reed, concede it to be very rare.

"Rheumatism" in the Mayo Clinic Case Study —In an examination of the complaint of rheumatism in the present cross-section, it was found to resolve itself into almost everything imaginable, from true multiple arthritis following scarlet fever and repeated attacks of tonsillitis, to the pain of slowly developing subclavian aneurysm without aortic signs, and the neuritic pains of early tabes dorsalis. The physician who asks his patient if he has had rheumatism and tonsillitis, or who obtains what he believes to be history of acute rheumatic fever and then proceeds to remove tonsils for the treatment of aortic endocarditis after obtaining single negative blood Wassermann reaction, may be overlooking good story of syphilis in disguise and missing syphilitic aortitis at the time when treatment for syphilis will be far more likely to check the trouble than tonsillectomy

Nine of 13 patients had some plausible explanation of their rheumatic fever besides streptococcal infection. In this group of 13 patients were 2 in whom the cardiac condition was almost certainly rheumatic, and 1 in whom it was impossible to decide whether rheumatic fever was responsible for the condition, although the patient had tabes dorsalis and may have had coincident rheumatic endocarditis with syphilis.

The history of heumatic symptoms may therefore, be no small part of the story of patient with syphilitic aortic valvulitis, and greater care should be exercised in ascertaining the clinical importance of the rheumatic factor This undertaking is by no means simple and syphilis may emerge from behind an apparently fair case of rheumatism, with the prompt recovery of the patient under treatment for the former I view of hat seem to be occasional false positive blood Wassermann reactions in patients with septicemia and subacute bacterial endocarditis, the production of "pseudosyphilis by the streptococcus with the production of "pseudorheumatism by syphilis, deserves fuller study

It is worth while to recall, too, the value of critical inquiry into the question of gonorrheal arthritis in patients who give history of rheumatism. This does not suggest that the valvular lesion is gonorrheal in origin, but that chronic gonorrhea with its prostatic complications is fertile source of rheumatic symptoms that may mislead the history-bound examiner int overlooking the underlying syphilis in case of aortic endocarditis. I considering the cause of an aortic murmur therefore the examiner should at least palpate the prostate before accepting history of rheumatism as of bonafide streptococcal or rheumatic origin, and hence the cause of the aortic lesion.

A high proportion of the patients, 120 (83 per cent) with full venereal history in this cross-section had had gonorrhea. Thirty-seven (20 per cent) gave histories of rheumatism of one sort or another Thirteen (7 per cent) gave a definite history of rheumatic fever or postscarlatinal arthritis. Of the 37 patients who gave a history of "rheumatism," 29 had had gonorrhea or syphilis or both, 23 had had gonorrhea, 19 had had both gonorrhea and syphilis, 18 could give no history of either 5 had had gonorrhea only 5 had had syphilis only 23 had had positive blood Wassermann reactions, 5 had positive spinal fluid, and 5 had neurological signs of syphilis. Of the 15 patients who had had definite rheumatic fever or postscarlatinal arthritis, in 4 the rheu-

Fig. 709

COINCIDENT VASCULAR SYPHILIS AND NEUROSYPHILIS. SEROLOGIC NEGATIVITY PROBLEM OF DIAGNOSIS OF MEDIASTINAL MASS. RECURRENT SYMPTOMS OF MEDIASTINAL PRESSURE CONTROLLED BY TREATMENT FOR SYPHILIS ANEURYSM WITH CLOTS (?)

Railroad man, aged fifty-two years, married.

Examined August 15, 1918.

Chief Complaint Hoarseness Recurrent attacks. First attack t enty three years before relieved by potassium iodid in eight months. Paralysis of the vocal cords fifteen years before, transient. Hoarseness recurred one week before.

Chancre thirty years before. Medication by mouth one year Potassium iodid for hoarseness. Rubs t elve years before

Dizziness, Nausea, Vomiting, Loss of Control of Legs Six months' duration.

Palpitation, two months.

Stabbing Pains, Knees and Shoulders, two months.

Examination Heart 1.5 by 8.5 cm Blood-pressure 100/72 both sides. Dullness left upper chest. Dilated veins

Larynx: Left recurrent paralysis.

x-Ray of Chest Tumor upper mediastinum.

Fluoroscopic: N pulsation.

Blood Wassermann Reaction Negative

Neurologic Examination: Fixed pupils, unequal, irregular Deep reflexes exaggerated.

Spinal Fluid Negative.

Treatment Six arsphenamin injections, mercury succinimid intramuscularly

Marked Improvement in all symptoms, though still hoarse.

Final Diagnosis on Clinical Grounds Aneurysm ith clot fixation.

Fluoroscopic Examination: No change

DISCUSSION

1 Apparently this patient had had at least one previous transient laryngeal paralysis. He had had prolonged relapsing hoarseness good ma y years after the period in hich it would be likely to be due to secondary stage, and there as no scarring to suggest gummatous laryngitis.

2. It seems possible that the recurring attacks had been due to recurring expansion of the aneurysm with associated exacerbations of mediastinitis and pressure phenomena, relieved by treatment, or by the fixation of the aneurysm from clotting

3 The long duration of the symptoms makes mediastinal tumor of other than syphilitic origin improbable

4 N urosyphilis, associated with the vascular picture, may easily have negative serology The picture wa not, however typical or advanced.

5 Unilateral pupillary inequality without fixation to light may be the result of aneurysmal pressure on the cervical sympathetic, or involvement of the nerve in mediastinitis and perivasculitis

matism followed gonorrhea (not necessarily immediately) and in 5 the rheumatism followed syphilis (not necessarily immediately)

Th Austin Flint Murmur.—The simulation of the murmur of mitral stenosis by the Austin Flint murmur has many times raised the question of mitral disease and rheumatic etiology in a case of syphilitic aortitis, for after all, the demonstration of mitral disease coincidently with aortic insufficiency is the critical point in the large majority of diagnoses of rheumatic aortic valvular disease. The remarks of Carter and Baker summarize this problem. They found typically characteristic Flint murmur present in 45 (50 per cent) of 70 cases, and in 4 found it to be associated with palpable thrill t the apex T quote them "It may be stated categorically we believe, that in the presence of conspicuous aortic insufficiency with greatly hypertrophied left ventri-

cle, the presence of the characteristic Flint murmur even when accompanied by a late diastolic thrill, call it presystolic if you will, does not justify the diagnosis of mitral disease except in the absence of all the criteria indicative of syphilitic disease and the presence of definite history of rheumatic infection and possibly previous attacks of recognized rheumatic endocarditis in the past and such clinical signs as increase in the intensity of the first sound at the apex and enlargement of the left auricle.

"This distinction cannot be too strongly emphasized. It has been forced upon us only after more than one humiliating lesson in the failure of the pathologist to confirm the clinical description in such cases.

Nichols (1940) in discussing differentiation of the Flint murmur insists on its presystolic time and "blubbering" or rumbling quality Kampmeier (1945) found it present in 16 per cent of 163 patients with insufficiency

Roentgenological Diagnosis—Aneurysm *versus* Tumor—From the Mayo Clinic experience it became apparent that one of the important practical differentiations in dealing with thoracic aneurysm is between this condition and tumor It is in the fluoroscopic differentiation of the two that the probable influence of perivascular and mediastinal incarceration of the sac in the surrounding inflammatory infiltrate reaches its greatest importance. Obviously by the roentgen ray if any enlargement whatever is disclosed, it appears as a tumor whose location may of course identify it correctly It is quite likely however to be indistinguishable from the lymphomatous tumors of the mediastinum, from mediastinal Hodgkin's disease, or lymphosarcoma, from malignant metastasis, and from substernal goiter

T these possibilities for confusion the following have been added: tuberculosis of the lung, rated by Kampmeier (1938) as the commonest error in descending arch aneurysms occluded bronchus with bronchiectasis; pneumonia or delayed resolution, sarcoma of the lung; bronchogenic carcinoma. Roesler (1943) includes also thymic tumor, teratoma, hydatid cysts, neurofibroma, ganglioneuroma, unilateral sacculated pericarditis, esophageal carcinoma and diverticulum, cold abscess of the spine. Roche, Steinberg and Robb (1941) report case of right-sided aorta with diverticulum confused with aneurysm.

The crux of the roentgenological differentiation, therefore, rests with fluoroscopic study But if pulsation is not apparent, the inclination is to diagnose a solid tumor (Fig. 713) occasionally allowing for the possibility of the aneurysmal sac fixed by intramural clotting (Fig 706) Our study indicates that this point of view is distinctly fallible and that the entire picture may be transformed by a short therapeutic test, which by resolving the mediastinitis and perivasculitis, permits the pulsation of the tumor to become visible under the fluoroscope (Fig 707)

The Therapeutic Test for Aneurysm *versus* Mediastinal Tumor—The therapeutic test for the diagnosis of aneurysm deserves much wider employment than it apparently receives, and should be particularly insisted on by the roentgenologist before he passes judgment on the character of a mediastinal shadow Nothing is sacrificed in inoperable cases by applying this test, either with or without a negative blood serologic reaction. Such a test must, of course, be begun with mercury and iodide, to avoid the risk of rupture from a too abrupt weakening of the wall, but in small tumors this preparation may be confined to four or five weeks, and three more weeks of small doses of neoarsphenamine or mapharsen will usually demonstrate pulsation if it is likely to appear This result is not, however invariable, and since little is to be lost at the present time in the relatively hopeless outlook of a malignant mediastinal growth by a delay of a few more weeks, the test may be prolonged

Fig. 707

THE CONFUSION OF AORTIC ANEURYSM WITH MEDIASTINAL TUMOR. INFLUENCE OF TREATMENT ON THE RESOLUTION OF PERI-AORTITIS AND MEDIASTINITIS, MAKING POSSIBLE THE DEMONSTRATION OF PULSATION BY x-RAY

Mechanic, aged forty-seven years, married.

Examined June 11, 1919.
Chief Complaint: Pain in the chest, especially right shoulder. Worse on exercise.
Mild Dyspnea. Slight Wheezing.
Penile Sore twenty years before.
No Secondaries.
Examination:
Heart left border 7.5 cm.
Heart sounds muffled, no murmurs.
Impaired resonance, prolonged expiration right upper.
Abdomen negative.
Knee-jerks absent.
Blood Wassermann Reaction Negative.

***x* Ray of Chest:** Mediastinal tumor probably aneurysm.
Fluoroscopic Examination: Non-pulsating, non-expansile tumor of mediastinum.
Sent for Therapeutic Test with Clinical Diagnosis of Mediastinal Gumma.
Treatment: Two weeks of rubs and potassium iodid followed by arsphenamin.
Pain in Shoulder Gone after second injection.
Able to Walk Any Distance after fifth injection. Wheezing gone.
Fluoroscopic Re-examination after sixth arsphenamin injection reports
Aneurysm of the Aorta; expansile pulsation.

DISCUSSION

1. *Note the paucity of physical findings.*
2. The fixation of the walls of an aneurysm by clots is more generally recognized as a factor in diagnosis than is its incarceration in the infiltration of a peri-aortitis or mediastinitis.
3. Cases of this type are at times treated with *x*-ray on a presumptive diagnosis of lymphosarcoma.
4. The application of a therapeutic test for syphilis to all mediastinal tumors would yield a fair return of aneurysms and gummatous mediastinitis. This should be an invariable practice before the patient is given up as beyond help.
5. The presence of palpable glands (Fig. 718) does not establish the malignant character of the process. They are not uncommon in mediastinal syphilis. A pathologic examination of such a gland may help to demonstrate, but does not eliminate malignancy.
6. On the other hand it must not occasion surprise if a therapeutic test fails, for there are cases in which it is impossible to distinguish clinically between syphilitic and malignant lesions of the mediastinum.

and roentgen ray treatment may be coincidently applied, if pulsation be used as the chief test for aneurysm.

Symptomatic Positive Test.—When marked symptoms accompany the lesion, they are often a fairly sensitive guide to the progress of the test, and the patient may notice distinct improvement in all his symptoms, especially the pain, dyspnea and hoarseness, if the cords are affected, some time before the tumor begins to show signs of pulsation.

False Positive Therapeutic Test.—While a positive therapeutic test is indicative of syphilis if signs of aneurysm are subsequently identified in the tumor, caution must be used in interpreting reduction in size or symptoms of mediastinal masses in which no pulsation is detected after reasonably prolonged treatment (two months). The influence of arsphenamine on the infiltrates of Hodgkin's disease and glandular tuberculosis may lead to a false diagnosis of syphilis from nonspecific effect, which will be reversed later by the ultimate outcome. For this reason, if these questions are raised, a soluble mercurial salt alone or inunctions should be used for a period of from four to six weeks before an interpretation is made. If the result is negative, the arsenical may then be continued for its nonspecific effect, if desired.

The Electrocardiogram in Syphilitic Cardiovascular Disease.—Electrocardiographic examination occupies a paradoxical but extremely important position in dealing with cardiovascular syphilis. It is the most valuable means

for determining the functional state of the myocardium, its need of treatment and its ability to withstand both toxic and therapeutic effects, especially those of induced fever (Lieberman and Katz, 1940). We have seen that heart muscle and conduction disturbances are rarities of the first order in secondary syphilis. The classified findings of Willius in the Mayo Clinic survey are given in Fig. 708. Abnormalities of the T wave and QRS complexes indicative of ventricular myocardial disease are foremost.

Juster and Pardee in an electrocardiographic study of 80 patients with syphilitic aortitis with ten autopsies found 85 per cent to present abnormalities of the T-wave and in 20 per cent this was of coronary type. The T-wave was abnormal in only 38 per cent of those without the valve lesions. Their autopsy study apparently connected the abnormality of the T-wave with the encroachment upon the lumen of the coronary orifices by the syphilitic disease in the sinuses of Valsalva. The greater frequency of the T-wave changes in the group with aortic insufficiency they believe is due to the fact that in these patients the aortitis involves the region of the valves near which the coronary arteries originate. For this reason, abnormalities of the T-wave in syphilitic aortitis should be viewed as an indication of serious coronary involvement but not necessarily as an indication of myocardial pathology. The grave prognostic significance of T-wave negativity in Lead I was repeatedly pointed out by Willius in the Mayo Clinic material. In Willius' later study summarized in Fig. 708, the very low incidence of electrocardiographic abnormality in cases of aneurysm is striking and in the main to be expected because of the relative exemption of the coronary orifices in the uninvolved aortic sinuses. Here in all probability lies one of the principal reasons for the better prognosis under treatment of aneurysm as compared with aortic regurgitation in our observation. Wood and Wolferth, and Parkinson and Bedford have identified electrocardiographic changes in proportion of cases of angina pectoris with coronary occlusion attributed in theory to ischemia of the heart muscle but not diagnostically significant. Smith and Blackford (1938) found the following changes to occur significantly more often in 108 patients with syphilis than in 300 patients with other types of heart disease: intraventricular conduction defect; left axis deviation; low voltage of T-wave. ST segment deviation. The occurrence of progressive increase in QRS slurring with decreasing voltage of the T-wave in the serial tracings was a most accurate and ominous sign of rapidly progressing fatal disease. Left ventricular preponderance and anterior wall infarction patterns are most frequent (Cole and Bohning, 1941).

Other electrocardiographic changes produced by syphilis and particularly by the arsphenamines are considered on pages 908, 925 and 945.

The Diagnosis of Peripheral Vascular Syphilis.—The manifestations of syphilis of the peripheral vascular system have been summarized in the discussion of pathology (page 903). Their clinical diagnosis is based largely on incidental recognition of the syphilis or of some manifestation which, in the absence of a positive serologic reaction and a good history, can still be interpreted as presumptive evidence of syphilis.

Syphilitics, like other patients with cerebral vascular disease, may exhibit such symptoms as fainting attacks, loss of memory hemiplegia and aphasia. The well-known tendency of syphilis to produce obliterative endarteritis as one of the fundamental pathologic changes which underlie

Fig. 709 —Ulceration and gangrene due to syphilitic obliterative endarteritis.

A young married carpenter ged thirty-fiv years, developed pain in the right little toe three years befor examination in the clinic. The skin came off and the toe turned blue. It finally healed. Then the right second toe turned blue and became gangrenous to the second joint. The whole toe was removed. There was no further trouble for nearly two years, and then the great and third toes of the right foot and the second toe of the left foot became affected in the same way The process ppeared in the fingers soon after involving the first on the right hand and the first and second on the left. Ther were no attacks of vasomotor spasm. The finger simply became discolored and the end became sore and dropped off, leaving the nail deformed. There was little discoloration or change in the foot.

At the time of examination the great toe of the right foot presented several sloughing punched-out ulcers. There were ulcers on the dorsum of the right third toe and left second toe, with cyanosis. The affected fingers also showed some ulceration.

The patient did not give history of either yphilis or gonorrhea. The wife, ho was in an insane hospital, had had tw miscarriages and tw pparently healthy children.

Examination failed to disclose any explanation of th process except the presence of strongly positive blood Wassermann reaction. The urine wa normal, the heart negative The blood-pressure, however as 180/84

Treatment resulted in the healing of all the ulcers xcept that of th great toe. Pain for time became more marked and then somewhat relieved, but still present. The patient neglected treatment and wa subsequently heard from indirectly as in another hospital with gangrene of the great toe, and doubtful positive followed by negative blood Wassermann reaction and negative spinal fluid.

Did this man hav syphilitic endarteritis? W have seen an almost identical case in somewhat younger man in whom not even syphilis could be advanced probable etiology

Against the vasomotor type of Raynaud' disease is the absence of history of paroxysmal spasm and temporary relief This process w slowly progressive

Against thrombo-angiitis obliterans would be the absence of migratory stage the absence of nodosities along the vessels, the invol ement of the hands.

No mention is made however of the condition of the nterior nd posterior tibial arteries, bvious and inexcusable versight on the part of the examiner hich makes complete differentiation in retrospect impossible

the clinical manifestations of the disease leads to an interpretation of any vascular symptom or accident as syphilitic *per se* provided it occurs in conjunction with syphilis. The question of direct etiology is exceedingly difficult to prove clinically nd there is little about the peripheral vascular lesions as such on hich to make the diagnosis. Arteriosclerotic changes are undoubtedly

associated with syphilis, but report of the percentage of positive Wassermann reactions obtained in cases of hypertension, for example, would give little clue to the proportion traceable to true syphilitic sclerosis.

Such an analysis has been attempted by Horine and Weiss (1930) for the American Heart Association symposium. The review of the literature emphasizes the wide divergence of opinion on this question. A number of the older reports rate syphilis high as causative influence Mattei and Tolson (1927) found syphilis the only etiologic factor in 14 per cent of 210 patients with hypertension. Stone and Van Zandt found syphilis in 28.3 per cent of 436 patients with hypertensive heart disease. Horine and Weiss point out that many of the prevailing estimates are determined, not by the influence of syphilis in the production of hypertension but by the frequency of syphilis in the clinical material studied. They therefore employed control series of 2000 nonhypertensive patients of similar ages and economic status.

Horine and Weiss concluded that the incidence of syphilis in their 600 patients with essential hypertension was essentially identical with that in the control group and that accordingly syphilis has no material etiologic bearing on essential hypertension. While investigations based purely on serological tests may be thought of as vitiated by the well-recognized frequency of seronegativity in some aspects of peripheral syphilitic vascular disease, our experience tends to bear out Horine and Weiss contention. Hypertension is not necessarily part of serious syphilis of the vascular

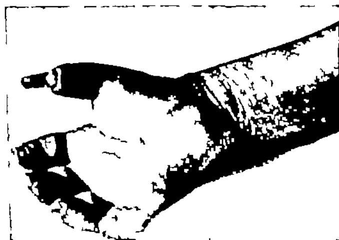

Fig. 710.—Gangrene from syphilitic (?) thrombosis of principal arterial trunk in syphilitic child. (Courtesy of Dr J C. Gittings.)

system, as is apparent from the really very moderate tensions exhibited in cases of advanced syphilitic aortitis and aneurysm with pronounced coronary sclerotic signs. Moreover as Elliott points out, syphilitic patients are not immune from the action of nonsyphilitic causes of hypertension. On the one hand, permanent reductions of arterial tension under treatment for syphilis undoubtedly do occur and the reductions are marked enough and lasting enough to give the impression of positive therapeutic test. On the other hand, so little is known of the etiology of essential hypertension, and it may be influenced from so many directions, that conclusions such as this are unsafe.

Peripheral vascular changes resulting in gangrene likewise present little that is distinctive of syphilis either clinically or pathologically (Figs. 709 and 710) One differential point, however we have found useful. If at the time of examination the patient has had repeated vasomotor spasm, in which the affected fingers or toes first blanch and then become suffused and swollen, or if he can give such history the condition is very unlikely to have syphilitic etiology The slowly but steadily advancing peripheral sclerosis with gradually developing pallor and coldness, blueness, and finally ulceration, is the type more often associated with syphilis, although of course this type may likewise be associated with arteriosclerotic changes secondary to age, diabetes, Buerger syndrome, and so forth.

The examination of tissue in suspected cases of syphilis for endarteritic changes is, in our opinion, unconvincing so far as syphilitic etiology is concerned. Aside from the fact that the bi-

opey wound may not heal and may force an amputation, endarteritis alone, especially in the skin, does not make diagnosis of syphilis, for exquisite examples may be seen in other conditions of as yet completely unknown but certainly nonsyphilitic origin. Buerger believed that the type of peripheral arteritis which he described, thrombo-angiitis obliterans, could be histologically differentiated from other obliterative lesions of the arterioles. The migratory character of the process in the Buerger syndrome is an important differential point.

The Therapeutic Test in Peripheral Vascular Syphilis.—The therapeutic test of so much value in the differentiation of syphilitic inflammatory lesions of the aorta and aortic valves has relatively little value in the differential diagnosis of peripheral vascular scleroses. The clinical changes which they present do not occur until the very end of the pathologic process, namely, the local or impending death of the affected part, or fibrosis which is practically not at all responsive to specific treatment. The resort to iodides, which is rational therapy in such cases, is not means of demonstrating syphilitic origin, for the drug is quite as effective, or rather more often as ineffective, in vascular conditions other than syphilis. Among the case reports is included an example of the nearest approach to a positive therapeutic test that we have been able to obtain in fully established case. It is quite possible that earlier arousing of suspicion at the time when tingling and pallor first appear with the recognition and vigorous treatment of the syphilis at that time, might result in complete arrest of the process. W have been dissatisfied with the results of therapy in intermittent claudication associated with syphilis.

Herrmann has used negative pressure in 5 syphilitic cases of peripheral vascular disease with benefit. Johnson (1941) described the case of a patient with severe Raynaud's symptoms, ulcers, scleroderma and sclerodactylia who obtained very little transient improvement after bilateral removal of the stellate and second dorsal sympathetic ganglia in 1932. The symptoms gradually became worse. In 1933 antisyphilitic treatment was instituted following which she had complete relief from Raynaud' symptoms through 5 winter seasons. Among the treatments which have proved useful in Buerger or Raynaud' disease are Buerger-Allen vascular exercise, diathermy, sitz, contrast, and whirlpool baths, tissue extract (*e. g.*, deproteinized pancreatic tissue extract), pavaex pressure-suction boot treatment, Sanders oscillating bed, intermittent venous hyperemia, vasodilating drugs (*e g* papaverine, choline compounds, etc.), mecholyl iontophoresis, sympathetic ganglionectomy periarterial sympathectomy (arterial resection), calcium orally 5 per cent sodium citrate or hypertonic saline solutions (3 per cent) intravenously and typhoid vaccine fever therapy

Clinically then, the recognition of syphilitic peripheral scleroses is a matter of exclusion of all other etiologic factors. Among the possibilities to be eliminated in cases presenting gangrene are diabetes, senile arteriosclerosis, infectious thrombosis and embolism Buerger's thromboangiitis obliterans, and the action of poisons especially damaging to the vessels, such as lead. Moreover obliterative endarteritis of fairly large vessels of absolutely undemonstrable etiology is known to exist, so that there remains a loophole through which any given case may escape If therefore an arterial obliteration with gangrene appears in a patient in whom a coincident syphilis can be demonstrated, treat the syphilis but suspend judgment on the diagnosis. Fig 700 is a good example of a strongly suggestive but not proved syphilitic etiology

The Diagnosis of Pulmonary Arterial Disease.—I 1917 Warthin reviewed the literature of this rare manifestation of syphilis in connection with case in which he demonstrated *Spirochaeta pallida* in the all of the aneurysm which had developed in the left upper division of the pulmonary artery The egg-shaped mass ith its surrounding adhesions appeared in the roentgenogram as mass in the body of the lung extending from the second to the fourth rib. The symptomatology included repeated pulmonary hemorrhages ithout other symptoms of tuberculosis or of aneurysm the signs included diastolic pulsation visible in the neck, marked diastolic murmur in the third intercostal space transmitted upward nd across. The blood Wassermann reaction as positive. Before death, which occurred from hemorrhage, to-and-fro murmur t the apex and marked difference in pulse bet een the two arms were recognized. The clinical diagnosis as gumma of the lung. In remarkable case in Stokes's practice seen h Wolferth in cardiological consultation, young man of twenty-four following pneumonia with markedly delayed resolution (seven week) was found to have a positive blood Wassermann re-

action, without history of syphilis or gonorrhea. Some months following his pneumonia he developed nodulo-ulcerative cutaneous lesions and in the examination at the time the heart was entirely normal but the patient showed signs slightly suggestive of prenatal infection. The cutaneous lesions responded to arsphenamine, mercury bismuth, iodide, and bismuth arsphenamine sulphonate, but after lapse of two years on returning for observation, systolic murmur over A2, systolic and diastolic murmur over P2 at the base of the heart were recognized. Several examinations by different consultants had established the normality of the cardiovascular system in the interval between the pneumonia and this first appearance of signs. The basal double murmur as detected by Wolferth, was markedly influenced by respiration and the diastolic phase began with the second sound and faded off in the latter part of diastole. Fluoroscopic examination showed definite prominence of the curve of the pulmonic artery with striking pulsation in comparison with the lesser pulsation of the aortic knob above. Wolferth believed the findings suggestive of pulmonary ring dilatation with aortic syphilis and probable syphilis of the pulmonary artery

For additional reports see page 903 (pulmonary aneurysm) including Segal 1940 (gummatous arteritis) and Allen and McCracken (1940).

THE TREATMENT OF SYPHILITIC CARDIOVASCULAR DISEASE

One of the few pleasures one derives from rewriting a textbook lies in the appreciation which it brings of the march of events toward rational solution. In no field of syphilis more than the cardiovascular is this rearranging into an ordered pattern of the elements of a crazy-quilt patchwork puzzle more apparent and acceptable. The original cardiovascular treatment section of this work was perforce confined to a somewhat broken array of landmarks scattered like boulders about a field. It is now possible, with our growing knowledge to place these boulders at least in a wall and to describe almost in a paragraph the fundamental principles now recognized as applicable to treatment of the syphilitic heart and great vessels.

The Literature.—Much of the literature of methods and results in treatment still preserves the impressionistic quality of individual, statistically uncontrolled or uncontrollable experience. Among notable contributions toward exactitude must be mentioned the direct studies of the effect of the arsphenamines on the heart (Reid, Koldel and Moore, Wilson, Wile, Wishart, and Herrmann). On the clinical side there has evolved an increasingly clear-cut and favorable opinion regarding the use of the arsphenamines, in properly selected cases, in aortitis and aneurysm. Notable contributors to the problem include Braun, Schottmüller Schlesinger, Horder Kothny and Müller-Deham, and the authors included in the recent symposium in the Dermatologische Wochenschrift, including Citron, Galewsky Klech, Lesshke, Ritter and Schlesinger and the observations of Conybeare, on arsphenamine in the treatment of aneurysm. The American contribution, particularly to the evaluation of treatment effect, has been striking one, including the American Heart Association symposium papers of Hines and Carr, and Moore and his associates. The paper by Moore, Danglade, and Reisinger, to which reference is constantly made, was at the moment the most complete in the literature and marks as substantial an advance in knowledge as did Moore and Kemp papers on early syphilis. Since the advent of mapharsen particularly fear of the arsenical is notably diminishing, and its earlier use in fuller dosage is being encouraged. W personally hesitate at too much relaxation of precaution at this point, as "hurry up rather than wisdom, and still counsel the cautious though not dilatory approach by preparation. The papers by Harlow Brooks and Wile present the more conservative viewpoint and the latter conception of therapeutic paradox may now be regarded as established, although the means of avoiding it without the necessary exclusion of the arsphenamines are open to debate. A well-defined body of opinion is developing in opposition to the use of the arsphenamines in angina pectoris and coronary sclerosis (Schlesinger et al., Handbuch) to which it was possible in the first edition of this work to present well-defined theoretical objections. The duration of life and comfort of the patient have been substantially advanced and the period of discouragement and reaction, in which we shared following the recognition of the unfortunate consequences of therapeutic shock and paradox from overintensive treatment, has given way to renewed hopefulness.

The Accepted Principles.—In Fig. 711 we have attempted to summarize from the foregoing literature as well as our personal experience what we be-

lieve to represent the current opinion on accepted principles in the treatment of cardiovascular syphilis. The details should be read with care.

Treatment Is Worth While—It has long been accepted that the use of mercury and iodide in syphilitic cardiovascular disease improves to some

Fig 711

SOME PRINCIPLES IN THE TREATMENT OF CARDIOVASCULAR SYPHILIS

1 Effective modern treatment of primary and secondary syphilis reduces the frequency of later cardiovascular involvement.
2 Complete arrest of an early cardiovascular involvement is possible.
3. With proper selection and proper management, treatment of later cases is worth while. It prolongs life and increases comfort and effectiveness.
4. All reactions to treatment should be avoided.
5. Treatment must be individualized for each patient. The treatment of each phase or type of involvement is a special problem. In general, more intensive and fast-acting methods are appropriate to early (uncomplicated) syphilitic aortitis. Later syphilis of heart and aorta must be approached with great caution even though subsequent treatment may be both intensive and prolonged.
6 The arsphenamines are intrinsically toxic for the syphilitic cardiovascular patient this is most true of 606, least of mapharsen.
7 None the less, they can and should be used because:
   (a) Toxicity can be controlled by dosage and selection.
   (b) Neoarsphenamine and bismuth arsphenamine sulphonate have little or no toxic effect in proper dosage. Mapharsen has least of all.
   (c) The results symptomatically are better with than without, especially in aortitis and aneurysm (relief of pain, dyspnea, etc)
   (d) The life expectancy is increased if proper selection and technic prevail.
8. But therapeutic shock and paradox are grave realities.
9. They can be avoided by
   (a) Completely examining the patient, including teleroentgenogram, fluoroscopic and electrocardiographic study before beginning treatment.
   (b) Never giving a patient with syphilitic cardiovascular disease an arsphenamine at the outset except in minute doses.
   (c) Never giving a large dose of an arsenical at any time
   (d) Beginning the treatment of decompensated or badly damaged hearts with mercury and iodide rather than bismuth or arsphenamine (exception, see bismuth arsphenamine sulphonate).
10. Marked coronary and myocardial disease is a relative but not absolute contraindication to the arsphenamines.
11 The patient with a syphilitic heart should be intelligently managed from the standpoint of both the syphilis and the heart condition, not from that of either alone
12. Cardiovascular disease takes precedence over all other complicating forms of syphilis in determining treatment procedure in any given case
13. Decompensation is a specially grave complication, to be avoided at all cost It disproportionately reduces expectancy and restricts the possibility of treatment after it has occurred.
14. Digitalis is less active in the syphilitic heart than in other forms of heart disease and especially so in the Negro.
15 Cardiovascular patients with fixed positive serological reactions should not be treated merely to reverse the blood test.
16. Treatment in all cases must be prolonged over several years.

degree the outlook of the patient. The younger clinicians now coming into maturity and the general practitioner unaware of the pitfalls awaiting him, witnessed in the years from 1919 to 1921 in this country the reaction against the use of the arsenicals in the then customary large doses, the impression of which is still so strong in the minds of conservative observers that it will

require much convincing to induce them to readmit arsenical derivatives to their confidence in the treatment of cardiovascular syphilis. This period of overuse and misuse established beyond all question the reality and dangers of therapeutic paradox and therapeutic shock.

A reconsideration of the logic of the situation a differentiation on physiopathologic grounds of cardiovascular syphilis into various types of impairment a dogged persistence and confidence in occasional good results on the part of certain observers, and some blind luck, led to the development of systems of treatment, among them the one which first attracted our attention, that of Kothny and Müller Deham in which small ascending doses of neoarsphenamine were demonstrably well tolerated by a large proportion of patients and with decided benefit. It has become gradually apparent that therapeutic shock, at least, is as much if not even more a matter of dosage than of selection of drug, and that it is possible so to use an arsenical in the treatment of cardiovascular syphilis as to avoid disaster immediate or ultimate. From this principle as a base, a number of observers named in the previously listed literature, like ourselves, have developed technics for the use of arsenicals in practically all phases of cardiovascular syphilis which are now in process of evaluation but which a reasonably experienced observer can, we think, unhesitatingly subscribe to as representing gains over the older methods As Moore Danglade, and Reisinger observed in their own material, it is very much more difficult to secure statistical data which will evaluate the incidence of therapeutic paradox. The principal approach to the problem at the present time must be in the estimation of gains in life expectancy and the results in this field are reviewed on page 959 under Prognosis.

Intrinsic Arsphenamine Toxicity —A substantial advance was made by Reid and subsequently confirmed by Wilson, Wile, Wishart and Herrmann, in examining electrocardiographically the effect of the arsphenamines on the heart. Arsphenamine cardiac collapse, which is discussed under Treatment Reactions, was emphasized by Moore and Keidel and by our own experience as source of disaster in treating cardiovascular syphilis, and they advanced the hypothesis that the effect was due to the induction of ventricular fibrillation by the drug Reid (1945) found that the effect of moderate doses of arsphenamine was to produce first, certain unimportant changes due to stimulation of the vagus, and secondly certain alterations in the QRS complex and the T wave indicative of alteration in conduction in the ventricular tissues. The aggregate effect of these changes in heart damaged by syphilis or as Reid says, "in bad metabolic condition, is to predispose to ventricular tachycardia and ventricular fibrillation through prolongation of the conduction period and shortening of the refractory phase. The ectopic auricular tachycardia is, of course, serious, the ventricular fibrillation fatal. Fortunately such effects must be rare.

Wilson *et al.*, in case of death following 0.3 Gm. arsphenamine in patient with syphilitic myocarditis and complete right bundle branch block, demonstrated an abnormal idioventricular rhythm following the drug Two other patients with aortic syphilis developed diphasic complexes suggesting incomplete bundle branch block with transient T-wave changes but greater persistence of the QRS changes. Similar treatment produced no changes in the electrocardiograms of five other patients with aortic syphilis, and intensive arsphenamine therapy in 20 patients with primary and secondary syphilis produced no electrocardiographic abnormalities.

Tung and Hu (1940) studied serial electrocardiograms in 22 cases of syphilitic aortic insufficiency to whom neoarsphenamine was administered. Mild or moderate change in the R-T or S-T segments or in the T deflections occurred 11 times out of 16 examinations in 5 cases. In 2 cases there were marked changes in the ventricular complex. From their observations the authors conclude that their study serves as warning that, if used indiscriminatingly the intravenous injection of neoarsphenamine may jeopardize, at least temporarily the coronary circulation, and possibly the life of the patient. Geiger and Sadusk (1948) performed serial electrocardiograms on 23 patients with early syphilis before, during, and after massive dose (five day drip) arsenotherapy In 21 of the experiments significant abnormalities during or shortly after treatment (*e g* diminution of the amplitude of the T wave in all leads, frequent inversion of T in all leads other than

the third, *etc.*) were observed, which findings returned to pre-treatment control values within a few weeks after treatment was discontinued.

Fig. 712

"TUMOR OF MEDIASTINUM. UNFAVORABLE PROGRESS UNDER TREATMENT. DEVELOPMENT OF PULSATING TUMOR, SHOWING MASS TO BE AN ANEURYSM

Man aged forty-eight years, married, laborer

Examined 6/19/18.
Gonorrhea Twenty-five Years Ago. No history of chancre or secondaries.
Duration of Symptoms: Eighteen months.
Symptoms:
Pain in left shoulder
No cough.
No voice changes
Abscess (?) over left scapula opened eighteen months ago.
Physical Signs:
Restriction of movement, left chest.
Dilatation of superficial veins.
No visible tumor
No *murmur thrill, pulsation, or tug.*
Palpable glands, both axillae.
Scar over left scapula.
Roentgenographic and Fluoroscopic Examination: No *pulsation.*
"*Tumor of mediastinum, probably sarcoma.*"
Serum Wassermann reaction moderately positive.
Treatment: Rest in bed one week with *Mercurial preparation.* Six inunctions, 4 injections mercury succinimid, potassium iodid by mouth.
Arsphenamin. 0.3 gm., 0.4 gm., 0.5 gm., 0.5 gm. at weekly intervals.
Relief: Loss of weight 10 pounds in six weeks.
Pulsating Tumor appeared with third injection arsphenamin at inner border left scapula and increased rapidly in size. Complete relief from pain.
Tracheal Tug Appeared. Aneurysmal pulsation now demonstrable by fluoroscope.

DISCUSSION

1 The roentgenographic diagnosis of malignancy was supported by palpable glands.

2. Not every mediastinal mass that does not show pulsation is a solid tumor nor is every mediastinal mass with an associated partial positive Wassermann reaction a manifestation of syphilis. Exploration has demonstrated sarcoma pathologically In general, however a therapeutic test should precede exploration.

3 A therapeutic test for syphilis may demonstrate an aneurysm previously unrecognizable. Such tests must be made with a prolonged mercurial and iodid preparation.

4 Two weeks of inunctions is not an adequate mercurial preparation. Four to six weeks is better

5 The rapid tissue change and the possibl serious effects induced in late syphilitic lesions by modern treatment for syphilis are well illustrated by this case. This patient should have had several weeks of rest in bed on mercurial and iodid preparation, with arsphenamin later rather than a therapeutic shock from such a rapid-acting vasculotoxic drug as arsphenamin at the outset. The initial dosage of arsphenamin was excessive. We have learned to prefer neo-arsphenamin 0.05 to 0.4 gm. in ascending dosage with weekly intervals.

6 The change in the roentgenologic and physical findings which appeared after the third week suggests late healing rather than early Herxheimer effect. The pulsation, visible tumor etc., previously unrecognizable, appeared presumably with the weakening of the vessel wall and the resolution of the peri-aortitis and mediastinitis which had caused the fixation and supported the vessel.

7 Provocative procedures may be dangerous in mediastinal conditions.

8. Treatment seldom produces much visible change in aneurysms. Occasionally, however they may resolve completely

Therapeutic Shock and Paradox as Illustrated by Case Records, in Aneurysm.—The degree of responsibility of therapeutic shock and paradox for serious or fatal outcomes in the treatment of the syphilitic heart is still somewhat a matter of guesswork, owing to the nonvisibility of the lesion. In the case of aneurysm however in the days of our earlier mistakes, we watched

Fig. 713.

NO PULSATION FLUOROSCOPICALLY. ANEURYSM VERSUS SUBSTERNAL GOITER. DEATH FOLLOWING FIRST ARSPHENAMIN INJECTION. NECROPSY SHOWED INNOMINATE ANEURYSM

Banker aged sixty-two years, married.

Examined 6/19/1917

Chief Complaint. Tabes and right subclavian aneurysm.

Chancre and Secondaries thirty-eight years before.

Substernal Pain and Bruit Over Sternum six years before. Diagnosed aneurysm. Right arm swelled up.

Tabes Diagnosed and Treated three years before. T courses of four and three weeks treatment each.

Present Symptoms. Precordial and substernal pain, lost voice on tipping head back.
- Sense of pressure in throat.
- Right arm still swollen.
- Pains in legs and other lower cord signs of tabes.

Physical Examination (Pollock)
- Slight ptosis of the right eyelid.
- Palpable thickening of right supraclavicular region, like lymphangitis.
- Superficial veins of upper chest marked, especially right.
- Suprasternal pulsation, no tracheal tug.
- Central dulness of upper sternum, with bruit.
- A_2 very sharp. Pulses synchronous.
- Heart enlarged to the left.
- Blood-pressure, right 190/120; left 170/120.
- Reflexes delayed.

Blood Wassermann Reaction Negative.

X-Ray of Chest. Large mediastinal shadow most marked on right. Arch either dilated or pushed over by mass. Fluoroscopic to differentiate aneurysm or substernal goiter; suspicious for latter.

Fluoroscopic Examination (Carman): "Can't see pulsation, right side mass, but must be aneurysm.

Sent for Antisyphilitic Treatment. Arsphenamin 0.2 gm. (he had had it three years before without incident).

Nausea, loss of appetite, malaise. Five days later he developed
- Stertorous breathing.
- Marked substernal pain.
- Marked hoarseness.
- Signs of pulmonary congestion.

Died two days later with signs of cardiac failure.

Necropsy: Anterior mediastinal tissues fatty and hyperemic. Fibrinous pericarditis. Large mass tumor-like 9 by 15 cm. upper anterior mediastinum. Sternal end of clavicle eroded. Esophagus and trachea pushed aside 5 cm. Left subclavian and carotid arteries pass along the left side, right subclavian and right common carotid emerged from it. Aneurysm of innominate, aortic arch pushed below and to the left of the mass. Many small aneurysmal pockets in the aortic wall.

The aneurysm eroded the anterior wall of the trachea, opening 1 cm. in diameter. The sac contained laminated pinkish-yellow clot, with central core of postmortem clot.

Discussion

1. It is apparent that an innominate aneurysm with clot fixation may closely simulate mass, such as substernal goiter. The previous diagnosis of aneurysm by competent internist was probably of some assistance. This clot fixation probably explains the absence of fluoroscopic pulsation.

2. At necropsy the mediastinitis and perivasculitis could be recognized. They were probably accentuated by Herxheimer reaction in the tissues following the arsphenamin.

3. This patient was treated several years before growing experience had taught us the value of mercury and iodid preparation. He had, of course, enough other pathologic changes to have caused his death, including the pericarditis which escaped clinical recognition and thrombus almost occluding the openings of the right common carotid and subclavian arteries.

4. At th age of sixty-two, iodid by mouth and few injections of mercury succinimid followed by mercury by mouth would probably have given this patient all the outlook possible under the circumstances, even had he not had the pericarditis.

with dismay and deep concern the rapid physical change for the worse with enlargement of the lesion that took place following the too-early too-intensive, or otherwise injudicious use of the arsphenamines. Figures 712 and 713 are strikingly illustrative of this complication.

Syphilis vs. Heart—Which to Treat First.—Still another group of problems vexing alike to internist and syphilologist during past years has been that of the relative importance, from the therapeutic standpoint, of the patient's syphilitic infection as compared with the state of his heart and vessels as a circulatory mechanism There are still two distinct groups in opinion on this matter Some observers, such as Wile take decompensation prior to treatment or at the time of beginning treatment as the dividing line in reaching the decision whether to initiate treatment for syphilis at once or to defer it. Wile (American Heart Symposium) especially if the patient has had previous thorough treatment, contends that the heart decompensating under such conditions is to be looked upon merely as a malfunctioning physical mechanism While this position seems eminently reasonable with the previous treatment provision inserted we believe it is too readily extended or altogether disregarded. The disposition of a number of clinicians is to claim the heart as a heart and to disregard its owner who has syphilis. The general rule that syphilis should be thought of as affecting unfavorably the structure and function of any organ once involved in which the process cannot be proved to be extinct, should be thought of in dealing with the decompensated syphilitic heart. Treatment for the two conditions, structural disease, and damaged function should go forward together the patient being placed at rest and digitalized, and otherwise, as will be presently described, treated as a heart case while the treatment for syphilis is cautiously initiated in accordance with the indications. Figure 720 dealing with the failure of cardiological methods until syphilological treatment was begun, is in effect a case report in support of this contention It is probably quite as often necessary to remind the practitioner and the syphilologist that the syphilitic patient with a heart complication and a positive serologic reaction must be managed as a heart case, as to remind the cardiologist and internist of the obverse of the situation.

The Preventive Value of Effective Modern Treatment in Early Syphilis.—We have seen that there is, in the course of early syphilis under treatment, a certain element of inevitability represented by perhaps ½ per cent of cases, in the incidence of cardiovascular involvement, regardless of the thoroughness of the treatment procedure. Fortunately the evidence collected by Moore and Kemp, by Moore Danglade and Reisinger by the Cooperative Clinical Group (1936) by Kemp and Cochems (1937) (Fig 715) and by Thompson, Comeau and White (1939) puts the matter in an even more encouraging light, and clearly demonstrates that what happens to the heart and aorta with respect to syphilis in the late years of the disease is the direct preventive responsibility of physician and patient in the period of primary and secondary manifestations Adequate treatment early can totally prevent cardiovascular manifestations late

The two first-named groups showed that of patients receiving from one to eight injections of an arsphenamine product, mercury being used not at all or less than one month, 9.0 per cent developed aortic lesions. Of the patients receiving one or two courses of arsphenamine with interim mercurialization, 5.0 per cent developed aortic lesions; while of 117 patients who had received three or more courses of arsphenamine and treatment with a heavy-metal preparation during the interim, not single one developed cardiovascular syphilis.

The Cooperative Clinical Group results are summarized in graphic form in Fig. 714

Kemp and Cochems very convincing demonstration is tabularly summarized from larger table in Fig. 715.

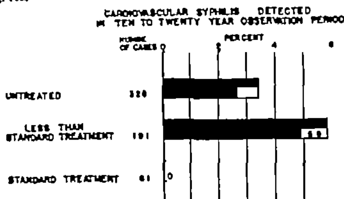

Fig. 714.—Probability of developing cardiovascular syphilis in treated and untreated syphilis. From Vonderlehr and Usilton, Ven. Dis. Inform. 19 396, 1938.

Thompson, Cesseu and White in fifteen to twenty-five year material showed though less clearly than the above studies, decline in cardiovascular syphilis with improvement in the intensity of what was at best only fair early treatment.

The Therapeutic Approach to Cardiovascular Syphilis.—As in all aspects of late syphilis, but perhaps more conspicuously in this field than in any other

Fig. 715.

EFFECT OF THE TREATMENT OF EARLY SYPHILIS ON THE INCIDENCE OF CARDIOVASCULAR SYPHILIS*

Amount of early treatment	Number of patients	Percentage with cardiovascular syphilis
None or very little	90	10 5
Inadequate	81	7 4
Adequate	240	0 4

After Kemp and Cochems Am. J Syph., Gonor. & Ven. Dis. 21 625, 1937

because of the sudden disaster that may punish a mistake or omission, the thoroughgoing appraisal of the patient is the first step to rational management. This appraisal should be sweeping and include all the patient s condition and resources, mental, physical, and material. A review of the situation by a cardiologist or a heart center is valuable and in many cases indispensable Certain of these considerations are discussed under special problems.

The basic physical matter for first consideration, both in the compensated and decompensated patient, is the state of the coronary and myocardial mechanisms. These, more than any other structures, limit the choice of treat ment agents and influence the prognosis. In estimating the myocardial situa

tion electrocardiographic studies are essential in addition to the experienced appraisal of the functional capacity of the heart muscle and the general state of the circulation. The gravity of inverted T waves in Lead I and of markedly aberrant QRS complexes should not be underestimated or evaded, and the risk of throwing such patients into serious condition by the use of an arsphenamine without prolonged preparation if not the desirability of its entire

Fig. 716.

EARLY ANGINA PECTORIS IN A YOUNG MAN WITH UNRECOGNIZED SYPHILIS. IMPROVEMENT UNDER TREATMENT ARREST OF THE PROCESS SHOWN BY SIX YEARS OF OBSERVATION

Machinist, aged twenty-nine years, married.

Examined 4/3/1917
Chief Complaint Gastric distress.
Heart-burn followed by exhaustion.
Pain in stomach runs into back and arms, especially left arm. Influenced by exertion.
History of Gonorrhea five years before.
N History of Syphilis.
Blood Wassermann Reaction Positive.
Positive on repetition.
Examination Moderate left ventricular hypertroph heart otherwise negative.
Blood-pressure 150/100.
Repeated, 132/80.
Nervous system *negative*.
x-Ray of chest, calcified area right upper
Electrocardiogram Rate 80 left ventricular hypertrophy
Consultant's Diagnosis *True angina pectoris* At his age probably syphilitic (W A. Plummer)
Treatment Begun Five injections neoarsphenamin, mercury succinimid intramuscularly inunctions.
Very Much Improved Only three attacks since treatment began. Weakness and dyspnea improved.
Septic Tonsils Removed.
Second Course of Treatment Very much stronger almost no distress on exertion.

Two More Courses Arsphenamin and Mercury 100 inunctions, 24 injections succinimid to date.
Blood Wassermann Reaction Fluctuates.
Spinal Fluid: Normal at first, developed a slight pleocytosis (10) year after treatment was begun. This as reduced to *normal and remained* so after 4 Swift Ellis treatments.
Arsphenamin Treatment Continued to 26 Injections.
Can Still Bring on Slight Attack by Exertion, but, on the whole, scarcely any disability
Repeated Cardiovascular Examinations have shown transient aortic murmur hich finally disappeared, leaving only the tambour second sound. Electrocardiogram negative.
The Patient Enthusiastic over the effect of mercury succinimid and sodium iodid intravenously which made him *feel* better than anything he had ever had. Wassermann permanently negative.
Total Treatment: Twenty-six arsphenamin injections, 100 injections mercury succinimid, 290, 30 *gr Hg* inunctions and 780 *gm.* sodium iodid intravenously Period of observation six years.

DISCUSSION

1 In sense the consultant took "long shot" t the diagnosis, but subsequent progress under treatment seems to support him. The improvement well advanced before the septic tonsils were removed.

2. This kind of therapeutic test is life insurance and is much more frequently justified than it is applied. With syphilitic background, or strong presumption, it is justifiable to treat an exceedingly early lesion such as this on suspicion.

exclusion from the treatment, must be most carefully weighed Personally we have tended to set down a high grade of myocardial involvement as a positive contraindication to the arsphenamines

Patients with syphilitic cardiovascular disease who present anginoid symptoms (see Fig 698) are coming to be accepted by an increasing number of observers as Schlesinger points out, and we have ourselves felt, as disqualified

for the arsenicals unless the most prolonged and painstaking preparation convincingly demonstrates both the reality and the permanence of their improvement. These statements apply full force to the later case and older patient. Undoubtedly there are exceptions in the case of younger patients with comparatively unimpaired cardiac and general physical reserves, as, for example in Fig. 716 but such occasional brilliant results do not offset the patient whose rapid relief of pain and spectacular improvement following the immediate employment of the arsphenamines may in six months or a year when the connection with his prematurely intensive therapy has been forgotten, pay the price in a rapidly failing heart and death from a therapeutic miracle. The return of the angina, the resort to surgery the increasing invalidism and eventual cardiac failure are still too familiar If the arsenicals are used at all in coronary cases, it must be in the minute doses appropriate to the worst and greatest rather than the least and most optimistic estimate of the damage already present, for necropsy repeatedly discloses in such patients a degree of involvement of the coronary orifices and obliteration of the vessels out of all proportion to the symptomatology during life.

The first breach of compensation is so serious as a warning of early fatal outcome that it must be accepted as indicating the most conservative procedure, and an avoidance of bismuth and the arsenicals at least at the outset. As the toxicity for the heart and general reaction-producing tendencies of newer drugs and agents, arsenical or otherwise decreases, this dictum may be modified.

Age while by no means infallible as a criterion, furnishes valuable clues to what may be expected in the form of resources and stamina under treatment. The patient who finally in his fifties, goes to the wall with a decompensated syphilitic heart, has very little recuperative power Much less can be expected of him in the way of treatment response than of the younger patient whose aortic murmur and evidence of syphilis are discovered while his heart muscle is still perhaps far from exhausted.

Appraisal of Treatment Tolerance.—It is extremely important, as Moore, Danglade, and Reisinger among others, have recently emphasized, to avoid all reaction to treatment in dealing with the syphilitic cardiovascular system. For this reason, all the considerations discussed in our chapters on reactions and complications and collateral factors, must be brought to bear. The patient in whose cardiac syndrome there is a marked element of renal insufficiency will tolerate a properly selected arsenical *in small doses better than mercury* or perhaps even bismuth. In hypertension the arsenicals in our experience are distinctly better tolerated than mercury and in some cases seem to produce, as in Fig 717 a definite if transient fall in blood pressure. In the earliest cases of aortic disease which we have dealt with a definite rise in blood pressure seems to occur between the first examination, in which no physical sign or only a systolic murmur was apparent, and the later examinations, after treatment, in which the process was supposedly showing healing sclerosis and had become stationary (Fig 719) In patients who present a coincidence of cardiovascular and visceral lesions as in hepatitis, the indications for the avoidance of treatment complications are much the same for both.

Coincident Cardiovascular and Neurosyphilis, as a Factor in Treatment.—In general we believe it is wisest to take the stand in a treatment appraisal, that the indications for the treatment of the cardiovascular phase of this combination should rule the decision.

Fig. 717

FLUOROSCOPIC DETECTION OF ANEURYSM IN THE ABSENCE OF OTHER SIGNS THAN THOSE OF HYPERTENSION (LATER AORTITIS) TEMPORARY REDUCTION OF BLOOD-PRESSURE UNDER TREATMENT FOR SYPHILIS. EXCEPTIONALLY LONG LIFE.

Housewife, aged fifty-eight years.

Examined 3/25/21

Chief Complaint: Debility rapid aging. Nervously distraught.

Marital History One miscarriage, two healthy children.

Swelling of Sternal End of Right Clavicle at age of thirty-two years. Supposed dislocation.

Seen by a Surgeon, Who, Without Comment, Gave Her Liquid Medicine to Take.

Examination: Heart enlarged to left.

Apex heaving Slight systolic blow at apex, not transmitted. Also heart at aortic area.

Aortic second accentuated.

Bony swelling right sternoclavicular juncture—Osteoma (?).

Blood-pressure 200/104. Repeated 198/100.

Nose and throat negative.

Urine negative.

Blood Wassermann Reaction Strongly positive. Evidently surprise.

Repeated, same result.

-Ray Clavicl negative.

N x-Ray Examination of th Chest at This Time.

Diagnosis, Syphilis. Essential hypertension. Slight anemia.

Treatment Begun Rest in bed, inunctions and potassium iodid 30 grains three times daily

Blood-pressure after third week in bed. 140/90

Neoarsphenamine Begun: 0.1 to 0.4 gm.

Blood-pressure after fourth week in bed. 120/78.

Up and Around. Four neoarsphenamine injections, mercury rubs, and iodid so far

Blood-pressure 130/88. (Patient up.)

Home on 40 inunctions.

Blood Wassermann Reaction still strongly positive.

Returns after five months for course of mercury succinimid and sodium iodid intravenously

Blood-pressure 168/96. Slight arrhythmia.

Re-examined After Another Seven Months with very little treatment.

Blood-pressure 168/90

Cardiac dulness 4.5 cm. by 13 cm.

No arrhythmia.

To-and-fro murmurs aortic area.

Capillary and Corrigan pulse.

Electrocardiogram: Diphasic T Derivation III. Right ventricular preponderance nodal premature contractions. Notched P wave in Derivation II.

Sent for x-Ray of Chest as part of the routine special cardiovascular examination.

Report: Aneurysm of the Aortic Arch.

Discussion

1. Observe that the surgeon who examined her in the pre-Wassermann days of clinical syphilology apparently made a diagnosis of sternoclavicular gumma and gave iodid. The first thought of her present examiner was anything but syphilis—osteoma.

2. This patient' aneurysm passed unrecognized by physical signs, through the entire period of her observation. She was closely studied by consultants, so that the lack of signs was not due to lack of skilled attention or to oversight.

3. Only the routine fluoroscopic x-ray examinations of the chest as part of the special cardiovascular examination by Willius revealed the aneurysmal lesion. There as no hoarseness, no pain, no significant dyspnea, and, of course none of the physical signs. \ comparison between the blood-pressure in the two arms had been made however

4 Note the ery striking course of the blood-pressure in this patient.

5 This patient lived fifteen years after the recognition of her aneurysm, in good health, life of exceptional though well balanced activity A moderate amount of bismuth and sulpharsphenamine in the earlier years was followed by annual courses of iodid. Only in the last year of her life did even slight signs of cardiac failure ppear She died suddenly age seventy-three cause not identified. Her blood pressure for a decade had been 220/115.

Fig. 718.

THE CLINICAL PICTURE OF SUBCLAVIAN ANEURYSM

This sketch is a composite of 2 almost identical cases, but neither completely examined. Both patients were men, and thirty-six and forty-one years respectively. The former is designated as "A," the latter as "B."

Chief Complaint: "B" "muscular rheumatism" left arm and shoulder. "A" pain in chest and "funny feeling" in neck.

"A" pain is brought on by any exertion.

"B" pain is almost constant, or lasts for days, originating at the upper edge of the scapula and running down the arm.

"A" feels as if he had something in his throat all the time. He is very short of breath on exertion.

"B" is less affected.

Physical Examination

"A" has heart out to the axillary line. There is a thrill on both sides of the neck much more marked on the left above the clavicle. There is likewise a bruit at the second left interspace. Pulse said to be equal both sides, but on measuring the blood-pressure it reads: Right 148/63, left 165/83.

"B" no heart measurements. Pulsating prominence, left neck. Dulness upper left chest. Double murmur at all points. Engorgement veins upper chest, shoulder and arms. Slight exophthalmos, left pupil pin-point, but still reacts to light, right normal in size and reaction.

Blood-pressure 125/50.

Blood Wassermann Reaction: "A" positive, "B" negative.

X-Ray of Neck and Chest: "A" none. "B" trachea slightly displaced to right, no apparent cause.

Treatment: "A" did not improve under arsphenamin and mercury—in fact, became weaker and felt worse. "B," on the other hand, became much better and his signs receded to the point where only an aortitis with regurgitation could be recognized two years later. At that time his electrocardiogram showed no signs of myocardial degeneration.

Both Cases Were Diagnosed as Left Subclavian Aneurysm, But "A" From His Symptoms, Had the Spasmodic Pain of Coronary Sclerosis and Other Signs of Myocarditis. "B," on the Other Hand, Had the Steady Aching Pain of Aneurysm and Almost No Evidence of Myocarditis.

"A" failed under treatment, and "B" recovered almost entirely.

Discussion

1. These two cases make a valuable comparison, for between them most of the signs of left subclavian aneurysm appear accompanied in the one case ("A") with the extreme precordial pain and marked dyspnea on exertion which is the symptomatic suggestion of myocardial insufficiency. Note the pulsation, thrill, and bruit in the left cervical and supraclavicular regions, the signs of aortic insufficiency in "B," the pinhead spastic pupil from paralysis of the cervical sympathetic on the left, the unequal blood-pressure in the two arms (not characteristic of the subclavian aneurysm alone however). Note that the x-ray does not disclose the aneurysm, but shows displacement of the trachea. Without the physical signs, substernal goiter might be thought of. Note also that the blood Wassermann reaction in "A" is positive, in "B" negative, though "B" recovered under treatment.

2. The contrast in the reaction to treatment seems to bear out other cases here presented in showing that the outlook in late syphilis of the cardiovascular system, and especially of the heart and aorta, is dependent to no small extent on the condition of the coronaries and the myocardium. If marked signs of myocardial damage, especially long-standing angina pectoris or precordial distress coupled with electrocardiographic signs such as T wave negativity in Leads I, II, or both, and aberrant QRS complexes are present, treatment accomplishes comparatively little except temporary relief of aneurysmal symptoms. If begun too precipitately much damage and even a fatal outcome may be the result. On the other hand, aneurysms seen fairly early with marked mediastinitis but sound myocardium, seem to tolerate treatment much better and achieve often quite striking results.

Moore, Danglade, and Reisinger give a vivid illustration of the critical problem that conjunction of paresis and cardiovascular syphilis may present in the person of patient with cardiovascular syphilis who was brought to the point, by cardiovascular management, at which he could undergo malarial inoculation, only to have the chills stopped as his cardiorenal mechanism began to fail and then, following further careful nursing, to have the malarial siege renewed with ultimate remission of the paresis.

Fig. 719

EARLY DIAGNOSIS OF AORTIC SYPHILIS CONFIRMED BY SUBSEQUENT OBSERVATION. ACCENTUATION OF SIGNS UNDER TREATMENT WITH PROGRESSION OF LESION. IMPORTANCE OF CARDIOVASCULAR STUDY IN THE FIXED POSITIVE BLOOD WASSERMANN CASE

Business man, aged forty-five years, married.

Examined August 21 1919.

Chief Complaint Stomach trouble. Vomiting after meals, emaciation. Five months duration.

N History of Syphilis; several ttacks of gonorrhea. Wif and three children well.

Left Testicle Removed for "Sarcoma year before present examination.

General Examination N gative including -ray of the stomach. Blood-pressure 118/70, heart negative. Achlorhydria.

Blood Wassermann Reaction: Strongly positive, repeatedly

Consultant Note "Stomach and testicle both syphilitic (?)

Treatment: Six injections arsphenamin, 15 mercury succinimid, 35 inunctions.

Spinal Fluid Negative.

Wif 's Blood Wassermann Reaction Strongly positive.

Children Three, one with peripheral choroiditis, Wassermann reaction negative on the blood.

On Return for Observation After Above Treatment, Greatly Improved, But Blood Wassermann Reaction Still Strong Positive

Because of This Blood Finding he was sent for special cardiovascular study by Willius.

Cardiovascular Examination (Willius) No cardiovascular symptoms.

Heart 4 by 9.5 cm. N arhythmia.

Second sound at base accentuated, especially t the aortic area where the sound accentuation is lmost rasping in character This suggests rigidity of the aorta indicative of peri-aortitis. N murmurs heard.

Blood-pressure 130/76. Pulse 60.

-Ray of chest negative.

Electrocardiogram Rate 53, sinus bradycardia, left ventricular preponderance.

Diagnosis Probably early peri-aortitis, syphilitic.

Treatment: Second course of 6 arsphenamin injections, 20 mercury succinimid, 36 inunctions.

Cardiovascular Re-examination: Nine months after the above. No complaints or change in symptoms. Blood-pressure 138/72. *Diagnosis* peri-aortitis.

Blood Wassermann Reaction: Still strongly positive.

Treatment: Third course of 6 injections of arsphenamin, 18 mercury succinimid; 24 injections mercury salicylate at home

Returned After Three Years' Absence Felt in best of health and condition. N complaint

Cardiovascular Re-examination (Willius) N complaints. *Heart dulness* 4 by 10 cm. N arhythmia. *Systolic murmur* t aortic area. *Diastolic blow* also heard with point of maximal intensity to left of midsternum.

Capillary and water-hammer pulse.

Blood-pressure 162/80, pulse 60.

Electrocardiogram: Rate 60 Sinus bradycardia. Inverted P wave III, Inverted T wave III, left ventricular preponderance.

Diagnosis Syphilitic aortitis and aortic regurgitation.

Fig 719 (*Continued*)

DISCUSSION

1 Note that at the time this patient presented himself he showed no sign, and has never made any complaint which would serve to identify the most serious aspect of his medical condition. Note that his wif had positive blood Wassermann reaction. Note that though the children's blood Wassermanns were negative one of them had peripheral chorioiditis.

2. The investigation of the patient' cardiovascular system was inspired by the fact that he had resistant positive blood Wassermann reaction. His chief complaint of stomach trouble, associated in this case with an achlorhydria and not with neurosyphilis, was promptly relieved by treatment.

3. The examination of the cardiovascular system disclosed an accentuated aortic second sound almost rasping in character interpreted as suggestive of rigidity due to peri-aortitis.

4. This cardiovascular examination was made after the patient had been under treatment six months. Does it then represent the progress of lesion not previously detectable, in spite of treatment, or sclerosis of the aorta either as result of involution of peri-aortitis or from the toxic action of the medication?

5 Of these possibilities it seems to me the more probable that we are dealing with sclerosis associated with healing, rather than lesion newly developed in spite of treatment.

6. During subsequent nine months, while the patient was under fficient treatment, the lesion showed no progress.

7 It was not until after three years of practical lapse from treatment, with the intervention of mercurial of low efficiency and cumulative toxic effect, that the process had dvanced to the point where the original diagnosis by Willius was confirmed by incontestable signs.

8. Note the course of the blood-pressure in this patient. At the outset it was 118/70. After six months of treatment had produced presumably some healing sclerosis, 130/78. After second course of treatment, 138/78. After three years absence, with the development of full aortic regurgitation, 160/80. This rise in blood-pressure during the treatment of an early aortic lesion has been apparent in some of our other cases. If the disease is arrested it becomes stationary In this case it progressed.

9 Are we to assume then that this case progressed because of or in spite of treatment? It is impossible to give categoric answer that will make the mechanism luminously clear t this stage of our knowledge. My personal hypothesis is that the lesion progressed in part because treatment was not carried far enough, and paradoxically because it was carried too far The progressive arteriosclerosis which this patient presents was first increased by the rigidity induced by healing fibrosis. The lesion then became stationary for time. But as soon as more intensive treatment was stopped, it resumed its progress. The slow action of mercury hich with an insoluble salt must have been prolonged through good deal of the period of lapse, may have contributed to the sclerosis. W forget too easily that mercury as well as arsphenamin is poison to the vascular system.

10. From the standpoint of the general diagnosis of syphilis note this patient's surgical history and the fate of probable gumma of the testis diagnosed sarcoma."

While such an example represents expert management at its best and while we have already reviewed the Continental opinions as to the relative benignity of cardiovascular syphilis in the presence of neurosyphilis, the treatment decisions and procedure involved certainly require more than ordinary judgment. Wagner-Jauregg maintains that cardiovascular syphilis tolerates pyrexial therapy well and while Jagic and Spengler take the same stand, our limited experience has not been so encouraging. Cardiovascular collapse is a grave risk to invoke if a method which avoids it is available, and the most disconcerting and, one might almost say unpardonable deaths which we have observed under fever therapy have seemed to be chargeable to cardiovascular complications. Tryparsamide therefore at least deserves first consideration

(Moore *et al* were prevented from using it in their case by the presence of optic atrophy) Wile (1941) has apparently found tryparsamide itself "singularly beneficial" in certain cases of early syphilitic aortitis and early aortic dilatation. We have also found the amount of arsenical and heavy metal constituting preparatory treatment in many cases of symptomatic neurosyphilis before pyrexia or tryparsamide, sufficient to improve markedly the cardiovascular lesion and status. It is well to remember in patients with marked cerebral arteriosclerosis, the great uncertainties intrinsically attendant on prognosis and to make no promises as to treatment results.

Arrest *versus* Palliation.—It is to be feared that reaction against the use of intensive treatment and particularly of the arsenicals in the treatment of cardiovascular syphilis will needlessly deprive younger patients with a favorable background of their outlook for complete arrest by an overcautious tendency to use the symptomatic approach essential in cardiac "wrecks. Figure 719 illustrates a situation of this kind which we feel would be duplicated in any extended review of the application of minimal treatment to cardiovascular syphilis. One way to meet the necessity for moderate intensity just as in the case of irregular and desultory treatment in early syphilis, is by prolongation and continuity In the effort to secure lasting results and genuine arrest in cardiovascular syphilis, nothing less than continuous treatment, practically without rest intervals, over a period of years, should be considered. In all such prolongation of treatment, danger of cumulative effects from the use of insoluble salts must be borne in mind and it is this which gives the better-absorbed bismuth preparations and the low-dosage arsphenamines their genuine advantage

In prolongation of treatment also, even with the minimal intensity of mercurial inunctions and iodides, lies the best hope for palliation in the cardiac wreck, so that the decision between an aim for arrest and one for palliation is primarily one of selection of drugs and dosage in the light of the patient's probable tolerance and potential reaction background.

Selection and Technic of Treatment.—While it is a safe general statement that the arsphenamines (except in very small doses or as bismuth arsphenamine sulphonate) should not be used at the outset in cardiovascular syphilis, it is not wise to underestimate the value of the arsphenamine phase in the treatment of cardiovascular syphilis. Reid observed in a series of cases that the life expectancy of patients who had had arsphenamine appeared to be longer than that of those who had had mercury alone. Conybeare in a small but well-controlled series of 23 patients with aneurysm 11 of whom were treated with neoarsphenamine and 12 observed as controls, found that even though the amount of the drug used was small in all but two of the cases (1 to 8 injections) seven were still living and four able to do heavy work over an average of forty months from the onset of symptoms while of the untreated patients, only four were living with an average duration of life of forty-five months and eight were dead in an average period of ten months. Kothny and Müller Deham employed neoarsphenamine intravenously in ascending doses of 0 05 0 1 0 15 0 2 and so forth every five days to a week until from eight to twelve doses had been given. The symptomatic results were satisfactory but no returns in terms of mortality were given. The majority of the systems from which the present consensus has developed combined the neoarsphenamine therapy with heavy metal, usually mercury Thus Schottmüller has advocated in spirited fashion a higher individual and total dosage (0.5 to 0 6

Gm neoarsphenamine) with numerous case reports but no satisfactory mortality statistics. Cotton treated 55 patients most of them with aortic regurgitation, with courses of neoarsphenamine and mercury reserving 55 untreated patients as controls and finding that the mortality in the treated patients was 25 per cent, that in the untreated patients, 34 per cent, over a five-year period. Herrmann and Jamison employed a neoarsphenamine dosage scale similar to the Kothny Müller Deham system with alternating courses of mercury iodide and bismuth totalling three courses of neoarsphenamine of 3 0 Gm. each. Their results, as analyzed by Moore, Danglade, and Reisinger indicate that of 40 patients who received little or no treatment the mortality was 70 per cent while of 58 patients who received a moderate amount of treatment, the mortality was 55 per cent.

The two most serviceable expositions of results produced by combined treatment with neoarsphenamine and a heavy metal now extant are those of Hines and Carr and the frequently cited results of Moore, Danglade, and Reisinger The former employing neoarsphenamine in doses of 0 1 to 0 45 Gm., the second dose being 0.3 Gm the neoarsphenamine injections weekly for eight to twelve weeks, the heavy-metal course weekly for six to eight weeks, the total period of treatment one year when patients could be induced to follow it, led to the following results. Symptomatic improvement due to neoarsphenamine as such, in the opinion of the authors, occurred in 57 per cent of the cases. Twelve per cent showed aggravation of symptoms. Temporary clinical improvement occurred in 72 per cent of simple aortitis, 41 per cent of aneurysm, and 40 per cent of aortitis with regurgitation. Pain and dyspnea and palpitation were relieved or improved in about one half of the cases. Moore, Danglade, and Reisinger studied 105 patients of whom one third (57) died, 13 of other causes than cardiovascular syphilis, using a method of treatment beginning with a bismuth preparation (0 1 Gm.) every four or five days with iodide 1.3 Gm. to 1.4 Gm. three times a day for ten to twelve weeks. If a satisfactory degree of cardiac reserve was established, neoarsphenamine was given intravenously in doses of 0 05 to 0 1 Gm. initial and 0.3 Gm. final dose with a course of 10 to 12 injections. These two types of courses alternate throughout a period of two years continuous treatment. The results achieved were as follows In 57 patients with aortic regurgitation who received little or no treatment, the mortality was 91 per cent as compared with a mortality in the well-treated patients of only 16 per cent. The average duration of life in poorly treated patients was thirty months, in the well treated patients, seventy-one months. In the case of aortic aneurysm, the mortality during the period of observation for poorly treated patients was 90 per cent, for well-treated patients, 40 per cent, and the average duration of life for the poorly treated patients, nineteen months as compared with seventy five months for the well-treated patients.

It should be emphasized that in the principal series here described adequate treatment of the heart from the cardiologic standpoint was carried on in conjunction with the antisyphilitic treatment, both in the test series and the controls.

From the theoretical considerations now familiar to us plus the methods described in these reports, neoarsphenamine has been accepted as the drug of choice. The dosage range lies between an initial dose of 0 05 and 0 1 Gm. with a maximum of 0.3 to 0 45 Gm. The advent of mapharsen is still too recent for its evaluation, but its nonreactive record in itself would seem to recom-

mend it in a condition where treatment reaction has such bad effects. Appel (1937) reports favorably on its use, which is steadily on the increase in clinical practice. The initial dose should not exceed 10 milligrams, the maximum 30 milligrams (Moore, Howles) In rare and exceptionally tolerant instances the dose of 0 06 Gm. may be reached. In all but the earliest and most uncomplicated cases of aortitis it is advisable to use a preparatory course of a heavy metal ranging from six to twelve weeks. If mercury is employed, the succinimide ⅙ grain (0 01 Gm) to ¼ grain (0 016 Gm.) may be given three or four times a week for a series of twenty to thirty injections. If bismuth is employed at the outset, we believe it wisest to give not more than 0 025 Gm. of a preparation averaging 50 to 60 per cent metallic bismuth for the first half dozen injections, using intervals of four to six days. Insoluble bismuth salts should be given at four to seven-day intervals after the average dose of 0 1 to 0.2 Gm of the drug is attained The water-soluble sodium bismuth tartrate twice a week often acts very well at one half the adult maximum dose. Small doses of bismuth (one third to one half adult dose at the maximum) can be given intramuscularly simultaneously with the intravenous arsphenamine to any patient who can tolerate the described dosage of neoarsphenamine alone. It is essential to carry treatment in alternating courses through from eighteen months to two years.

Bismuth Arsphenamine Sulphonate.—The favorable impressions produced by this drug on Stokes, Miller and Beerman, have been confirmed tentatively by Moore, Reinnger and Danglade. It should be given in an unbroken series of from 40 to 80 intramuscular injections, the first 10 of which are at three- to five-day intervals, the later injections five to seven days. The initial dose is 0 025 Gm intramuscularly increasing gradually to 0 1 Gm. in 10 to 20 injections. The remaining injections are increased quickly to the full adult dose of 0.2 Gm., which is then continued throughout the remainder of the series. There seems to be no limit to the tolerance of the drug in all but occasional patients, and the tonic effect is marked.

Beerman, Shaffer and Livingood (1942) in fourteen year follow-up study of the patients in Stokes, Miller and Beerman group as well as 70 additional patients, considered bismarsen as safe and effective drug for patients with cardiovascular syphilis.

Mercury in Cardiovascular Syphilis.—Mercury while it practically never gives rise to significant therapeutic shock effects, does not *ipso facto* constitute adequate treatment for early cardiovascular syphilis in which there is hope for arrest of the disease. Mercury by mouth in particular is only allowable in the late cardiovascular wreck whose myocardial and coronary involvement is such that nothing more effective can be tolerated or as interim rest treatment in patients receiving courses of more intensive treatment. Mercury by inunction is a satisfactory use of the drug either alone or as a preparation for later arsphenamine treatment. Among the disadvantages of mercury in cardiovascular disease must be included a certain amount of depressing and hemolytic effect, especially serious in anemic patients. The bed patient probably gets the best effect from it. Clinicians dealing with the heart too often forget that the inunction is a very slow method of putting a patient under antisyphilitic medication and that it scarcely begins to take effect in less than two or three weeks after it is begun. Accordingly some weeks or even months of inunctions may be needed for an adequate preparation for either bismuth

or the arsphenamines used intensively for curative effect. For this reason, particularly in the decompensated syphilitic heart, the use of a soluble mercurial salt intramuscularly is much more effective than the inunction. The insoluble salts of mercury given intramuscularly have lost ground since the advent of bismuth and need rarely be used.

The Iodides in Cardiovascular Syphilis.—In the treatment of cardiovascular syphilis the iodides deserve a high though in many respects an intangible place. They should be used invariably and from the outset in every case of actual syphilitic vascular disease They should not be used in treatment given as a therapeutic test for syphilis, for their action is too nonspecific. An exception to this rule may be made where the issue is between syphilis and malignancy when iodide may be used to hasten any favorable result on which a decision may depend. For a time we used the sodium salt, believing it less depressing to the heart, but since Osborne showed that the sodium ion is substituted for the potassium as the drug appears in the circulation, we have returned to the use of the potassium salt without observing any notable disadvantage. Stewart and Smith (1941) however have warned of the serious toxicity of potassium for the heart as shown by EKG studies which would seem to interdict large doses. If there is marked idiosyncrasy sodium iodide by mouth is the better tolerated The dosage should range, for prolonged constitutional effect, between 5 and 10 grains (0.33-0.66 Gm.) three times a day Where gastric irritability is a serious issue, the organic preparations siomine and lipoiodine may be used. There are no advantages that we have observed in giving sodium iodide intravenously to cardiovascular patients, and there is risk of overloading the circulation. In the general picture of cardiovascular-renal disease with hypertension, associated with syphilis, iodide is sovereign, and should often be used alone for some time before mercury or arsphenamine is considered. Intravenous sodium iodide appears to have no significant effect on peripheral arteriosclerotic gangrene associated with syphilis.

Technic of Therapeutic Test.—This is essentially identical with that for the treatment of the various types and grades of cardiovascular lesions, for above all no harm should be done in the attempt to reach a diagnosis. If there is a question whether the lesion is streptococcal, rheumatic, or syphilitic, it is conservative to employ only mercury and iodide for a considerable period, for arsphenamine shows definite evidence of some nonspecific effect on streptococcal lesions elsewhere in the body On the other hand, too intensive use of mercury may unfavorably affect a septic type of process. No attempt should be made in such cases to confuse the issue by removal of tonsils, administration of salicylates, and so forth, until the therapeutic test for syphilis has had a reasonable period of trial. This should be a minimum of six to eight weeks, and it should be recalled, too, that some transient exacerbation of symptoms may occupy part of this time. The time schedule of the action of a soluble mercurial salt may be inferred somewhat from Fig. 720 We know of no definite data on the rate of action of soluble bismuth salts (sodium bismuth tartrate, iodobismitol) which would be preferable, with proper caution in dosage, if there is renal embarrassment.

The Prognosis of Cardiovascular Syphilis—Life Expectancy—The improvement in life expectancy under modern methods of treatment has been touched upon in reviewing the advocated methods of procedure. The comparatively dreary outlook of the large proportion of cardiovascular cases without treatment or under ineffective methods may be inferred from the

earlier reports, and the improved prognosis under adequate treatment in the later ones (1933 onward)

Locke and Rea quote several authorities on the duration of life after the clinical recognition of aneurysm as ranging from twelve to thirty months. Reid also emphasized the relatively short duration of the symptoms before the death of the patients in his most recent series, in more than half the cases, less than eight and a half months. He quotes Emerson as finding that death usually follows within two years after the development of disabling symptoms. Scott found that the agreed average duration of life after the onset of symptoms in untreated patients with aortic regurgitation is only from one to two years. The average age of the patient with syphilitic cardiovascular disease at the time of death, according to Willius, ranges from forty-nine to fifty-four years, and the average duration of the disease in his series was from twenty-three to twenty-six years.

More recent figures clearly show increased life expectancy after adequate antisyphilitic treatment in cardiovascular syphilis. Grant (1935) concluded from a comparison of the survival periods in 82 cases treated with neoarsphenamine and mercury with those in 160 treated with iodide or with no antisyphilitic therapy observed for ten years, that specific treatment after discovery of cardiovascular syphilis definitely prolonged life. Over one third of his series survived the 10-year observational period, the death rate being 64 per cent which was no higher than in other forms of heart disease in his collection of 1000 cases. Padget and Moore (1935) in a study of 106 patients with aneurysm divided almost evenly between inadequately and adequately treated, observed for more than one year more than twice as many of the patients who were adequately treated survived this period of observation, and of those that died, their average life duration was nineteen months longer than in the inadequately treated group. This trend was even more apparent among 71 patients with syphilitic aortic regurgitation, also almost evenly divided as to adequate and inadequate treatment, among whom almost three times as many deaths occurred among the inadequately treated group as in the adequately treated patients. Cole and Usilton with colleagues of the CCG (1936) reported that of 102 patients with uncomplicated syphilitic aortitis who were inadequately treated (i. e., received less than 15 arsenical with interim heavy metal injections), 77 per cent were still living with an average duration of fifty-three months since detection of cardiovascular involvement, and 23 per cent were dead after an average life duration of forty-two months Of 165 patients who were adequately treated 89 per cent were still alive after an average duration of sixty-two months, and 11 per cent were dead after an average duration of seventy-seven months. Thus the authors conclude adequate treatment after detection of uncomplicated aortitis not only practically doubled the duration of life but lessened the frequency of cardiovascular syphilis as a cause of death. (7.9 per cent of deaths were considered to be due to the vascular lesion in the inadequately treated cases as compared with 2.4 per cent in the adequately treated group) Of 191 cases of aortic regurgitation observed for one year or longer the survival period was based on the totals in living and dead In the inadequately treated it was forty months and in the adequately treated fifty-five months, the authors concluded that adequate specific treatment of aortic regurgitation definitely prolongs life. In 59 cases of aneurysm observed for more than a year the average duration of life after detection of the lesion was thirty-seven months under inadequate treatment but seventy-five months under adequate therapy

Personally we have been impressed though by only a few cases, with the very good prognosis of simple aortitis with dilatation and aortic aneurysm, when recognized early A long life expectancy is possible where aneurysm is early recognized thoroughly treated at the outset, and not overtreated in the later years. So much depends however on invisible and intangible factors in the physical state of the heart and circulatory system and so much on the ability of the patient to follow an ideal cardiologic regimen, that genuine prognostication is practically impossible

Effect of Decompensation.—The unfavorable effect of breach of compensation on the prognosis of syphilitic cardiovascular disease is, of course, well known At least a part of the more favorable prognosis of aneurysm as compared with aortitis and aortic regurgitation rests here. Moore Danglade and Reisinger found that only 27 per cent of their patients with aneurysm

Fig 780.

DECOMPENSATION IN SYPHILITIC MYOCARDIAL DISEASE, AS INFLUENCED BY TREATMENT FOR SYPHILIS

Housewife, aged forty-two years, complains of loss of control right side, weakness, insomnia, very slow heart.

Examination Very sick patient, broken compensation, thyroid adenomas, mid-diastolic murmur markedly dilated heart, edema of legs and abdominal wall, fluid both bases.

Abstract of Notes. 1

Day 1 Tincture digitalis 8 c.c. by rectum.
2 Slightly better
3 Diagnosis Decompensated Chronic Mitral Endocarditis with Stenosis. Chronic Myocarditis with Auricular Fibrillation.
Digifolin 1 c.c. every three hours, doses.
Worse in afternoon; 800 c.c fluid withdrawn from right chest.
4 Feels better Digifolin 1 c.c. t. i. d. Aspiration left pleural cavity 800 c.c. withdrawn.
5 Still cyanotic. Crepitation right axilla and precordium.
Blood Wassermann Strongly Positive.
More restless. Heart rapid (160) Grating over precordium.
Patient found out of bed.
6 Digifolin 1 c. t. i. d. *hypodermic*.
Syphilologic Consultant Advises No Treatment for Syphilis Until Compensation Restored. Pupils irregular and sluggish.
7 More fluid right base, more distress, orthopnea.
8 Weaker, fluid accumulating Tincture digitalis 2 c.c. t. i. d.
Reconsideration. Antisyphilitic Treatment Begun. KI 10 to 30 gr t. i. d.
Right pleural cavity aspirated, 600 c.c.
9 Mercury Succinimid Intramuscularly ⅛ grain daily

Abstract of Notes. 2

Day 10 Heart fibrillating slowly Right chest filling up again.
Continued in very serious condition.
Vomited. Another course of digifolin.
Liver 4 cm. below costal margin.
11 Weaker could hardly breathe. Orthopnea.
12 Rested More Comfortably
13 Slight Improvement. Still Fluid in Chest, but Patient Could Lie Prone Most of the Time.
14 Looks Better. Fluid higher in chest.
Definitely improved.
15 Edema Decreased. No Edema of Legs, Pulse Volume Good. Patient more comfortable. (Succinimid daily Iodid daily Tincture digitalis 2 c.c. t. i. d. in three-day periods.)
18 Little increase in fluid.
20 General improvement.
21 Bradycardia, heart regular strong, rate 56.
23 Neurologic examination. Paralysis right arm now apparent.
24 Up in chair
27 Fourteen injections mercury succinimid to date. Iodid continuously since eighth day Improvement began third day after succinimid was begun.

DISCUSSION

1 Digitalis and digifolin, rest, morphin, aspiration of chest, and so forth, seem to have failed to produce any response in this patient until after the institution of mercurial therapy The digitalis preparations used were not chance lots and hence possibly worthless, but the stock preparation of a large cardiac service. The improvement began at about the time when the good effects of a soluble salt in a therapeutic test usually appear

2. While a result apparently as clearly traceable as this is unusual the treatment of decompensated syphilitic patients by mercury and iodid, or with bismuth, may well be begun as soon as the syphilis is recognized.

3. It is almost an axiom that syphilis, even though apparently only concomitant, and not causative affects unfavorably almost every type of disease or lesion. To treat it is, therefore, part of the treatment of the primary process, whatever it may be. In this case the valvular lesion was probably not primarily syphilitic.

had previously suffered from congestive failure at the time of admission, while 46 of those with aortic regurgitation had so suffered. They found that the appearance of cardiac failure before treatment is begun, shortens life on the average from six to fifteen months. It is not, however, a necessary barrier to the successful outcome of treatment. The incidence of cardiac failure in patients who had experienced it before treatment was twice as great during or after treatment (82 per cent) as in those who had never sustained a failure (40 per cent). The seriousness of the situation of the large body of patients, especially Negroes, who are under the necessity of earning a bare living by heavy manual labor can be imagined and in all probability Moore's figures read high because of the high proportion of this type of patient in the clientele of the Johns Hopkins Clinic. The outlook in private practice should be materially better.

Restoration to usefulness, take it all in all, and the regaining of the livableness of life mean almost as much as life itself to a proportion of cardiovascular patients. Conybeare, Schottmüller, Stokes, Miller and Beerman, and Moore, Danglade, and Reisinger have observed striking instances of restoration even to full physical working capacity. The last mentioned authors found that of their 56 surviving patients, 21 were symptom-free and still able to work and only 9 were entirely incapacitated. Twenty-eight of the 47 who could still work had been well treated for syphilis.

Relief of Symptoms.—Our experience with bismarsen has been mentioned in connection with that drug and represents optimum results. The results obtained by Hines and Carr with a neoarsphenamine-mercury regimen are mentioned in discussing systems of treatment. Moore *et al.* found the probability of symptomatic relief to be in direct proportion to the amount of treatment given. In aneurysm under inadequate treatment, half the patients obtained relief; under adequate treatment, nine tenths. In aortic regurgitation approximately 30 per cent obtained relief; of well treated patients, 85 per cent.

Special Problems—Management of Decompensation and Congestive Heart Failure.—We have already noted the seriousness of decompensation from the prognostic standpoint in syphilitic cardiovascular disease, and we have noted its greater frequency as described by Moore *et al.* in untreated and poorly treated cases, in comparison with those effectively treated. We have also pointed out the desirability of coincident treatment with a mercurial for the syphilis which underlies breach of compensation in a previously untreated patient. The first step in the control of this complication should be restricted activity and in the more serious cases, complete bed rest during the introductory phase of treatment. We have repeatedly observed, particularly in those cases which have reached the border line between simple aortitis and aortic regurgitation, that with anything approaching an attempt to push treatment for arrest, the patient passes through a phase of several weeks duration in which there may be slight edema of the ankles, slight dyspnea, definite increase in the size of the heart, accompanying the symptomatic Herxheimer-like increase of precordial stress. This obvious cardiac embarrassment is the probable forerunner of those instances of breach of compensation after treatment is started which have been observed by a number of authors and which rest, restricted activity and intelligent digitalization in the earliest stages of treatment might prevent. The edema and dyspnea particularly respond almost at once to small doses of the tincture of digitalis.

In therapeutic tests of early lesions in which rest might produce a false

improvement in symptoms with subsequent relapse, due allowances may have to be made, but in the later cases it is safer to conduct the therapeutic test under some restriction of activity even if the results are less promptly distinguishable.

Total Thyroidectomy in Angina Pectoris and Congestive Heart Failure.—Blumgart, Riseman, Davis and Berlin have undertaken with apparent success the total ablation of the thyroid as a last resort in congestive heart failure and angina pectoris. This procedure, carried out in 10 cases, acts through reduction of the basal metabolic rate. Beam's report (1941) and Parsons and Purks (1942) shows current experience to support its use in angina rather than heart failure. Long term follow-up at the University of Pennsylvania Hospital (Rose) is favorable.

Digitalization.—When congestive heart failure actually occurs, several observers, including Brooks, Carter and Baker and Moore, Danglade and Reisinger have observed that cardiovascular syphilis, especially in Negroes, seems to be more refractory to digitalis than other forms of cardiac failure. The last mentioned authors recommend the use of powdered digitalis in a dosage of from 0.1 to 0.2 Gm. daily even for use in ambulant patients with a low cardiac reserve over long periods of time. Carter and Baker have found patients refractory to doses of 0.4 to 0.6 Gm. up to a total of 4 or 5 Gm. In the patient (Fig. 720) illustrating the therapeutic effect of mercury in decompensation, there was no response to digitalis until antisyphilitic treatment was begun. Willius (1942) cautions against the routine or indiscriminate use of digitalis in coronary disease.

Diuresis in Syphilitic Cardiovascular and Hepatic Disease.—The newer mercurial diuretics, mercupurin, salyrgan (mersalyl) and novasurol (merbaphen) have proved quite effective in anasarca from cardiac decompensation and in ascites. Levitt and Levy (1940) rate them as more valuable than digitalis in syphilitic heart failure. Evidence of toxic reaction to them and even death is reported and summarized by De Graff and Nadler, Brown *et al.* and others in J.A.M.A. 119: 998–1011, 1942.

Rowntree, Keith and Barrier secured excellent diuresis in 19 of 20 cases of ascites due to portal cirrhosis, syphilitic cirrhosis and Banti's disease by the use of novasurol, and pointed out that better results were obtained if ammonium chloride was used in conjunction with it. Tarr and Jacobson reported only two instances of mild stomatitis and one of wrist drop in 8000 injections of salyrgan and believe that it is quite as effective as novasurol and much less toxic. Grossmann in 10,000 injections, could recall no damage from salyrgan and was able to continue the use of the drug for months at a time. Wiseman found salyrgan particularly effective, and productive of an enormous diuresis (4 to 6 quarts) in a woman with cardiac edema who received 270 injections over a period of five years. Novasurol was used at the outset. The dose of salyrgan, at first 2 cc., was increased to 4 cc. At autopsy no evidence of injury to the kidneys was detectable.

Nervous Strain and Cardiac Neurosis.—Rest and restricted activities mean more than lessened physical labor although rest from physical work is, of course, important. Business worry, the strain of the thought of syphilis, anxiety about the family and the expense of treatment, must be promptly dealt with and reduced to the lowest possible terms by the therapist. One is called on, moreover, in cardiovascular disease, as we see it, to deal with a definite neurosis, dependent on knowledge that something ails the heart, the center of existence. We have been able to present two patients with very similar lesions simultaneously in our clinic, one of them robust, smiling, and care-

Fig. 781.

SYPHILIS OVERLOOKED IN FIRST EXAMINATION. NEUROSYPHILIS LATER DEMANDED ATTENTION. MYOCARDIAL DISEASE (ARBORIZATION BLOCK AND AURICULAR FIBRILLATION) SUBSEQUENTLY RECOGNIZED. UNEXPECTEDLY LONG LIFE WITH SERIOUS LESION

Railroad man, aged fifty years, single.

First Examined 9/1/1913.

Chief Complaint: Hernia.

At the Time of This Examination Absent Knee-jerks Were Noted.

The examiner curiosity carried him no further. Not even Wassermann test was taken. The patient was operated on with good result.

There was note of gonorrhea, but no mention of syphilis.

Four Years Later Patient Returned. He was having difficulty in walking down the aisle. Slight diplopia.

H Gave a History of Chancre thirty-three years before, with one year of treatment by mouth.

Blood Wassermann Reaction Strongly positive.

Neurologic Examination Knee-jerks reduced, otherwise negative.

Treatment: Six injections of neo-arsphenamin. No mercury

Excellent Response to Treatment: Blood Wassermann reaction negative since. Spinal fluid some months later negative.

No Note of Any Cardiac Abnormality Placed on mercury with chalk and iodid.

Two Years Later First adequate general examination.

Heart 4.5 by 11 cm. Blood-pressure 150/70.

Total Arhythmia.

Aortic roughening.

Electrocardiogram Rat 150, auricular fibrillation, arborization block.

Left ventricular hypertrophy

"Prognosis not good.

This Discovery was Almost Accidental. The patient was sent for general ex- amination as routine, and had no complaint to suggest the necessity for it.

Two Years Later: No cardiovascular complaints. No signs of revival of tabes. Had been taking 2 gr mercury with chalk three times daily intervals. In excellent health, able to do full work.

Heart 8.5 by 10.5 cm.

x Ray of chest. Heart enlarged, some aortic dilatation.

Electrocardiogram Rate 150, auricular fibrillation, slurred QRS all leads. Left ventricular preponderance.

One Year Later: Some puffiness and shortness of breath. Signs essentially the same except for:

Heart 6 by 14 cm. (chest ray)

Aberrant QRS complexes all leads. Auricular fibrillation.

No Treatment for Syphilis. Good response to digitalis. Seen fourteen months later, active and carrying on his usual ork without embarrassment. Several normal bloods and spinal fluid examinations in past four years.

DISCUSSION

1 There is nothing specific about myocardial lesion that clinically proves its syphilitic character The association of myocarditis with clinical syphilis creates presumption of but does not demonstrate, cause and effect. On the other hand, this presumption is strong, and is supported by necropsy and microscopic evidence. Aortic roughening and dilatation here add to the force of the presumption of syphilis as the underlying cause. There are no specific electrocardiographic signs of syphilis of the heart.

2. A therapeutic test on myocardial lesion may show positive results early but later it is likely to be obscured by the irremediable effects of degenerations which leave no outlook for ultimate recovery This is apparently the case here.

3. This patient points th moral that an electrocardiographic death warrant may still be subject to stay of execution if compensation can be maintained.

4 Digitalis (tincture—Upsher Smith) 15 drops three times daily for few days, helped this patient ver his first tight place.

5 From th standpoint of the clinical diagnosis of syphilis, this patient illustrates th following points

( ) The worthlessness of year of treatment by mouth, for cure

(b) The low inde of suspicion of an examiner who noted absent knee-jerks and did nothing about them

(c) It was from cases like this, in which w acted therapeutically on the presenting syphilologic aspect (this se tabes) verlooking some other and more serious aspect of the disease, that we learned the necessity of complete ppraisal of the patient t the outset, if one is properly t comprehend and manage syphilis.

(d) It is conceivable that the short but vigorous arsphenamin course hich this patient received precipitated or accentuated the myocardial damage. It is also possible that the sign now present are the residua of healing fibrosis in the coronaries and myocardium, and that he may live years if he stays within his compensation limit

free the other palpitant, trembling, pale, and ill with fear The most determined and authoritative reassurance is a positive therapeutic asset in these cases, and one is justified at times, at least when talking to the patient, in going well beyond the reasoned limits of the prognosis. The real outlook may be disclosed to a trusted member of the family It is the sudden assumption of an overload, physical or mental, which must be impressed on these patients as being the chief menace to their safety If they remain within bounds, they may as in Fig 721 astonish the prognosticators by their ability to survive their myocardial death warrants.

Sedatives and Occupational Therapy —Certain patients with cardiovascular syphilis do not react well to sufficient rest in bed, and must have more liberty of movement. This difficulty in hospitalization, however has been greatly reduced by the advent of occupational therapy which patients speak of in the highest terms as a life-saver The bromides, formerly so useful in the treatment of nearly all cases, have been largely replaced by the improvement of the barbital derivatives yet they are still helpful if not too depressant. Quinidine 3 grains twice or three times a day for a day before and a day after an arsenical, is occasionally useful and was proclaimed by one of our patients as a godsend in dealing with his tachycardia. Willius (1942) cautions against its routine use in arrhythmias when coronary disease is present.

Diet.—Restriction of fluids and in general a moderate reduction in the entire diet to prevent gains in weight will be necessary respectively in the edematous and in obese patients. Caution must be used, however in attempting too vigorous reduction. For patients who are annoyed by distention after meals, small amounts of food at more frequent intervals are advised, and Hoffmann s anodyne or peppermint may assist in relieving the gaseous eructation It should not be too readily assumed that all the gastric complaints of a patient with cardiac disease are due to the heart and not to the stomach, and roentgen-ray examination, though not a test meal, should be given to those who are not relieved soon after treatment is begun, provided their cardiac condition permits. There is definite danger in passing a stomach tube in patients with advanced myocardial damage or coronary sclerosis.

Amyl Nitrite, Etc.—Amyl nitrite and nitroglycerin, while valuable for symptomatic relief conceal the favorable or unfavorable progress of angina pectoris and should not be recommended for patients who are being studied for therapeutic outlook. As with the too frequent use of digitalis, they also encourage the patient to overestimate his reserve. The xanthine drugs, aminophylline and theocalcine as vasodilators (LeRoy 1941) are gaining popularity and are demonstrably more effective, though Willius (1942) rates their usefulness by mouth as controversial. He cites the dramatic virtues of the ounce of whiskey when ¼ grain morphine has failed.

Spinal Fluid Examination.—Whenever it has not been carried out as part of the diagnostic study of the case a spinal fluid examination should be made early in the treatment of all patients with cardiovascular lesions, whose age or grave condition does not contraindicate it. This measure is essential in decisions concerning treatment. A patient with an active, even though symptomatic, neurosyphilis, and a well-marked vascular lesion, is definitely restricted in having his neurosyphilis treated by the limitations set by his vascular lesion. He will almost certainly need tryparsamide, and thus should be arranged for from the start. The spinal fluid examination, even if normal on the first occasion, should be repeated at least once during the first year or

eighteen months observation, to be sure that nothing has been lighted up in the nervous system which was previously quiescent.

Focal Infections.—On the general ground that infective foci may be responsible for cardiovascular disease, that they may reduce the tolerance of the patient for treatment and react unfavorably on syphilis in general, we have made it a practice, while our patients are at rest, to remove definitely infected teeth and tonsils if compensation is not endangered thereby. Too strenuous dentistry including the removal of impactions merely because they are potential foci, should not, however be practiced in these cases.

Occupational Disability and Insurance Readjustment.—The existence of disability clauses in many insurance policies now in force may make necessary the certification of patients for total and permanent disability. In the case of large aneurysms in patients with pronounced angina pectoris and marked myocardial damage as evidenced by the electrocardiogram disability from necessary restriction of activity may well be total. On the other hand, the physician should not be dragooned by the pressure of friends and of the patient himself into certifying total disability where it is obvious that such does not exist. The management of some of the problems of cardiac neurosis, to say nothing of outright malingering in this connection, may require the utmost tact, some firmness, and reinforcement by cardiological consultation.

Special Treatment Methods—Control of Pain.—Material advances have been made in recent years in the use of various methods of nerve block and resection for the relief of the pain of aneurysm of aortic disease and angina pectoris.

The more recent reports deal chiefly with paravertebral sympathetic block with alcohol (Levy and Moore 1941) section of posterior roots (Haven and King 1942), severing of preganglionic fibers (Raney 1939) The results are 50–60

Aneurysm under proper conditions of treatment, rest and control of the patient should rarely require other than general antisyphilitic treatment. The treatment of peripheral aneurysms in accessible vessels is surgical.

The wiring operations for the induction of intravascular clotting (Hare 1927 for example have had limited application and decline in use, with recent more encouraging reports based on important technical modifications in wire insulation, current and temperature control, mode of introduction (see Blakemore and King, J.A.M.A., 1938) Johnson quotes Colt indications: aneurysm saccular not fusiform general favorable physical status of patient; failure of response to rest, etc., with rapid progression, aneurysm should have reached and involved chest all.

Cardiovascular Involvement in Congenital Syphilis.—This subject is presented in Chapter XXI (Congenital Syphilis)

CHAPTER XX

LATE SYPHILIS OF THE NERVOUS SYSTEM

Late syphilis of the nervous system is the business and responsibility of the general practitioner While certain aspects of its diagnosis and treatment may demand the help of a specialist, its earliest detection and its effective treatment by an intensive systemic therapy must be in the hands of the average patient's home physician. If he will perform his whole duty by the first two or three years of a syphilitic infection, there will be a reduction of five sixths in the incidence of consequences in the nervous system.

Late syphilis of the nervous system, long regarded as untreatable except by palliative measures, is yielding so rapidly to improved methods of diagnosis and treatment that it is not too much to say that it also can be mastered from the practical standpoint by any reasonably equipped and interested practitioner The spinal fluid examination alone has placed practical though not minute diagnosis on a plane of accuracy undreamed of two decades ago. This chapter is intended to meet the needs of the average well-informed student and practitioner

The Pathology of Late Neurosyphilis.—The most modern conceptions of neurosyphilis attempt to deal with the pathologic changes on the basis of parenchymatous, meningeal, and vascular processes. The older conception of parasyphilis and metasyphilis has lost much of its importance since Noguchi and Moore demonstration of direct spirochetal etiology in 1913. It is still matter for question as to whether processes such as tabes and general paresis are actual syphilids of the nervous system or whether they should be classified as primary or secondary direct or indirect toxic degeneration phenomena. This question is debatable largely on theoretic grounds, and the steady progress which is being made in successful treatment, especially in general paresis, compels an almost daily revision of viewpoint. The term "interstitial" as distinguished from parenchymatous neurosyphilis refers to the embryogenesis of the involved tissues. Mesodermal or interstitial neurosyphilis involves the vessels, membranes, and supportive (glial) tissues, while parenchymatous syphilis involves the nerve cells as such. Nonne's more detailed classification describes four processes interwoven through three groups of structures. These are syphilitic neoplasia or gummatous infiltration; chronic hyperplastic or fibrotic inflammation; vascular changes including thrombosis, obliteration, and miliary aneurysm with hemorrhage and finally primary parenchymatous degeneration. This classification, very satisfactory for pathologic study does not dovetail with the clinical vernacular at present in use. Shaffer and Stokes attempted to combine the two types in practical classification of symptomatic neurosyphilis shown in Fig 788.

While this rearrangement lacks much of being satisfactory it gives the clinician some clue as to the whereabouts of the process and the pathologic equivalents in the conditions with which he deals. Simple meningitis is the earliest detectable symptom and sign-producing aspect of neurosyphilis. Vascular changes are close successors and may like the meningeal changes, begin to give rise to symptoms within few months after the onset of the infection. Meningeal syphilitic processes localize first at the base of the brain and secondly at the convexity The vascular processes, while frequently affecting the circle of Willis, may involve the finer capillary circulation primarily Acute and chronic syphilitic basilar meningitis therefore colors most of the symptomatic pictures in syphilis of the brain, giving rise to lesions in the chiasm, the interpeduncular space, and the Sylvian fissure. The involvement of N II, III, IV and VI, and lesions in the seventh and eighth cranial nerves are therefore highly suggestive guides in the diagnosis of late as well as early neurosyphilis Gummatous changes in the pituitary body occasionally occur and diffuse plaquelike or tumor-forming gummatous changes in the meninges are common. The dura is most frequently involved, the arachnoid next, and combinations of gumma and fibrous hyper-

plasia may affect all three layers of the meninges at once. Caseation and softening in gummatous tissue occur precisely as elsewhere in the body. The vascular changes of neurosyphilis are not pathognomonic of the disease. Even the obliterative endarteritis can be simulated in tuberculosis and neoplasia. Perivascular plasma and round-cell infiltration (coat-sleeve type) is, however, one of the chief histologic clues in neurosyphilis. Atherosclerotic changes are frequent in the background of vascular neurosyphilis and are not to be clearly differentiated (Nonne) on histologic grounds from those of other infections and intoxications. Vascular neurosyphilis may give rise, then, t atrophy softening, and degenerative change through injury to large vessel at a comparatively distant point, to the slow degenerative results of chronic inflammation with capillary obliteration and to the comparatively sudden effects of leakage or hemorrhage from damaged vessel wall. Parenchymatous degenerations, while occasionally primary as in disseminated syphilitic encephalitis (Barrett), are more frequently as in tabes and paresis, thought of as secondary in origin. Many observers, however still contend that degenerative changes in these conditions are primary rather than secondary

The accepted classification groups are not self-contained and mutually exclusive. Within the same general clinical picture may be grouped varying proportions of vascular meningeal, and parenchymatous change. This overlapping and interchangeability may sometimes make it extremely difficult to differentiate, for example, paresis from cerebrospinal syphilis. A single symptom such as phasia may t postmortem be found to result from hemorrhage from old organized exudate in local meningitic lesion, or from deeper obliterative change in the arterial blood supply with secondary softening. The difficulty of reconciling serological with clinical pathologic findings, at first very pronounced, is becoming clearer as experience shows the mean-

Fig 728.

A CLASSIFICATION OF NEUROSYPHILIS

Preponderantly meningeal
  Early symptomatic and asymptomatic neurosyphilis.
Meningeal (late) and meningo-vasculo-parenchymatous:
  Cerebrospinal syphilis.
Preponderantly vascular neurosyphilis:
  Hemiplegia, arteriosclerosis.
Preponderantly parenchymatous and parenchymato-meningo-vascular:
  Tabes dorsalis.
  Paresis also paresi (symptomatic latent preparetic neurosyphilis).
  General paralysis

ing of the individual serological items and combinations. There is still, however a large margin of uncertainty in which localized meningitic lesions may accompany general negative serological picture and high-grade degeneration appear and progress without apparent change in the spinal fluid.

Immunology of Lat Neurosyphilis.—The two questions of paramount importance at the present day are those of neurotropic strains of infection and of induced neurotropism through the use of arsphenamines in treatment. The work of Nichols and Hough Levaditi and Marie, and other observers on spirochetal neurotropism has been referred to. Schlossberger and Haines and Severac have artificially induced neurotropism by passing *Spirochaeta pallida* through the brains of mice. Georgi and Prausnitz have found biochemical changes t occur in stock cultures of *Spirochaeta pallida* grown in contact with brain tissue. Plaut and Mulzer have not been able to confirm the claim of an intrinsically neurotropic type of organism, but believe that they have produced such type by ineffective arsphenamine treatment of rabbit syphilis. Some of the strongest evidence comes from the clinical side although it must be conceded that much of it is, like the experimental, contradictory

The entire question is admirably reviewed by Jahnel in the Jadassohn *Handbuch* and by Hutton (1941)

The rarity of somatic syphilitic lesions in patients with neurosyphilis favors the neurotropic strain theory and when such lesions coexist they may be an expression of the two strains not being incompatible with each other (Hopkins, 1930; Hutton, 1941 cf Shaw 1940.) Strong evidence for neurotropic strain is afforded by study of conjugal infections. (Hutton, 1941.) Nonne in 19 pages of case reports and summaries from the literature among which are illustrations of multiple infections by the same woman (as high as 5—Erb) with neurosyphilitic accidents in all the

cases; syphilis presenting the same type of neurological involvement, *transmitted by one partner* (male or female) to successive marital partners; examples of apparent neurotropism in the involvement of the nervous systems in parent and child. Most famous of the "paretic strain examples is that of Martha X (Morel-Lavallée) whose career as *fille de joie* brought three medical students, chemist, an engineer and her last partner to death or paralysis with various forms of neurosyphilis. The converse relation, in the form of what seems familial predisposition of the host to the incidence of neurosyphilis regardless of the source of the infection, is equally well illustrated. Moore and Keidel, and Moore and Kemp, in successive studies from the Johns Hopkins clinic, found that conjugal neurosyphilis occurred in 37 per cent of the patients whose spouses they were able to examine, and that there was definite predisposition to the appearance of parenchymatous neurosyphilis among the partners of persons with parenchymatous involvement, while no such tendency existed among patients with cerebrospinal neurosyphilis. Marie has reported examples of pluriconjugal neurosyphilis in polygamy Livingood and Beerman (1941) described case of transfusion syphilis in two brothers (one the donor the other the recipient) both of whom developed asymptomatic neurosyphilis.

Additional suggestive support for the theory of neurotropic strain is lent by evidence from congenital infections. Kemp and Poole from study of 20 families, found neurosyphilis eight times as frequent in the parents of congenital neurosyphilitic children as in the parents of children suffering from other types of congenital syphilis. These findings are substantiated by our experience and by that of others. (Grotjahn, 1936; Menninger and Grotjahn, 1936 Curtius and Schlotter, 1934; Dekeyser Longuet and Anglade, 1937; Riser Becq and Coundou, 1936; Sakane, 1939 and de France, 1936).

Induced Neurotropism, Through the Use of Arsenicals.—This subject has already been in part reviewed in discussing the general principles of treatment, neurorecurrence and early syphilis of the nervous system. The gist of the matter is this: there is no convincing evidence that the adequate and effective use of arsenicals predisposes in any way to syphilis of the nervous system. On the other hand, there is abundant evidence that an increase in the incidence of neurosyphilis is predisposed to by *inadequate* use of the arsphenamines although treatment may shorten the incubation period of some forms of neurosyphilis. If our present evaluations are sound, very few observers at the present day particularly on the neurological side, are dealing with neurosyphilis that has been even inadequately treated with the arsphenamines, to say nothing of adequately treated. Guy' review of this question brought him to the conclusion that, in this country at least, the incidence of paresis is stationary or slightly on the decrease and the mortality definitely decreasing, which would not be the case if arsphenamine were stimulating the development of neurosyphilis. The observations of Lauter, Marburg, Mattauschek, and Hyder tended to show that cerebrospinal syphilis was exhibiting an earlier onset than in prearsphenamine years; but again the evidence appears to show that it is the inadequate use of the drug which is responsible, rather than its proper use. Moore study of neurorecurrence showed clearly that this manifestation of neurotropism is confined practically entirely to inadequately treated patients and that its incidence rapidly decreases with increase in the amount of treatment, including arsphenamine. Stoner in survey of representative clinics and institutions in the United States, found that in general there was definite decline in incidence of neurosyphilis in the years 1923 to 1927 as compared with 1917 1922. Weatherby in study of 250 cases, found no evidence that arsphenamine given in the early stages of syphilis predisposes to the development of paresis, but that the complication appears in the undiagnosed, neglected, and inadequately treated patient. He noted tendency to earlier onset of cerebrospinal syphilis which might, however in his opinion have passed unrecognized in inadequately treated patients. The majority of his tabetics, while less obviously neglected than his paretics, had had no previous treatment. O'Leary and Rogin examined the records of 500 cases of neurosyphilis entering the Mayo Clinic, at random, during the years 1919–1929 finding that in 78 per cent of the entire series treatment had not been given for syphilis before the patient came to the clinic; 13 per cent had had desultory treatment without arsenicals; 12 per cent had been inadequately treated with arsphenamine and mercury The severer parenchymatous types of neurosyphilis preponderated in the patients who had not been treated during the early stages of their infection, the milder types in those who had been treated. Approximately 80 per cent of the patients in their series experienced some degree of improvement when placed on treatment for syphilis, including the arsphenamines.

The consensus of European authoritative opinion was collected by the German Dermatological Society in 1928 through questionnaire yielding 120 replies from the foremost experts of Europe. On the basis of their opinion the Society unhesitatingly announced that modern treatment for syphilis, especially with the arsphenamines, when properly used in conjunction with mercury and bismuth, is not responsible for any increase in neurosyphilis; and that neurorecurrence is steadily on the decline. Many later studies, notably that of the Cooperative Clinical

Group, have repeatedly discussed and reemphasized this protective action of antisyphilitic treatment (Dedman and Morgan, 1933 Hall, 1935; Wile, Poth and Barney 1936 Kemp and Menninger 1936 *Strandberg, 1937 Vonderlehr and Usilton, 1939 Harrison, 1940- Bottema, 1940-* Barrett, 1941, and others)

Specific Drug Neurotropism.—This holds an exceedingly small place among the complications of arsphenamine therapy Peripheral neuritis is one of the rarest of arsenical complications. Even injury to the optic nerve has been dismissed by such authorities as Igersheimer and Nonne as insignificant. W consider this particular neurotropism more real objection to the use of arsenicals than the alleged general neurotropism. Indirect injury to the nervous system through vascular accidents as in hemorrhagic encephalitis, the occasional precipitation of hemiplegic attacks in vascular neurosyphilis, increased irritability of the cortex in epilepsy and the nervous hyperirritability of the overtreatment syndrome have been genuine but extremely rare complications in our experience. One occasionally sees also evidence of the unfavorable action of arsphenamine on meningeal lesion independent of the therapeutic shock. The successive exaggeration of symptoms with each arsphenamine injection and the enormous rise in cell count are in both of Stokes s patients inescapably associated with the continued administration of arsphenamine, and recovery followed the transfer to mercury and iodides.

The Incidence, Course and Response of Early Neurosyphilis Under Treatment.—The treatment of early which is of course overwhelmingly asymptomatic neurosyphilis recognized only by examination of the spinal fluid, has been discussed from the preventive standpoint in Chapter XIV (Treatment of Early Syphilis) The incidence of asymptomatic neurosyphilis as reported by various authors depends on the stage at which the spinal fluid is examined. An incidence of slight to marked abnormalities, including slight rise of cell count, appears in 40 to 60 per cent of early cases, declining in the early latent periods to from 20 to 30 per cent. The incidence of neurorecurrence or outright symptomatic flare-up following inadequate treatment is estimated at from 1.5 to 10 per cent, the first figure representing fairly adequate modern clinic treatment, the second the disastrous results of the misuse of arsphenamine in its early days. Moore, from special study of the question, estimates 0.2 per cent as the reasonably expected incidence of neurorecurrence in clinical practice with early syphilis. I an analysis of 81 cases he established the gravity of neurorecurrence from the standpoint of ultimate prognosis in neurosyphilis b finding that 40 per cent developed clinical signs and 4 out of 14 cases progressed in spite of thorough treatment. Paresis was observed in 3 patients following neurorecurrence and the rate of development of serious late neurosyphilis may be greatly hastened by antecedent neurorecurrence. In his excellent study of Johns Hopkins Hospital experience, he showed that of 342 patients, 20 4 per cent still had evidence of asymptomatic neurosyphilis after one or two energetic courses of treatment. Classified on the basis of spinal fluid findings, two groups, one with slight pleocytosis and slight increase in globulin, and the other with marked pleocytosis and negative or mildly positive spinal fluid Wassermann reaction, responded to routine continued or slightly intensified treatment. The third type, presenting strongly positive W ssermann reaction on all concentrations of the spinal fluid and marked increase in globulin and cell count, proved resistant to all but intraspinal and prolonged intensive systemic measures. This third group corresponds essentially to the preparetic type with first-zone colloidal test. Its striking resistance to treatment (double that of the milder types) was clearly show in the Cooperative Clinical studies (p 674) In our discussions of treatment it ha been clearly indicated that this third group is the recruiting ground in early neurosyphilis, of the late neurosyphilitic material of present-day practice.

In Fig 793, representing the experience of the Bonn Clinic under the direction of E. Hoffmann, is strikingly shown the rise in the incidence of neurosyphilis early in the disease simply with lapse of time, its decline after two years, and the striking differences produced by adequate as compared with inadequat treatment for the disease. After two inadequate courses the incidence of neurosyphilis is seven times as great as after two adequate courses and after three adequat courses more than fifty times as great.

The Fate of Patients with Normal and Abnormal Spinal Fluids in Early Syphilis.—Particular interest attaches to the pronouncements on this matter by Paul Ravaut, to whom syphilology owes the introduction of the conception of asymptomatic neurosyphilis recognized by spinal fluid examination. Ravaut, while not presenting exact statistical evaluation cites numerous cases to illustrate the following principles. Among patients studied in the early stages of syphilis who presented abnormal spinal fluids, three great evolution-

ary groups appear as follows (1) Patients with spinal fluid abnormalities which persist without clinical signs, completely latent for various periods of time and vanishing without complications (2) patients presenting coincidently both abnormal fluids and slight clinical signs, both of which disappear completely without unfavorable progression in variable lengths of time (3) patients exhibiting progression of both symptoms, signs, and spinal fluid changes throughout a period of years until some clearly characterized neurosyphilitic syndrome appears.

By far the larger part of spinal fluid abnormalities (86 per cent) in Ravaut opinion disappear at the close of the septicemic stage of early syphilis and do not reappear Of the remainder presenting all grades of abnormality from slight to severe, an unnamed and unpredictable proportion may return completely to normal, as evidenced by his observations extending over twenty years. A second group develops trifling clinical signs of neurosyphilis, and thereupon heals as ef-

Fig 722.

Later ("old") (over 2 years)		85 3	50 0	14 3	0	30 1	78 5	56 0

Adequate course includes 12 injections of neoarsphenamine 0.6 Gm. (men) with 12 simultaneous injections of bismuth salicylate, intervals of three to four days between the combined treatments.

fectively as the first group. The third group, after preclinical period of marked or intense abnormality leads to definite and grave neurosyphilis. A fourth group whose existence was contested by Sicard throughout his lifetime, includes those patients with pronounced abnormal reactions of the spinal fluid, including strong positive Wassermann reactions, who never throughout their lives develop any signs whatever of neurosyphilis. Sicard contended that no such group exists, but Ravaut cites number of case examples.

Outcome of the Negative Spinal Fluid.—Ravaut contends that it is impossible to predict which of the various roads above described given case of neurosyphilis will follow His study of the patient who has negative spinal fluid at the outset of his infection leads him to the following conclusions. There are undoubtedly patients who never at any time in the course of their syphilitic infection have an abnormal spinal fluid. None the less, the large majority even of such negative cases pass through what Ravaut calls the period of instability in which the fluid may become slightly positive, either spontaneously or under the provocative influence of treatment and particularly of injudicious or overstrenuous treatment with the arsphenamines. At the end of this unstable period of one or two years the case takes definite turn either toward stability and normality of the meningovascular tissues or toward the development of definite pathologic characteristics. He distinguishes in his prognostic estimate of the significance of the negative spinal fluid, two groups of patients, one which has been continuously negative without ever exhibiting the slightest trace of abnormality and the other which has for time been abnormal even though

Group, have repeatedly discussed and reemphasized this protective action of antisyphilitic treatment (Dedman and Morgan, 1933 Hall, 1935 Wile, Poth and Barney 1935 Kemp and Menninger, 1936 Strandberg, 1937; Vonderlehr and Usilton, 1939 Harrison, 1940; Bottema, 1940 Barrett, 1941 and others)

Specific Drug Neurotropism.—This holds an exceedingly small place among the complications of arsphenamine therapy Peripheral neuritis is one of the rarest of arsenical complications. Even injury to the optic nerve has been dismissed by such authorities as Igersheimer and Nonne as insignificant. We consider this particular neurotropism a more real objection to the use of arsenicals than the alleged general neurotropism. Indirect injury to the nervous system through vascular accidents as in hemorrhagic encephalitis, the occasional precipitation of hemiplegic attacks in vascular neurosyphilis, increased irritability of the cortex in epilepsy and the nervous hyperirritability of the overtreatment syndrome have been genuine but extremely rare complications in our experience. One occasionally sees also evidence of the unfavorable action of arsphenamine on meningeal lesion independent of the therapeutic shock. The successive exaggeration of symptoms with each arsphenamine injection and the enormous rise in cell count were in both of Stokes patients inescapably associated with the continued administration of arsphenamine, and recovery followed the transfer to mercury and iodides.

Th Incidence Course, and Response of Early Neurosyphilis Under Treatment.—The treatment of early which is of course overwhelmingly asymptomatic neurosyphilis recognized only by examination of the spinal fluid, has been discussed from the preventive standpoint in Chapter XIV (Treatment of Early Syphilis) The incidence of asymptomatic neurosyphilis as reported by various authors depends on the stage at which the spinal fluid is examined. An incidence of slight to marked abnormalities, including slight rise of cell count, appears in 40 to 60 per cent of early cases, declining in the early latent periods to from 20 t 30 per cent. The incidence of neurorecurrence or outright symptomatic flare-up following inadequate treatment is estimated at from 1.5 to 10 per cent, the first figure representing fairly adequate modern clinic treatment, the second the disastrous results of the misuse of arsphenamine in its early days Moore, from special study of the question, estimates 0.2 per cent as the reasonably expected incidence of neurorecurrence in clinical practice with early syphilis. In an analysis of 61 cases, he established the gravity of neurorecurrence from the standpoint of ultimate prognosis in neurosyphilis by finding that 40 per cent developed clinical signs and 4 out of 14 cases progressed in spite of thorough treatment. Paresis was observed in 3 patients following neurorecurrence and the rate of development of serious late neurosyphilis may be greatly hastened by antecedent neurorecurrence. In his excellent study of Johns Hopkins Hospital experience, he showed that of 832 patients, 26 4 per cent still had evidence of asymptomatic neurosyphilis after one or two energetic courses of treatment. Classified on the basis of spinal fluid findings, two groups, one with slight pleocytosis and slight increase in globulin, and the other with marked pleocytosis and negative or mildly positive spinal fluid Wassermann reaction, responded to routine continued or slightly intensified treatment. The third type, presenting strongly positive Wassermann reaction on all concentrations of the spinal fluid and marked increase in globulin and cell count, proved resistant t all but intraspinal and prolonged intensive systemic measures This third group corresponds essentially to the preparetic type with first-zone colloidal test whose striking resistance t treatment (double that of the milder types) was clearly shown in the Cooperative Clinical studies (p 674) I our discussions of treatment it has been clearly indicated that this third group is the recruiting ground in early neurosyphilis, of the late neurosyphilitic material of present-day practice.

In Fig 743, representing the experience of the Bonn Clinic under the direction of E. Hoffmann, is strikingly shown the rise in the incidence of neurosyphilis early in the disease simply with lapse of time its decline after tw years, and the striking differences produced by adequate as compared with inadequate treatment for the disease. After two inadequate courses the incidence of neurosyphilis is seven times as great as after two adequate courses and after three inadequat courses more than fifty times as great.

The Fate of Patients with Normal and Abnormal Spinal Fluids in Early Syphilis.—Particular interest attaches to the pronouncements on this matter by Paul Ravaut, to whom syphilology owes the introduction of the conception of asymptomatic neurosyphilis recognized by spinal fluid examination. Ravaut, while not presenting exact statistical evaluation, cites numerous cases to illustrate the following principles. Among patients studied in the early stages of syphilis who presented abnormal spinal fluids, three great evolution-

The grading of spinal fluid according to the degree of involvement is a valuable guide to the treatment and prognosis in asymptomatic neurosyphilis. For patients who have a positive spinal fluid at the time of first examination repeated investigation of the changes in the various tests is essential. It is thus possible to note the tendency of the spinal fluid to improve or to assume more malignant features (trend) Patients with the milder types of positive spinal fluid show serologic reversal to negative following comparatively small amounts of treatment. (The types of cerebrospinal fluid and their prognostic import have been discussed on p 120.) It is the only type of neurosyphilis in which it is possible to appraise readily the results of different systems of treatment, and the effect of the various schemes of treatment gives a good clue to the status of the patient's mechanism of defense against the disease.

Incidence.—The Negro has lower incidence of asymptomatic neurosyphilis than either the white male or white female. Among patients whose syphilis was inaugurated by an extragenital chancre the incidence of asymptomatic neurosyphilis was 11.7 per cent in the cases in which the chancre was located above the neck, and 6 6 per cent in those in which the extragenital chancre was below the neck.

Duration of Infection.—The incidence of asymptomatic neurosyphilis tends to decrease as the duration of the infection increases, while the symptomatic form of the disease increases up to the twentieth year as far as the patients could be followed. The earlier in the course of the disease that treatment is started, the lower the incidence of clinical neurosyphilis.

The Scheme and Amount of Treatment.—The scheme and amount of treatment administered during the early stage of syphilis are potent factors in the prevention of asymptomatic neurosyphilis. Adequate treatment given by the continuous system resulted in the lowest incidence (11.7 per cent) Further evidence is offered that the modern treatment of syphilis does not predispose to the development of asymptomatic neurosyphilis. In 60.5 per cent of the cases in which patients did not receive any treatment for acute syphilis the examination of spinal fluid was found to be positive.

Blood Tests.—The Cooperative Clinical Group study was based on the older serologic technics, since the flocculation tests were not employed during the time these patients were under treatment. The blood Wassermann was negative in 30 0 per cent of the cases in which patients with early syphilis had been treated at the time the spinal fluid as first found to be positive, while of those with asymptomatic neurosyphilis detected during the late stage of syphilis, 22 per cent had negative blood Wassermann tests. A negative blood Wassermann in treated patient does not, therefore, obviate the need for examination of the spinal fluid. Of patients with latent syphilis whose spinal fluid was negative, less than 1 per cent subsequently developed positive spinal fluid. The blood test, either positive or negative, is not guide to the presence of positive spinal fluid in latent syphilis, whereas in early syphilis, the persistently positive blood Wassermann is associated with positive spinal fluid in 74 per cent of the cases. The spinal fluid test was positive in 17.1 per cent of cases in which patients were adequately treated for early syphilis and developed blood Wassermann negativity A blood Wassermann relapse from negative to positive in cases in which treatment has been given is frequently associated with spinal fluid relapse or by an increase in the severity of involvement of the spinal fluid.

Wassermann Fastness.—Wassermann fastness is of more significance in early syphilis than in late syphilis because of the higher incidence of asymptomatic neurosyphilis in the former.

Treatment of Asymptomatic Neurosyphilis.—Treatment by the combined methods as previously described resulted in reversal of the spinal fluid to serologic negativity in 64 4 per cent of 565 cases. In 83 6 per cent of patients with group I spinal fluids and in 44.9 per cent of those with group III spinal fluids treatment produced serologic negativity while for group II type of fluid serologic reversal occurred in 65.3 per cent of the cases. The bulk of these reversals occur by the end of the fifth year of treatment. Of the 565 cases in which the patients were treated by the routine use of arsphenamines and heavy metal alone there was serologic reversal of the spinal fluid in 13.3 per cent at the end of the first year and 26.9 per cent by the end of the tenth year routine

and intraspinal therapy reversed to negative an additional 15.8 per cent by the first and 26 4 per cent by the end of the tenth year routine and tryparsamide treatment increased the reversals by 1.2 per cent the first year and by 5 7 per cent at the tenth year malaria therapy when used after the other types of therapy had failed brought about an additional reversal of the spinal fluid in 2 per cent the first year and 3 9 per cent by the tenth year A few cases in which malaria and all of the other combinations of supplemental therapy were used showed a reversal of the spinal fluid in 1 per cent of cases by the fifth year and 1 6 per cent by the tenth year

Clinical Progression.—In 712 cases in which patients were treated, clinical progression was noted in 2.8 per cent of the early cases and in 7.9 per cent of the late cases. Of the 239 late cases in which patients were adequately treated, 4 6 per cent showed clinical progression, while in 218 in which patients were inadequately treated 11 9 per cent gave evidence of clinical progression. In early syphilis the adequately treated and the inadequately treated patients showed practically the same clinical progression. The prognostic significance of grading the spinal fluid was noted here also in that 2 per cent of those with group I fluids, 6 7 per cent of those with group II and 8.8 per cent of those with group III fluids showed progression to clinical signs of neurosyphilis.

Of these 712 patients 43 (6 per cent) developed clinical forms of neurosyphilis, of whom 12 had dementia paralytica (one previously had progressed to tabes and one to meningovascular syphilis) 10 meningovascular 9 tabes dorsalis, 3 optic atrophy 2 taboparesis, 2 meningeal neurosyphilis, 2 neuroretinitis, 1 neurovascular syphilis, 1 eighth nerve deafness, and 1 neurorelapse. The majority of these progressions appeared by the fifth year of treatment. Of the 364 patients 3 developed clinical signs of neurosyphilis after the spinal fluid had become negative and 14 showed progression in other manifestations of syphilis, such as cardiovascular disease.

The treatment of asymptomatic neurosyphilis may be summarized briefly as follows The patient first should be given the advantage of the simpler routine methods of treatment, especially when the spinal fluid is reported as one of the milder types. If the response is slow that is, if after two courses of treatment improvement in the fluid is not noted, intraspinal or fever therapy should be employed. If the fluid is the paretic type when treatment is started, routine and intraspinal treatment for one or two courses should be used If no material change is noted in the reports of the fluid either the malaria or machine methods of fever therapy are employed, as fever therapy is even more efficient in the prevention of general paresis than in its treatment. Persistence with chemotherapy for several years is sometimes necessary after fever treatment has been instituted, although occasionally the spinal fluid will rapidly become negative after fever therapy and further treatment will not be required. In either event, treatment should be continued until the spinal fluid reverses to and remains normal.

Frequency f Neurosyphilis in Medical Practice.—Most of the estimates of the frequency of neurosyphilis in neurological practice antedate modern serological study and have hence little present-day value Nonne placed the proportion as low as 1.5 per cent in figures based on the years 1903 to 1907 while Grinker estimated that 63 per cent of the organic neurological material in the wards of the Cook County Hospital, Chicago, and approximately 10 per cent of that in private practice, was neurosyphilis.

The frequency of neurosyphilis in general medical practice depends to large extent upon

the thoroughness of the search for signs of neuraxis involvement and the frequency with which the spinal fluid examination is employed. The incidence may be roughly estimated from the diagnostic work of the Mayo Clinic, in which syphilis as whole affects 4 per cent of patients. Repeated surveys have shown that 65 to 75 per cent of the syphilis seen in the Mayo Clinic has neurosyphilitic aspect. Neurosyphilitic patients should, therefore, constitute about 2.5 to 3 per cent of the medical entrants from a rural population. Walker and Haller in 4000 medical patients examined, among whom were 600 persons with syphilis, found 3 per cent of the total number to have neurosyphilis. Grey in small group of 63 nephritics, found 8 patients with unsuspected syphilis, 3 of whom had neurosyphilis as shown by spinal fluid examination. Wender and Sampson found that 17.2 per cent of the admissions to the Corozal Hospital, Canal Zone, during five consecutive years, were suffering from neurosyphilis. Vonderlehr and Usilton (1938) found (Fig. 90) that patients with early syphilis observed ten to twenty years developed 16 9 per cent symptomatic neurosyphilis if untreated, 10.5 per cent if they received less than standard treatment and in 1.6 per cent if they received standard treatment. The probability of developing asymptomatic neurosyphilis under the same circumstances was 6.1 per cent, 5 7 per cent and 1.6 per cent respectively Moore found asymptomatic neurosyphilis to be twice as frequent in the white patients of the Johns Hopkins Hospital as among the colored. Zimmermann states that in late syphilis the difference between colored and white patients consists mainly in the frequency of tabes and paresis, the incidence of cerebrospinal syphilis being the same in both, ith tendency

The proportion is higher in admissions than inmates because of the short life of patients admitted for insanity due to syphilis.

on the part of the Negro to develop cerebral vascular lesions. If the incidence of syphilis in city hospital population be accepted t the conservative 10 per cent, it may be estimated from the above proportions that 6 to 7 per cent show evidence of neurosyphilis on complete examination. Goldblatt and Vanderem (1939) in study of 1871 Negroes in the Shoemaker Clinic, Cincinnati, upon whom spinal punctures had been made found that the female had less frequent neural and cardiovascular syphilis than the male. They noted greater incidence of asymptomatic neurosyphilis than previously reported, indicating that the percentage of neurosyphilis in the Negro tends more nearly to approximate that in the white race. Eighty per cent of neurosyphilis in the Negro was of the mild type. The incidence of asymptomatic neurosyphilis according to age was shown to parallel that of syphilis; symptomatic neurosyphilis tended to make its greatest appearance about eight years later. Unsuspected abnormality was found in the spinal fluid in an average of 14 per cent of all cases of syphilis, exclusive of those of late active disease in which abnormality of the spinal fluid occurred in 33 per cent. Most of the cases of asymptomatic neurosyphilis occurred during the first five years after contraction of the disease but the majority of the cases of symptomatic neurosyphilis occurred during the eight to fifteen-year period following contraction of the disease.

Frequency of Various Types of Neurosyphilis.—The standard citation in this field is from the group of 4134 syphilitic Austrian Army officers studied by Mattauschek and Pilcz. Of this group, 4.8 per cent developed paresis, 2.7 per cent tabes, and 3.8 per cent cerebrospinal syphilis. The slightly greater frequency of paresis as compared with tabes is borne out by statistical experience in general (Nonne). Pusey quotes Fischer, 2.5 per cent of 1170 syphilitic men and 0.85 per cent of syphilitic women as developing paresis, while 1.6 and 0.32 per cent respectively developed

tabes. Pick and Bandler found 2.1 per cent of syphilitic men developing paresis. The ratio of male to female incidence of paresis determined by Furbush survey for the National Committee for Mental Hygiene is as 6 is to 2.

The incidence of paresis and tabes for the population at large is given by the Metropolitan Life Insurance statistics (as cause of deaths) previously quoted, as ranging downward from 16.0 per 100,000 to 13.1 per 100,000. Kirby gives the hospital admissions for paresis in New York State over a period of years as 8.4 per 100,000. Marie gives the incidence of paresis in Egypt as 5.5 per 100,000

The incidence of the arious types of symptomatic neurosyphilis in the Cooperative Clinical Group material is given in Fig. 725.

	113	182	295	38.3

As a factor in neuropsychiatric work paresis is rated by May the cause of 11 per cent of 70,000 first admissions to 48 hospital in 16 different states. Richards, in White and Jelliffe text (quoted by Southard and Solomon), states that paresis constitutes 5 to 7 per cent of all military cases of mental disease in the French, German, American, and Russian armies.

The proportion of mental disease due to syphilis is summarized from survey covering 84 hospitals in this country by Donaldson, in Fig. 724. Merriman (1935) estimated that neurosyphilis occasioned 11.2 per cent of all admissions to civil stat hospitals during the year end of 1933. In a more recent survey M. Moore and Merritt (1936) found that syphilis is responsible

for the psychosis in 9.3 per cent of 26,157 first admissions of psychotic patients to the Boston Psychopathic Hospital in the first twenty-two years of its existence (1912 to 1934) Fig. 727

THE GENERAL SYMPTOMATOLOGY OF NEUROSYPHILIS

Clinical literature and case material usually represent signs to be more conspicuous than subjective symptoms. Yet the subjective symptom not infrequently furnishes a valuable early clue to the recognition of the process. Symptoms such as headache, paresthesias, lightning pains are irritation phenomena and accompany the treatable early phases of the disease. Argyll Robertson pupils and lost reflexes show relatively little response to treatment and represent, on the whole, irremediable damage. The preventively-minded observer therefore will develop side by side with his alertness for early signs a high index of suspicion for symptomatology Habitual painstaking complete examination is the only means for the detection of the earliest objective signs. While symptoms and signs in neurosyphilis have a certain localizing value headache, for example, suggesting cortical or basilar meningitis, lost knee jerks accompanying lower cord degeneration seizures, hemiplegias, and aphasias, suggesting cerebral involvement it is more often true that multiplicity wide distribution and shifting character rather than intense localization, suggest a neurosyphilitic process.

Some neurosyphilitic pictures lack specificity and not all neurological symptoms in the course of syphilis are due to syphilis of the nervous system. Particularly effective illustrations can be found in multiple sclerosis, sarcoma, myelitis, glioma, and tuberculous Pott s disease with paraplegia. An examination of the spinal fluid usually but not always clarifies the diagnosis. In some cases a therapeutic test is a final resort, and even here as in multiple sclerosis and glioma, nonspecific therapeutic response makes this procedure of uncertain value.

Such a tabulation as Fig. 728 cannot of course convey the impression of

Fig. 783

AN APPROXIMATE CHRONOLOGY OF NEUROSYPHILITIC SYMPTOMS AND SIGNS

	Symptoms.	Signs.
First to fifth year	Headaches and head pain. Alopecia and leukoderma. Ringing ears and dizziness. Impaired vision. Other symptoms of cranial nerve lesions (diplopia, deafness, facial palsy) Neurasthenoid symptoms: nervousness, lassitude, malaise and pains, phobias, and emotional disturbance. Insomnia. Early hemiplegia and epilepsy	Fixed or relapsing positive blood Wassermann reaction. Spinal fluid findings: Cell count, Wassermann test, etc. Pupillary irregularities, anisocoria, disturbed light and accommodative reflexes. Fundus signs of involved N. II: Papillitis, neuroretinitis, early disk pallor, etc. Disturbed reflexes, usually accentuated. Cranial nerve lesions: Ocular paralyses, facial palsy, low bone conduction, etc.
Fifth to tenth year	Headache and head pain. Stomach trouble. Backache Neuralgias (or root pains) Cerebral neurasthenia: Tremor, fatiguability, irritability, insomnia, memory loss. Seizures and "Spells": Aphasic, epileptiform, apoplectiform, hemiplegic. Paresthesias: Prickling, numbness, burning, tingling	Spinal fluid findings. Pupils, irregular, unequal, or slow Isolated paralyses and pareses. Lower cord reflexes, diminution and loss, or early accentuation and spastic changes. Early sensory changes: Widespread with reduction in pain, bone and muscle-joint sense. Alterations of personality
Tenth to twentieth year	Reduced libido and potentia. Difficulty in urination. Ataxia, noticed first after dark. Failing vision. Diplopia and ptosis. Lightning pains. Girdle sensation and other paresthesias. Visceral crises. Seizures. Mental symptoms. Cardiovascular symptoms.	Argyll Robertson pupils, anisocoria, mydriasis, myosis. Romberg or Babinski and spastic signs. Optic atrophy (primary). Extra-ocular palsies. Lost lower cord reflexes. Hemiplegias and hemipareses. Dysarthria and aphasia. Grandiose and paranoid delusions, conduct slump. Trophic joints and spontaneous fractures. Mal perforans.
Twentieth to fortieth year	Advanced ataxia or paraplegia. Severe paresthesias and pains. Tabetic infected bladder with cystitis. Attacks of fever (pyelitis) Uremic symptoms. Advanced mental deterioration. Arteriosclerotic changes. Apoplexies.	Further progression of the foregoing signs. Rising blood urea and declining renal function.

This summary combines the observations of Fordyce *et al.*, Moore, Lucke, Nonne, Klauder, Riddoch, Kagawa, Mannesheimer, Bolton, Petts, Stokes *et al.*, Gennerich, Leyberg, Nonne, Wile.

the rich and variegated symptomatology which characterizes neurosyphilis as a whole, nor can it make adequate allowance for its restricted specificity But it is a fair representation of the neurosyphilology of ordinary medical practice. The unfolding of the picture may be stopped at any point by the arrest of the disease, or accelerated so that the symptoms of the last decade may furnish the closing episode of the first.

Miscellaneous Clues.—The neurosyphilitic who is up and about presents, in the aggregate, signs three times as often as he does subjective symptoms (Fig 729) The relative importance of various eye signs is shown in Fig 730 Moore, in a survey of 642 early cases, found that of those presenting the symptoms of the first to fifth year (Fig. 728) four times as many (29 per cent)

had neurosyphilis as among those in whom these symptoms were absent Leyberg found 52 per cent of patients with leukoderma and 60 per cent with alopecia to have involvement of the nervous system (see Chapter XII) Cardiovascular syphilis as an accompaniment of neurosyphilis was found by Nonne in 17 to 24 per cent of paretics and tabetics, chiefly the latter Chiari found 47 per cent; Straub, 82 per cent (postmortem examination) and Fritsch has recently reported 39 per cent in 115 cases (20 per cent in paresis, 48 per cent in tabes, and 35 per cent in cerebrospinal syphilis) Conversely we found (Chapter XIX) 54 per cent neurosyphilis in patients with cardiovascular syphilis, and 40 per cent abnormal spinal fluids. Hopkins, in 1571 patients with clinical neurosyphilis, found 12.9 per cent to present complicating tertiary lesions, 8.1 per cent of the cardiovascular mechanism, 5 per cent of the bones

and 2.4 per cent of the skin. Shaw (1940) showed from a review of the literature and his own experience that all forms of neurosyphilis occurred in from 13 to 32 per cent of patients with mucocutaneous or osseous tertiary syphilis.

The practitioner should then, apply the same objectivity to his diagnosis of neurosyphilis as to any other aspect of the disease. While the patient's subjective complaint may suggest it to him much more often his first clue will be found in the eye signs and the lower cord reflexes, taken as part of a routine physical examination.

Important Symptoms.—A very simple group of tests (see p. 46 and Chapter II) and a brief routine questioning will lead to the detection of a large part of symptomatic neurosyphilis in general medical examination. The overenthusiastic must, however, be cautioned here, as elsewhere, to realize that an isolated symptom does not make a diagnosis, and that convulsions, for example, or papillitis, occur in a variety of neurological conditions, and cannot stand alone as evidence of syphilis. Resort to spinal fluid examination now enables the average physician, discouraged by previous complexities, to reach a diagnosis for his patient in a much larger proportion of cases.

Headache.—This symptom of neurosyphilis may vary from a diffuse moderate, and persistent pain to the severe boring and blinding pain of brain

tumor with projectile vomiting. It is usually paroxysmal and so severe as completely to unnerve the patient. It may be confused with the pain of osteitis of the skull. The roentgen ray may assist in differentiation.

Extremely severe headache with stiff neck accompanying basilar meningitis has been relatively uncommon in our experience. It is really remarkable what apparently pronounced grades of meningeal involvement of a basilar type may be associated with little subjective distress. Similarly in what are presumably localized meningeal lesions near the chiasm, pronounced objective signs, including high-grade choked disk, may, apart from impairment of vision, be relatively symptomless.

Lightning pains and paresthesias are not only frequent but also extremely early symptoms. The typical lightning pain is sharp, stabbing, spotlike and may recur again and again in the same place, often singling out a spot such as the heel or the instep for repeated shocks. It is most often described as "like electricity" and of agonizing intensity. Of a different type is the deep aching prolonged "bone pain" of tabes.

In other cases, the pains may come in showers over a considerable area, leaving the skin tender to touch for some hours or a day after the shower subsides. There is no aching quality to the pain, no tenderness to pressure, no accentuation with movement as in myositis and myalgia, and no prickling, numbness, or burning as in neuritis. Accentuation with fatigue and unfavorable

weather changes, and with the onset of infections is the rule and probably helps as much as anything to bring about the common diagnostic misinterpretation of rheumatism.

Paresthesias.—These may consist of fleeting attacks of numbness, tingling prickling, constriction, sensations of cold or heat, shifting from point to point or involving an entire limb or side of the body

Fig. 731

UNSUSPECTED ONSET OF NEUROSYPHILIS

Chief Complaint Stricture of the urethra.
History Locomotive engineer gonorrhea fifteen years ago married twelve years, no pregnancies; t time of Neisser infection had two small warty lesions, called chancroid no treatment no secondaries observed.
General Examination Stricture of urethra. *Soft systolic murmur aortic area* (complains of slight dyspnea, no palpitation) Serum Wassermann negative. Because of venereal history referred for special syphilologic investigation.
Syphilologic Examination No genital scar no leukoplakia.
Provocative negative throughout.
Bone conduction Minus 5 *lowered high fork, moderate eighth nerve atrophy*
Eye examination Negative except for *hyperemia of both fundi.*
Cerebrospinal fluid WR negative; Nonne negative; lymphocytes *18* gold sol 1111100000.
Neurologic examination History of lumbago (?) three years ago *pain and burning* (*right leg; heavy feeling in calf prickling in foot, pain in sacral region.* Would not make diagnosis of CNS lesion on findings. Sciatica (?).
Effect of Treatment Advised to begin treatment on above findings. At completion of first course arsphenamin, "Feels 100 per cent. better All symptoms except prickling in foot disappeared. CSF WR negative; Nonne negative; lymphocytes *5* By the end of the second course the prickling in the foot had disappeared. CSF WR negative; Nonne negative; 4 lymphocytes.

They may be highly localized, fixed or slowly extending, as in the ascending numbness of the extremities which we have learned to interpret as an unfavorable sign in patients under treatment. The sensations of cushion feet and of walking on cotton batting are familiar in tabes. Obstinate

Fig. 732.

ONSET OF NEUROSYPHILIS IN PARESTHESIA (?).

Chief Complaint Burning of the skin of neck, fifteen years. Asked to see skin specialist for this. Wife in hospital for operation.
History Locomotive engineer; gonorrhea twenty-seven years ago, no history genital sore or secondaries. Rheumatic pains in right leg fifteen years; left leg two years, left arm now also. Burning in feet began year ago.
General Examination Blood-pressure 140/86, otherwise negative.
Serum Wassermann negative. Diagnosis indeterminate.
Neurologic Examination Slight impairment of hearing to watch tick. Tinnitus left, Romberg, 1 foot, moderate positive. Slightly diminished bone fork and joint sensation. Left Achilles and triceps obtained with difficulty
Eye Examination Negative.
Bone Conduction Not taken.
Cerebrospinal Fluid WR negative; Nonne negative; lymphocytes *32*
Therapeutic Test This was advised on the above indeterminate findings. Spinal fluid taken with the fifth arsphenamin injection showed Wassermann negative Nonne positive lymphocytes 2, and five months later in declining to return for observation, the patient wrote "All the symptoms I came there with have entirely disappeared and I feel you have made permanent cure. Diagnosis still indeterminate.

Itching at given point or burning of the skin may bring the patient to the dermatologist (Fig. 732). Sometimes the patient detects an anesthesia and seeks relief for it, as in the circumanal anesthesia in which the patient cannot feel his stool pass. The girdle sensation of the tabetic, sense as of tight constricting band about the waist or lower thorax, is highly characteristic paresthetic symptom. Disorders of taste and smell may occur but are decidedly rare.

An interesting theoretical discussion of the mechanism of tabetic pain is given by Pochin (1938)

Disturbances of bladder control and of the sexual reflexes are coming into recognition as important early signs of lower cord changes and as among the first warnings of tabetic neurosyphilis in particular The onset of the bladder symptoms may be so insidious that the patient is entirely unaware of the gradually developing atony of the bladder musculature from paralysis due to impairment of its innervation. He believes himself to be emptying the bladder completely when in reality a residual urine of 100 to 500 cc. may be present. The first warning of trouble comes when the patient wets the bed at night from overflow through a contracted sphincter from a distended bladder "Hard to start" is the phrase most patients use to express the difficulty of relaxing the sphincter and emptying the bladder by its own contractility in the earlier irritative phase. "Dribbling" after a supposed complete evacuation indicates either sphincter atony or a retention of urine in an atonic distended bladder The physician has an unmistakable responsibility in detecting these cases, and the repeated catheterization of a patient without an examination of his reflexes and a search for other neurological signs of syphilis is inexcusable. Cystoscopic examination furnishes valuable and usually conclusive evidence of the nature of a bladder retention, but should be resorted to only when actually necessary for diagnosis.

Ockerblad (quoted by Marshall and Carlson) found 30 per cent of tabetics to have disturbances of micturition and 60 per cent to have bladder symptoms. Shaffer' series showed "cord bladder in 43 per cent (Fig. 759). Marshall and Carlson find that the uninfected atonic tabetic bladder has capacity of from 600 to 1,000 cc. without discomfort, as compared with a normal of 300 to 400 cc. Among Emmett and Beare s (1941) series of 977 patients on whom the diagnosis of tabes was made in the Mayo Clinic from 1934 to 1940 there were 419 (42.8 per cent) who complained of symptoms referable to the urinary bladder Rose and Deakin have proposed the measurement of the capacity of the bladder ("cystometry") as method of differentiating the myogenic and prostatic obstructive changes from those of neurosyphilis. The trabeculation of the relaxed atonic bladder is spoken of as neurogenous or "cord bladder which, hile it may occur ith spina bifida and cord tumors, is overwhelmingly more common in tabes than in other neurological conditions. The late infected tabetic bladder may be hypersensitive small and contracted, and the mucosa inflamed and velvety instead of pale and smooth between the trabeculae. It should not be forgotten that a neurogenous bladder and an enlarged prostate may coexist, so that manual examination of the prostate is not substitute for cystoscopy if the neurological signs are equivocal. Attention to neurological signs and spinal fluid examination may do way with the apparent necessity for prostatectomy as pointed out by Dowling.

Cystometry now has had experimental as well clinical evaluation. It is now rated as a technical procedure which may reveal the earliest sign of injury to the cord in neurosyphilis, obtainable before the development of any but minor urinary complaints and even before other objective evidence of neurologic damage can be demonstrated. The interpretation of cystometric abnormalities when neurosyphilis is asymptomatic is as yet difficult since similar abnormalities may occasionally occur in studies of apparently healthy persons (Boyd and Smith, 1938). Cystometry is also of value in differentiating between damage to the posterior columns in the spinal cord as in tabes dorsalis and lesions of the cortico-spinal tracts as in other forms of neurosyphilis. It may also be useful in determining the proper method of treatment, i. e whether one should use acetyl betamethyl choline hydrochloride (mecholyl) as a parasympathetic stimulant or atropine as a parasympathetic depressant, or presacral sympathectomy A complet bibliography of this subject is given in the review by Moore and Mohr (1939)

In the irritative stage of lower cord involvement the patient may as in Fig. 725, present such a symptom as priapism, though this is rare. More commonly there is transient increase in sexual activity usually not recognized as significant, followed by disappearance of potentia and libido, occurring in our series in 23 per cent of cases W have seen Argyll Robertson pupils and loss of potentia the only signs of tabes which had evidently been quiescent for thirty years

The ocular symptoms and signs of neurosyphilis are dependent in the earlier years on meningeal lesions and especially on basilar involvement, al-

Fig. 733.

EARLY LOWER CORD IRRITATION IN CEREBROSPINAL SYPHILIS SIMULATING MULTIPLE SCLEROSIS

Male, aged *forty-seven*, married.

Complaint: Priapism.
Slight difficulty in urinating.

Prostate Negative. Relaxed bladder sphincter some trabeculation, atonic or cord bladder (?)

Neurologic Examination: Pupils slightly sluggish to light. All lower cord reflexes increased. Babinski markedly positive. Midabdominal and anal reflexes absent.

Diagnosis Probably *multiple sclerosis*. "Rule out syphilis.

Syphilologic Examination Negative history one antemarital exposure.

Blood Wassermann Negative.

Eye: Slight blurring of disks.

Spinal Fluid Wassermann negative on 0.2 c.c., positive on 0.4 and 0.5 c.c.; Nonne negative.
Small lymphocytes, 5?
Gold sol, 0144410000.

Treatment Three courses neo-arsphenamin, 16 injections. Mercury succinimid, 2 courses, 20 injections, 100 inunctions in two years.

All symptoms disappeared and patient has been clinically and serologically normal for four years.

COMMENT

An excellent illustration of the clarifying effect of an examination of the spinal fluid in a puzzling case.

Note that the remainder of the examination is frankly negative for syphilis except for the doubtful cord bladder

Excellent therapeutic results, equalling anything in the field of serious medical treatment, can be secured in neurosyphilis by early effective attack, following prompt diagnosis.

Fig. 734.—Slight ptosis and diplopia due to partial paralysis of the third cranial nerve (right) Note the beginning outward and slight downward deviation of the eyeball. The patient recovered under treatment.

though meningitis of the convexity may likewise occasionally give rise to ocular lesions (Nonne) The ptosis, diplopia, and strabismus are parts of the

general group of cranial nerve syndromes (see Chapter XII) and may be slight or pronounced, translent or permanent (Figs. 734–737) Failing vision may be due to primary or secondary changes in the optic nerve While it may ac-

Fig. 735 —Total paralysis of the right third cranial nerve, with complete ptosis, turning of the eyeball outward nd somewhat downward, pupil dilated and immobile, accommodation paralysed, and crossed diplopia. This paralysis was permanent.

company an active inflammatory process, it does not necessarily do so, and vision may be unaffected by a choked disk of several diopters or a marked neuroretinitis. Papilledema of syphilitic origin may occur as a result of basilar

Fig 736.—Right seventh nerve paralysis disclosed by the attempt to smile The eye on the paralysed side cannot be completely closed.

meningitis or optic chiasm arachnoiditis (Alpers and Yaskin 1935) It may occur without increase in intracranial pressure in lesions at the chiasm (Hausman, 1942)

Nonne emphasizes, as do many other authors, that the detection of the real extent of optic nerve involvement cannot be done by clinical signs, but must be accomplished by routine ophthalmoscopic examination and the taking of perimetric fields on *all* patients with syphilis. *Lillie*, in examining a series of Mayo Clinic cases, was impressed with the fact that failure to take visual fields before treatment is begun is responsible for the impression that some drugs cause much damage to the visual tract, when in reality much of the damage is caused by syphilis itself.

Secondary optic atrophy following inflammation or papillary edema is not as significant of grave or extensive neurosyphilis as is the pale gray sharply defined disk of primary optic atrophy. Of the latter Nonne says that practically invariably tabes or paresis is a forerunner or a sequel.

Hausman (1937 1941) made careful studies of the syndrome of syphilitic chiasmal arachnoiditis which may manifest itself as the classic form of primary atrophy of the optic nerve, with heteronymous visual field defects or multiple cranial nerve lesions adjacent to the optic nerve or as the less frequent form of papilledema without internal hydrocephalus or increased intracranial pressure. In differential diagnosis one must rule out an expanding lesion (tumor cyst or aneurysm) which may be intrasellar suprasellar or parasellar arachnoiditis (nonsyphilitic or syphilitic);

Fig. 737.—Bilateral external ophthalmoplegia due to paralysis of the external ocular muscles without involvement of the ciliary body and iris (partial nuclear involvement of the third nerve).

trauma or heredodegeneration. The nature of the pathologic process is such that it compresses the optic nerves and chiasm but it is not known why this local process around the chiasm should produce atrophy of the optic nerve in one case and papilledema in another. Since antisyphilitic therapy offers little relief in these cases, Hausman considers surgery the method of choice. In one of our cases no relief was obtained from both methods of therapy.

The study of the pupillary reflexes as a guide to early neurosyphilis is one in which the personal equation and experience of the examiner plays some part.

The conditions for testing eye reflexes described in Chapter II are not acceptable to some ophthalmologists, who demand a preliminary stay in the dark room and flash testing of the light reflex. If the slightest response of the pupil to light is obtained, it cannot be described as of the *true Argyll Robertson type. Spiller on the other hand, from the neurological standpoint insists* that overemphasis on absolute fixation discourages recognition of early and "abortive" changes.

It is a temptation to insist, for its dogmatic teaching value, that marked irregularity of the pupils, sluggishness, or an outright loss of light reflex, with preservation of accommodation is pathognomonic of neurosyphilis. Nonne, in an excellent review of this question in the light both of the literature and

his experience, concludes that, in the main, reflex fixation of the pupil to light with reaction to accommodation is regarded as distinctive of neurosyphilis in the overwhelming proportion of cases. Adie has defined the Argyll Robertson pupils as small pupils, constant in size, unaltered by light or shade, contracting promptly and fully on convergence, dilating promptly again when the effort to converge is relaxed and dilating slowly and imperfectly to mydriatics.

The value of pupillary signs in the diagnosis of neurosyphilis must be critically considered in the light of our growing comprehension of arteriosclerotic phenomena of lethargic encephalitis and of Adie syndrome. Nonne states that the pupillary disturbances of arteriosclerosis are not typical, but that chronic alcoholism, delirium tremens, the onset of syringomyelia, occasional cases of nicotine poisoning, multiple sclerosis, and congenital abiopinaus may present reflex pupillary rigidity to light. These instances are, however rare exceptions. Riddoch points out that lethargic encephalitis and cerebral tumor involving the part of the midbrain concerned in the light reflex, may give the picture of Argyll Robertson pupil. Adie believes there is a benign syndrome of absent light reflexes and absent knee reflexes not due to syphilis. Menninger found only 34 per cent of the 176 abnormal pupil cases identified in 1000 examinations to be syphilitic —but he did not, apparently examine the spinal fluids. The importance of the encephalitis group of pupillary disturbances has certainly increased in the last several years. An enlarged left pupil, fixed to light, was recognized in a patient with absent Achilles reflexes and attacks of abdominal pain, simulating abdominal angina pectoris. The pain was later shown to be due to gallstones and absolutely no signs of either syphilis, encephalitis, or arteriosclerosis developed on complete examination and observation.

Adie's Syndrome (Pseudo-Argyll Robertson or Tonic Pupil).—In 1932 *Adie* described a syndrome consisting of tonicity of the pupils and absence of tendon reflexes which occurs in otherwise healthy and neurologically normal persons, mostly females. In its complete form one finds a combination of tonic convergence reaction, apparent absence of direct and consensual light reaction, and absence of tendon reflexes. In incomplete forms one may find (*a*) tonic pupillary reactions alone (*b*) atypical phases of tonic pupillary reactions alone; (*c*) atypical pupils with absent tendon reflexes; or (*d*) absent tendon reflexes alone. Adie pupil is frequently unilateral (80 per cent of cases, Kennedy Wortis, Reichard and Fair, 1938) and is usually dilated. The convergence reaction which is normal or hyperactive in Argyll Robertson pupils is tonic in Adie's syndrome, *i. e.*, one finds strong contraction of the pupil on convergence and for several minutes after it has ceased. While the Adie pupil appears to be lightfast in ordinary testing of the light reaction, if the patient remains in the dark quarter hour or longer the tonic pupil gradually dilates and on exposure to strong light slow contraction sets in. The reaction to mydriatics while poor in the Argyll Robertson pupil is normal in Adie pupil. There is no hereditary factor in Adie's syndrome nor any relationship of this syndrome to syphilis. It may be due to partial degeneration of the post-ganglionic fibers from the ciliary ganglion to the sphincter muscle (Scheie, 1940; McKinney and Frocht, 1940; E. Spiegel, 1941; Lowenstein and Friedman, 1942; Dynes, 1942.) Ophthalmologic consultation is desirable.

The rechecking of doubtful cases by complete syphilological examination has convinced us that it is safer for the diagnostician to regard pupillary disturbances as presumptive of neurosyphilis and to trace this possibility to the ground by adequate study than to accept too readily the likelihood of occasional exceptions. A spinal fluid examination and a complete serological and neurological examination are *sine qua non*.

Isolated Pupillary Signs and "Tabes Imperfecta."—It should not be too readily concluded that the isolated pupillary abnormality without other signs or symptoms, is merely a scar and that the process which brought it into existence is inactive or burnt out."

Dreyfus, in 1918, as result of thorough study of series of cases to which, however only short course of treatment was given, concluded that in 35 to 40 per cent of such cases the pupillary anomaly was residuum of previous "saturation of the nervous system by the infection, and that it was not, in such cases, necessary evidence of an active process. Nonne personal observations

lead him to the belief that there exists distinct type of "tabes imperfecta in which isolated pupillary anomalies, even coexistent with an abnormal spinal fluid, may remain nonprogressive over period of many years if not for life. He concludes with definiteness, on the basis of completely studied case with autopsy that if the spinal fluid be normal in the presence of an isolated pupillary anomaly the syphilitic process may be regarded as healed. This, it seems to us, is still *sub judice*, in view of growing evidence of the fact that negative spinal fluid is entirely compatible with progressive and serious neurosyphilis.

Pallor of the Disks.—Somberg in 2000 syphilitic patients with paretic symptoms found 4.2 per cent to have pallor of the disks which went on to optic trophy in 20 per cent. In 60 per cent of the group, however the fundus picture of optic atrophy was not followed by functional impairment even over period of two years.

None the less, Nonne's warning that slight fluid abnormalities accompanying isolated pupillary changes must not be too unfavorably interpreted in estimating prognosis is a valuable caution, for examples of negative fluids with isolated pupillary disturbances and apparently completely quiescent or "cured" infections, especially in women, do occur

The Seizure or Convulsive Attack.—This is one of the common symptoms of diffuse, or cerebrospinal, and of paretic neurosyphilis. It may appear within a few months after infection in precocious cases, or after a lapse of many years. Prodromal or abortive seizures may recur for years before coming to full intensity or the first attack of the apoplectiform type may be fatal. Localizable types, with the characteristics of jacksonian epilepsy and nonlocalizable types, indistinguishable clinically from idiopathic epilepsy are recognized. The frequency of seizures in neurosyphilis is a matter of dispute.

Nonne, while unable to offer figures of his own, contrasts the views of Neanya who saw only one example in 105 cases, and Heubner who saw 28 examples in 45 cases of cerebral syphilis. Southard and Solomon quote Kraepelin as finding 30 to 40 per cent of seizures in paresis, and 65 per cent of paretics were found to have had seizures on admission to the Munich hospital. Our own observations on general material showed 9 per cent to have suffered loss of consciousness, and among known neurosyphilitics, largely nonparetic, 6 per cent to have had epileptiform convulsions or petit mal attacks.

The description of various types of seizures given by Southard and Solomon is excellent, and is quoted verbatim.

"The most frequent seizures are epileptiform and bear resemblance t cortical epilepsy; but more rarely these seizures resemble the ordinary epileptic attack or consist of general shaking of the whole body A variety of initial minor disorders usher in the attacks; the temperature is often increased. The attacks are over after one or at most, few hours. Kraepelin speaks of one that lasted fourteen days. Sometimes *status paralyticus develops, suggestive of the status epilepticus*. Another rare form of characteristic seizure is the apoplectiform, which can hardly be told from an ordinary stroke, and may be followed by the usual postapoplectic phenomena. A good many of the strokes leading to sudden death in middle life are probably cases of neurosyphilis, although often set down as early arteriosclerosis of nonsyphilitic nature. Besides the epileptiform and apoplectiform seizures, there are certain seizures of less definite and complete nature, ranging from simple fainting spells, dizzy spells and petit mal ttacks to various special forms of irritative muscular contractions and temporary speech disorders. Sometimes these attacks occur with complete preservation of consciousness. Transient paresthesias, visual field defects, and especially ttacks of vomiting which, according to Kraepelin, may precede paresis by years (of course in this connection gastric crises of tabes must be thought of), may be counted as sensory seizures.

Paralytic phenomena may assume the form of monoplegias affecting single member or limb, or group of muscles in the face or elsewhere, or they may be true hemiplegias with complete involvement of one side. The onset may be sudden, or gradual, extending over weeks or months. These symptoms are usually the result of regional obliteration of the vascular supply of special areas with resultant softening, or of the invasion of the area by gummatous infiltration, either within the brain tissue itself or from the enveloping meninges.

The immediate prognosis of the epileptiform seizures in paretic neurosyphilis, without treatment, is good but it is a distinctive feature that with each attack the recovery only carries the patient to a point somewhat short of the recovery which he made from the preceding attack. There thus ensues a cumulative deterioration, with ultimate complete degenerative and fatal outcome. According to Southard and Solomon, no gross pathologic change can be recognized in the vessels and membranes, the pathologic change being evidently one of microscopic injury

Braetsch and Bahr (1937) reported 5 cases of syphilitic epilepsy in 4 of which multiple gross lesions of the brain cortex were present which were due to syphilitic vascular disease. In the fifth patient microscopic areas of softening in the central convolutions were associated with syphilitic endarteritis of the cortical capillaries. The pathology in all cases was characteristic of the meningovascular type of neurosyphilis. Epileptiform seizures, usually of petit mal type, are an annoying residue of otherwise reasonably successful treatment of cerebral neurosyphilis, particularly juvenile paresis in occasional cases under our observation. They are controllable by sedatives but may be part of a slow deterioration.

Speech Disorders.—These include especially aphasia and the dysarthria of the paretic. The former is, of course, a function of damage to a particular cerebral area, and hence chiefly associated with vascular gummatous, and meningeal lesions It has been our experience that the fugitive, transient, incomplete aphasic attack with recovery repeated again and again from an otherwise clear symptomatic sky has a more unfavorable ultimate prognosis than the sharply defined single attack from which recovery is slow or imperfect. It may precede by years the appearance of true paretic changes.

In studying speech symptoms care must be taken not to read aphasia into every moment of confusion due to fatigue alarm, language difficulty weakness, deficient thought control and nervous exhaustion, especially in taking the medical history The effect of nervous excitement in accentuating symptoms of this sort, is pronounced, and we have known them at the first interview t give an entirely false impression of the patient condition.

The dysarthria of early paresis is essentially a slurring of words. Together with relaxation of the facial muscles it makes a combination that arouses suspicion on sight.

So long as the patient retains the clipping sharpness of his speech one is tempted to say from therapeutic experience at least, that degenerative changes are still in the future. When the tongue begins to loll around the words, elisions to appear in the syllables, and the base of the tongue is swallowed in the effort to articulate a sentence, paresis has really begun. The test phrases, emphasizing the "r" are the ones which most quickly bring out significant defect—"truly rural, and "third riding artillery brigade. The implication of the tongue innervation and musculature in tic-like spasm is certainly suggested at times by the way in which the patient will bring the tip of the tongue forward by licking or sucking the lip, and then manage to bring out the phrase more nearly intact The effect of practice at repeating test phrases in reeducating the patient with insight to pronounce them better must be considered in estimating improvements based on speech changes It is better to depend on conversation than tests in observing the patient' progress.

Speech defect secondary to outright paralysis, as in the recent hemiplegic, must also be distinguished from the dysarthria of paresis.

Cerebral Neurasthenia.—The neurasthenic syndromes of syphilis have in our experience with the medical recognition of neurosyphilis, been among the chief sources of diagnostic error The distinction from true neurasthenia is undoubtedly at times extremely difficult to draw and there will be occasions when even the conscientious examiner will hesitate at carrying his study to the point of spinal fluid examination in a patient who offers no suggestive clinical or anamnestic signs. Yet it may be confidently asserted that nervous breakdown in middle life is so frequently a stalking-horse for paresis, and for

less fatal though ultimately incapacitating syphilitic lesions of the nervous system, that spinal fluid examination, to say nothing of routine and repeated blood serologic tests on all patients with nervous breakdown, can scarcely be too often resorted to. When syphilis is suggested at any point Nonne has well phrased the situation by saying that "a neurasthenic with syphilis in his history suggests a paretic." In all such cases examination of the spinal fluid is imperative. All syphilitic neurasthenia is not, however incipient paresis, as will subsequently appear

The multiplicity of somatic and psychic symptoms to which neurosyphilis can give rise affords the widest possibilities of error Of some of these possibilities the cases cited offer interesting examples.

Fig. 738.

"LATENT" SYPHILIS

Male, laborer, aged thirty

Chief Complaint: Pain in the knee, three months duration.
History Pain and stiffness of gradual onset. One month ago railroad doctor told him he had syphilis, but gave no treatment. Knows nothing of any infection, but had gonor rhea eighteen months ago. General health excellent.
General Examination Some grating in knee, no pain or tenderness, no limitation of motion, no swelling. Ray negative. Serum Wassermann positive. Result distrusted, but was positive on repetition. Referred to syphilologist.
Neurologic Examination Congenital divergent strabismus, slight pupillary irregularity neurologic examination negative.
Cerebrospinal Fluid (done routinely ... kh second arsphenamin injection) WR ///; Nonne positive; lymphocytes 18 1; colloidal gold 5554333810.

No Examination for Syphilis or of Syphilitic is Complete Without Full Study of the Spinal Fluid.

Backache simulating sacro-iliac strain, headache, ill-defined paresthesias, and often conspicuously gastro-intestinal symptoms, may dominate the scene, all to vanish on the institution of effective treatment for the underlying neurosyphilis. The tendency to dismiss from observation with reassurance only an apparently neurasthenic patient who has negative physical and elementary laboratory examination, stands next to inadequate physical examination, the over looked blood serologic, and neglected spinal fluid test, as cause of error Periodic reexamination will still make reasonably early correction of an error possible.

On the other hand hasty diagnosis of neurosyphilis from gastric crises to paresis should not be made in the absence of clinical or laboratory evidence of syphilis in patients with tension syndromes, anxiety neuroses, focal lesions of infective nature and vagus-sympathetic disturbances leading to spastic functional symptoms, etc.

It is unfortunately impossible to point to a distinctive symptomatology for syphilitic neurasthenia (Fig 739)

Fournier emphasized syphilitic insomnia; the early appearance of increasing difficulty of concentration, and the memory loss for recent events are frequently spoken of. Crises of confusion, depression, hyperactivity flightiness, and even maniacal excitement may occur Tremor especially of the lips, often seems an early warning. Riddoch states that the headache of the neurasthenic is discomfort, that of the syphilitic pain. None of these items has pathognomonic value.

The ultimate resort must be the painstaking history the thorough-going physical and the neurological examination, repeated blood Wassermann tests, the spinal fluid examination, and insistence on observation.

Delusions, character change, and what Southard and Solomon very aptly term *conduct slump* may precede by months and even years the appearance of gross symptoms of cerebral or paretic neurosyphilis.

These early and often insidious mental changes form the basis for business upheavals and collapses, family tragedies and crimes of violence occurring seemingly without medical or social background. An increasing expansiveness, accompanied by a diminution of critical faculty or merely increasing egotism with decreasing justification, such as one sometimes associates with the presenile state, develops. Exultations and depressions may become gradually more pronounced and causeless. An overgrown tendency to enter upon new enterprises at an age when conservatism usually comes to the fore, inability to see obvious obstacles, overliberal speculative use of resources in the face of existing responsibilities may be the first warning of impending trouble. The handwriting signs of omitted letters and words and tremor may be detected in the patient's signature, business correspondence, and check writing. Causeless rages directed against children or animals may early attract attention, although the patient may remain for a long time amenable to reason and repentant after each outburst. The sudden slackening of a previously rigid sexual morale may be a significant symptom. Before diagnosis becomes apparent the patient may be involved in

Fig. 729

"NEUROSIS AND OVERWORK" IN MIDDLE LIFE

Man, aged forty-five.

Chief Complaint. For several years has been having backache, pain in abdomen and rectum, headache, lassitude, sore throat, constipation, nervous breakdown eight years ago. No energy, especially in damp weather. Loss of weight.
Operations. Appendectomy for abdominal distress, no relief. Dilatation of sphincter and curettage of rectum for rectal distress—no relief. Tonsillectomy for sore throat—no relief. Turbinectomy for headache—slight relief.
Significant findings first examination. Liver palpable, eyes negative (refraction only), ears negative, rectum negative, but sphincter relaxed. Redundant sigmoid.
Diagnosis (3/29/16). Neurosis, overwork, needs vacation.
Overlooked in First Examination. Wassermann; history of venereal warts and gonorrhea, leukoplakia, pupillary reactions and deep reflexes.
Additional symptoms on return (6/17/16). Numbness, cushion feet, urine hard to start.
Additional findings on return. Unequal, slow pupils, absent right patellar, left Achilles reflexes, positive Babinski, joint sense —3.
SWR. Negative.
Spinal Fluid. WR *+++*. Nonne positive. Cells 8. gold sol 0012333100.

bigamy or be pilloried by a breach of promise suit. Carelessness in the details of dress and toilet may become apparent before any definitive signs sufficient to bring the patient to the physician appear. The "spotted waistcoat" goes with the increasing flabbiness of mental and physical tone. Persecutory ideas (paranoid state) may after a considerable period of silent brooding, come suddenly to the front in a single phrase or outburst that may subside again only to take form months later in some well-directed attack upon an object. The comparative clearness of the mental background from which explosions may sometimes arise well emphasizes the care that should be taken in releasing from custodial control the cerebral syphilitic who has once shown definite signs of persecutory delusions. J.H.S. has received telephone warning in the small hours of the early morning that a former patient, released long before from a state asylum after symptoms of mental disturbance due to neurosyphilis, by no means distinctively paretic in type, had just attempted the cutting of his wife's throat with the family carver and was on his way for medical advice. The intellectual "front" of such a patient may be unbroken a moment before such an occurrence; the tearful depressed or even the morose neurosyphilitic may be less dangerous.

Caution in Interpreting Early Mental Signs.—It should be emphasized that there is little of absolute specificity in any of these early signs. They may in mild forms be the earmarks of arteriosclerotic degenerations, the cap-

illary thromboses emphasized by Alvarez of encephalitic processes other than those of syphilis, of cerebral neoplasms, and of nonparetic syphilitic as well as true paretic dementia. None the less they may come early to the attention of a careful medical examiner and demand further study including at least a blood serologic test, a checking of pupils and reflexes, and further observation. The entire picture rather than the isolated details makes the diagnosis. Foster Kennedy's emphasis on fatigue is summarized below

In taking the history of such patients indirect evidence from the statements of others should be examined critically with respect to motive, for friends, associates, and even marital partners may have personal reasons for prejudiced testimony or may be unduly suggestible. The physician may at times be made the tool of a scheme to secure a power of attorney, the sequestration of a wealthy person, or the replacement of a chief by some ambitious and unprincipled subordinate. In critical cases involving important persons and interests the slowing down of the process of examination to allow time for better acquaintance with the patient himself, and a development of his confidence in the examiner may lead to valuable clues and correct mistaken impressions.

The Common Objective Signs of Neurosyphilis.—Among the important objective signs of early neurosyphilis, the sensory changes detectable by neurological examination take a place comparable to that of pupillary abnormality. It is a mistake to limit the search for these signs to the obviously tabetic or paraplegic case. They furnish some of the earliest warnings, especially of thoracic and lumbar cord and sensory root involvement, even in the seemingly healthy individual. The tendency of these changes is to appear earliest in the regions supplied by the lower segments of the cord, *e. g.* over the feet, legs, and thighs, and the lower thorax and abdomen. Sensitiveness to pin-prick especially should be carefully tested for the "islands" of analgesia, sometimes but not always symmetric, may be less than a palm-breadth in diameter. Gordon Holmes emphasized the dissociation of sensation, so that while a patient may exhibit an analgesia to pin-prick in a given area, his reaction to touch or to heat and cold may be normal or much less reduced. Reduction in vibratory sense as obtained with the tuning-fork (C 128) over the tibia and the malleoli, and decreased sensitivity of the Achilles tendon on pinching are common and suggestive early changes. In higher cord involvement and basilar lesions the upper extremities and the face are more affected, but it is not unusual to see the most extensive sensory changes in patients whose subjective symptomatology suggests only lower cord involvement.

Loss of the sense of motion and position, which means essentially that the patient, with his eyes closed, cannot tell where his members are or in what direction they are moving or being moved, is the basis of tabetic ataxia, and may be early detected by finger-to-nose and heel-to-knee tests, and by having the patient describe the direction of movement of a passively moved member with eyes closed. In the latter case it is important not to permit a clue to "leak through" by way of the pressure sense.

The importance of a sensory examination of the patient with early neurosyphilis is not alone diagnostic, but serves a valuable purpose as a base-line in subsequent rechecking of the progress of his disease, which, as we have mentioned, may take place in spite of a negative spinal fluid examination, and be evidenced only on his sensory chart and in his increasing disability. Unfortunately the detection of these finer sensory changes calls for experience and practice, and should not be too rashly undertaken by the practitioner.

The Romberg test and ataxia can be observed in any office examination. The patient should be questioned as to the onset of unsteadiness on the feet

when he is deprived of his sense of sight, as, for example, in washing the face or after dark. In doing the test the patient stands with toes and heels in contact and eyes closed He should be protected from falling As a remedy for the inclination of an oversuspicious examiner to interpret the slightest wavering in the patient, the checking of normal persons, and an occasional test on himself will not come amiss. Unsteadiness in standing on one foot with eyes closed must be interpreted with caution. The ataxia of the tabetic may range from the slightest tendency to come down hard on the heels and to separate the feet in walking, to almost a total paraplegia, in which the knees cave outward and the sole slaps the pavement with a resounding thwack, the foot being thrown ahead almost as an inert object. The spasticity of combined sclerosis may first appear in the toe gait or steppage or be recognized by slight stiffness in gait and slight tremor and tension of the calf muscles. The halt foot limp or slight dragging of the foot and the slightly flexed arm on the same side may be the first sign of a slowly developing hemiplegia, or the residuum of an acute accident. The wearing of the toe of the shoe on the affected side may be early noted Tests for ankle clonus and plantar flexion of the great toe (Babinski) and "push-and-pull" and "hand-grasp" tests of muscle power on each side detect the beginnings of these changes

As in the case of test phrases in detecting speech defect it is possible for the patient with ataxia to improve himself by practice and thus to vitiate the effect of subsequent tests by a succession of examiners.

SEROLOGICAL FINDINGS IN NEUROSYPHILIS

After reference to foregoing discussions and especially to Chapters IV and XII (early neurosyphilis) the serological status of neurosyphilis as a guide to clinical neurosyphilis may be reviewed from Figs. 740–741

Menninger and Bromberg (1935) found among 400 cases of various types of neurosyphilis with positive spinal fluids that 31 per cent gave negative blood serologic reactions and 69 per cent gave various grades of positivity (44 per cent, "4 plus") In an extended study of the serology in general paresis, Blalock and Hesse (1938) noted that of all patients, irrespective of the kind of treatment they received, 8 1 per cent had a negative blood Wassermann reaction prior to therapy. This corresponds with the 8 6 per cent of paretics untreated with arsenicals with positive spinal fluids and negative blood serologic reactions observed by Kierland, O'Leary and Vandoren (1942) or to the 10 4 per cent in paretics treated with arsenicals prior to the tests.

Provocative Reaction in the Spinal Fluid.—Inasmuch as clinical symptoms may be lacking, the provocative spinal fluid test may become an important factor either in diagnosis or in determining the activity of a known syphilitic process apparently quiescent on ordinary examination. The unreliability of the provocative effect on the blood should be recalled P 77

The observations of Solomon have been confirmed by subsequent reports and by our own experience. Cestan, Riser and Bonhoure in a study of 69 cases found that in no case was a provocative effect on the spinal fluid, either in the form of a positive Wassermann reaction or an increase in albumin or lymphocyte count obtained in the absence of syphilis, or in syphilis devoid of previous clinical or serological evidence of the disease The activation of a negative fluid occurs only when neurosyphilis is present, and may be produced by as little as a single injection of neoarsphenamine although several injections may sometimes yield a delayed positive result.

The delay occasionally observed in appearance of the provocative effect is in keeping with the slower reaction and greater inaccessibility of the nervous

system and has been confirmed in our experience. It is best for this reason to perform the spinal test at the end of a complete provocative procedure, seven to ten days after the arsphenamine injection, or even later to detect the development of positive signs.

Costan et al. find reactivation of the Wassermann reaction to be the most frequent occurrence. They believe the spinal fluid provocative test to be of principal value in determining the status of seemingly inactive or "burnt out" neurosyphilis, of asymptomatic cases, and of

Fig. 740.

FREQUENCY OF COMBINED NEGATIVE BLOOD WASSERMANN AND NEGATIVE SPINAL FLUID IN SYPHILIS IN GENERAL

	Per cent.
Early cases	16
Treated cases after second year	47
Late syphilis	16–18
Untreated syphilis	4–7

These estimates are based on the summaries of Stokes and McFarland, Stokes and Brown, Stokes and DesBrisay and Fordyce and Rosen, aggregating 1635 cases.

patients who have been under treatment. Dunlop could find no evidence of nonspecific provocation of positive Wassermann reaction in the spinal fluid by the administration of neoarsphenamine.

It is important to stress the fact that the slightest suggestion of a provocative effect in a quiescent neurosyphilis should be followed by enough treatment to insure against a dangerous revival of activity and that a second examination some months later is needed to determine the return of the fluid to normal. Otherwise there may ensue the dangerous "reactivation" of the process, as emphasized by Ravaut and others.

Fig. 741.

FREQUENCY OF A NEGATIVE SPINAL FLUID IN UNDOUBTED NEUROSYPHILIS

	Per cent.
400 patients with preponderantly late syphilis had neurosyphilis in	73
400 patients with preponderantly late syphilis had abnormal CSF in	63
Proportion of negative spinal fluids in neurosyphilis	*13*
405 patients with neurosyphilis (treatment study) had negative CSF in	7
76 patients with tabes dorsalis had negative spinal fluids in (Walker and Haller)	16

The Spinal Fluid Wassermann.—The most frequently quoted interpretations of blood and spinal fluid Wassermann tests in late syphilis are those of Nonne, who very properly laid much stress upon the amount of spinal fluid used. He all but suggests that the strongly positive Wassermann reaction on 0.2 cc. of spinal fluid is one of the earmarks of general paralysis. He obtains from 85 to 90 per cent positive Wassermann reactions in this concentration in paresis as against 20 per cent in tabes and 20 to 30 per cent in cerebrospinal syphilis. On the other hand, with 1 cc. of spinal fluid most tabetics yield positive Wassermann reactions; paretics and taboparetics are practically invariably positive, and patients with cerebrospinal syphilis also yield almost 100 per cent positives. Gennerich stresses relatively low proportion of positive spinal fluid Wassermann reactions in combined tabes and myelitis. One of the most interesting groups of figures (Fritzsche)

ness with a consequent decline in social status, has aptly been designated by Collins as "psychic scar" and occasionally occurs in vascular syphilis. Cases seemingly typically vascular at the outset, may go for years without other signs, ultimately only to pass over into general paresis.

Fig. 744.

CHARACTERISTICS OF PARALYTIC ACCIDENTS IN VASCULAR NEUROSYPHILIS

Paralyses may be partial or total, mono-, hemi-, or triplegias.
Onset may be sudden, but is often gradual with gradual recovery.
Gradual ascending or descending paralysis may occur.
May be no signs of insult such as loss of consciousness, convulsions, etc., even in sudden and total paralyses.
Lesions may be central, not cortical.
Triplegias are uncommon; both extremities of one side, one of the other.
One paralysis may follow another or convulsions may affect a previously paralyzed limb.
Marked tendency to recovery is the rule; rarely fatal. The commonness of thrombosis as contrasted with arteriosclerotic hemorrhage is the explanation.
Aphasia is common often with a monoplegia or hemiplegia or seventh nerve paralysis. Usually motor in type and transient.
Bulbar symptoms may develop from thrombosis of the frequently involved basilar artery; ocular paralyses, disturbance of speech and swallowing reflexes, with crossed paralysis of the extremities.
No sensory disturbance in most cases.
Pupillary changes usually absent (uncomplicated cases).
Occasional central hemianopsia.
Serology: Blood usually positive, spinal fluid negative or only slightly abnormal (Type I).

Fig. 745.

DIFFERENTIAL CONSIDERATIONS IN VASCULAR NEUROSYPHILIS

Patient too young for arteriosclerosis.
Syphilitic history may be obtainable (or may not).
External collateral signs of syphilis are likely to be lacking.
The blood serologic reaction may be positive (or may not).
The spinal fluid examination may be positive (or may not).
The therapeutic test may be meaningless (spontaneous recovery).
The diagnosis may have to be made by exclusion:
No gross arteriosclerotic signs (inspection, palpation, blood-pressure).
No demonstrable renal insufficiency (uremic hemiplegia or convulsions). Urine and blood were normal.
No cardiac lesion to explain thrombosis or embolus.
No acute infection.
No disease causing vascular injury: Leukemia, pernicious anemia, diabetes, alcoholism, metallic poisoning (arsphenamine, etc.).
Among the possibilities consider: Arteriosclerosis, idiopathic apoplexy in youth, brain tumor; multiple sclerosis, uremia, hysteria, migraine with hemiparesis, general paralysis, solitary tubercle of the pons, heart disease in young syphilitic patients.

Cerebral Meningeal Neurosyphilis.—The symptomatology of cerebral meningeal neurosyphilis is outlined in Figs. 746 and 747.

In order to facilitate comparisons, the symptomatology of meningitis of the convexity of the brain is given in Fig. 747 also by recalling that the two processes may combine, and especially so in the later cases. In general, as one reviews the chronological perspective of neurosyphilitic lesions, those of the base and particularly of the optic and the seventh and eighth nerves, a

might be expected, appear more conspicuous early in the disease, while the nuclear lesions come to the front later

Importance of Recognizing Prodromes.—It is apparent that meningitis of the convexity with its essentially nonspecific symptomatology can be much more readily diagnosed objectively

Fig. 746.

SYMPTOMATOLOGY OF BASILAR MENINGITIS

Headache: Usually severe; pain deep in the eyes, sensitive to percussion over the brows.
Dizziness and Vomiting Not unusual and not distinctive.
Stupor or Excitement: Elaborate psychotic disturbance rare and usually due to combination with other lesions.
Fever: Not unusual, but apt to be atypical. Occasionally but rarely high, rarely subnormal temperature.
Optic Neuritis and Papilledema: Most important nerve lesion, more frequent than in any other form of brain syphilis. Examination of both fundus and fields essential.
Ocular Muscle Palsies Partial oculomotor (N III) palsies the commonest type, ptosis, diplopia, pupillary disturbance, strabismus. Total third nerv paralysis (accommodation also) usually late. Ptosis the commonest symptom. Combined pupillary and accommodational disturbance suggests tabes or paresis (Nonne)
Other Cranial Nerve Lesions: The combination of second and third nerve lesions with those of other cranial nerves suggests cerebral syphilis as against tabes dorsalis.
Polyuria, Polydipsia, Pituitary Syndromes Relatively rare may take the form of diabetes insipidus, infantilism, dystrophia adiposogenitalis, etc.
Symptoms of Bulbar Lesions and lesions of the ninth, tenth, eleventh, and twelfth cranial nerves rare. Glycosuria, central deafness, trapezius paralysis, tongue paralyses, etc.

when combined with enough basilar involvement to supply the more distinctive signs of cranial nerve palsies. Combinations with vascular lesions may materially increase the complexity of the picture without altering its general trend. In If it may be quite impossible to separate meningeal from vascular symptoms, and only the outstanding localized lesions will be clinically identified by the average physician. The emphasis should be placed on the similarity of the early symptoms

Fig. 747

SYMPTOMATOLOGY OF MENINGITIS OF THE CONVEXITY

Headache Diffuse or localized, often boring; frequently but not invariably worse at night patient may seem deafened.
Tenderness on Percussion: May be localized over special area of the skull; not pathognomonic.
Attacks of Dizziness Occasionally the chief or only complaint.
Vomiting Not specific in character but sometimes suggesting the crises of tabes dorsalis.
Pupillary Anomalies Occasionally Isolated symptom.
Psychic Disturbances: Resemble those in vascular syphilis of the brain neurasthenic symptoms, occasionally delirium suggesting infection, more frequently progressive dementia, apathy amnesia, inertia and hebetude, altered personality and retarded (not aphasic or dysarthric) speech.
Papilledema or Choked Disk: Occasionally
Epileptiform Convulsions Generalized or jacksonian, or both combined frequency matter of dispute.
Hemiparesis and Paralysis Rarely monoplegias.
Cortical Speech Disturbances Aphasia, short duration, incomplete, speech groping. Associated with motor disturbances of face and extremities.
Hemianopsia Rare

and prodromes of the various later and more serious changes in both vascular and meningeal syphilis of the brain. No persistent or severe stupefying headache should ever escape at least the check of blood serologic test, nor should negative result be uncritically accepted. Alterations of personality and neurasthenic beginnings should not be dismissed as overwork or "nervous breakdown, nor mental disturbance be given merely symptomatic label without review of the possibility of syphilis, regardless of the person involved Resort should be had more fre-

quently in the consideration of all affections of the nervous system, to the steps of an elementary neurological examination which identify partial palsies and reflex changes, and to a search for pupillary and fundus signs whose importance is paramount in the symptomatic picture of treatable cerebral syphilis. Even granted some initial opposition to a spinal test, the physician can in most cases, once a definite neurological complex becomes apparent, secure consent to clear the diagnosis at once by a properly performed serological examination if no contraindications exist.

Acute syphilitic meningitis, while unusual, is not excessively rare. It is essentially the homologue of acute syphilitic nephritis and acute syphilitic hepatitis. Fahr case developed in the ninth week after infection, with fatal result. The 5 cases which Stokes has seen, while less fulminating, had the classical signs of acute meningitis, including headache, Kernig sign, neck rigidity and fever but without delirium or pupillary changes. The spinal fluids in all cases showed turbidity and cell counts over 1000 per cubic millimeter. The negative smear and culture and the positive blood and spinal fluid Wassermann established the diagnosis, and recovery took place under mercury and iodide, followed by arsphenamine.

Merritt and Moore (1935) in an important study of the literature and 80 cases of their own found that from 0.2 to 5 per cent of cases of early syphilis develop meningitis. Most of the cases occur within the first six months of the infection in patients who are untreated or inadequately treated. These authors describe 3 groups. (a) Acute syphilitic hydrocephalus (26 cases): These patients have headache, nausea and vomiting, choked disks and meningeal signs (involvement

of posterior fossa interfering with the circulation of the cerebrospinal fluid and causing internal hydrocephalus). (b) Acute vertical meningitis: Headache, nausea and vomiting, convulsions or mental symptoms indicating involvement of the meninges over the vertex of the brain. (c) Acute basilar meningitis: cranial nerve palsies indicating involvement of the meninges at the base of the brain. (See Fig. 748.)

The blood serologic tests are positive in 60 per cent of the cases. Pleocytosis in the spinal fluid is moderate or marked (25 to 2000 cells). The spinal fluid Wassermann is positive in 90 per cent of the cases and spirochetes have been found in the fluid.

Psychic Scar in Meningeal Neurosyphilis.—Meningeal, like cerebral vascular syphilis, may produce the picture of healing with defect even in cases exhibiting a minor subjective symptomatology at the outset and making an apparently rapid response to treatment both clinically and serologically. The impression may be one either of unfavorable progress or the onset of paresis. The picture may appear to change from one form of disability to another or from a minor form such as a cranial nerve palsy to a major one of profoundly altered personality as the patient "recovers." In this way a business man of fair capacity may be transformed into a mediocre day laborer as his disease comes to a standstill. Such homologous paradoxic exaggeration of signs in the

process of healing is, of course, familiar in cardiovascular syphilis. It is necessary in cerebrospinal syphilis to make frequent allowance in prognosis for those large, "silent," and inaccessible portions of the nervous mechanism whose condition cannot be seen or tested for but which may provide a degenerative aftermath that mars recovery

THE CLINICAL PICTURE OF GENERAL PARALYSIS (PARESIS) OF THE INSANE

The foregoing summaries have made it apparent that not every syphilitic patient who has mental symptoms is *ipso facto* a paretic. Syphilis of the brain has a fairly rich psychotic background from which paretic neurosyphilis can be separated in some cases with ease, in others only with the greatest difficulty if at all.

Fig. 749.

CLINICAL CLASSIFICATIONS OF GENERAL PARALYSIS

Nonne.	Hecht (161 cases, 128 males)	Per cent men.	Per cent women.
1. Typical paralysis	1 Simple dementia	66 5	65 7
2. Lissauer' focal paralysis (vascular changes)	2. Agitated and expansive	18 8	17 9
3. Atypical paralysis	3. Depressive	5 7	10 2
Catatonic.			
Senile.			
Fulminating.			
4. Stationary paresis	4. Circular	3 3	2 6
	5. Galloping	3 8	None.
	6. Atypical (paranoid and hallucinatory)	3 3	None.
	7 Undetermined	4 1	2 5

The characteristics of the syndrome were first established by Alzheimer and Nissl, and two clinical classifications are given in Fig 749

The pathologic changes themselves vary as widely as the symptoms, as Solomon has pointed out, even in cases receiving diagnosis of paresis t competent hands. The main pathologic essentials include diffuse inflammatory reaction in the cerebrum, chronic spirochetal encephalitis, localizing about the vessels and meninges, with coat-sleeve lymphocytic and plasma-cell infiltration about the capillaries and degeneration of the parenchymal cells ith compensatory gliosis. These elements vary in their relative proportions, so that in some cases extreme atrophy and little inflammatory change is apparent, in others the vascular picture and plasma-cell infiltrations are prominent. So-called atypical general paresis" would appear from the analysis of Hermel to include nearly every known pathologic change associated with such an infection as syphilis, including miliary gumma and endarteritis with and without the demonstrable presence of *Spirochaeta pallida*.

Even though we can no longer make a fatal issue the test of the diagnosis of paresis, it is certainly possible to say that syndromes with very different onsets and symptomatology and with extraordinarily long and extremely short courses, with and without remission can none the less end in the symptomatic picture of paretic dementia and paretic neurosyphilis. Thus one may observe a "vascular" type of paresis, in which the progressive deterioration

is punctuated by typical accidents, transient or permanent. One sees patients who have typical basilar meningeal lesions cleared up by treatment, who yet, after periods of years of seeming symptomatic inactivity go into paretic decline One finds paretic dementia run the *slow* course of arteriosclerotic senility or sees arteriosclerosis, in the absence of syphilis, produce excellent imitations of paretic dementia. Even the strongly positive serological findings of paresis which have held out best and been most emphasized as diagnostic criteria in recent writing on neurosyphilis may occasionally *fail* in practice

Fig. 750.—*Treponema pallidum* in brain tissue from general paralysis. Stained by Nageotte's method of silver impregnation of nerve tissue (× 1000) (Collection of Dr Nageotte.)

and paresis with negative blood serologic reaction, and even with negative spinal fluid after treatment, be proposed for consideration. While nondescript symptoms or neurorecurrence presents the serology of paresis with complete recovery or as in tabo-paresis with optic atrophy with symptomatic arrest.

Symptoms of "Typical" Paretic Neurosyphilis.—In presenting a symptomatic summary combined from several tables by Southard and Solomon and our own experience therefore it should be understood that only a central core is proposed whose possibilities of confusion with the general territory of

meningo-vasculo-parenchymatous neurosyphilis are apparent enough when Fig 752 is compared with those which have preceded it.

Fig. 751 —Granular ependymitis in the floor of the lateral ventricles. The patient had a "paretic" spinal fluid, but no symptoms, and an advanced aortitis unrecognized during life.

Fig. 752.

SYMPTOMATOLOGY OF PARETIC NEUROSYPHILIS

Amnesia: Especially for recent events.
Consciousness clouded; intake impaired, *fatigability* increased, hallucinosis rare.
Judgment impaired; oversuggestibility fantastic delusions, grandiose, paranoid; insight into illness, slight or nil.
Quick-shifting Emotions.
Irritability or Hebetude.
Character Change.
Conduct Slump Violent rages, sexual escapades and excesses.
Nervous Disorders: Headache, visual disturbance, tremor ataxia.
Speech Disorders Dysarthria, aphasia, vocal change.
Writing Disorders Tremor omission of letters and words.
Pupillary Changes: Argyll Robertson pupils, pupillary irregularities, transient anisocoria. Pupillary changes may occasionally be slight.
Reflex Changes Exaggeration most common (taboparesis excluded)
Seizures Epileptiform, hemiplegic, aphasic, most typically transient and repeated.
Facies: Flattened nasolabial fold, Relaxation, mental "let down," tremulousness, vacuity
Serologic Picture Strongly positive blood and spinal fluid Wassermann, positive globulin, cell count under 100, repeated first zone colloidal test. (Type III.)
Paralyses and Contractures (late).

The pupillary changes, including Argyll Robertson pupils, associated with paresis, are not necessarily sufficient to identify the clinical combination known as taboparesis, and form, therefore, an integral part of the picture of paresis. Joffroy found pupillary changes in part as follows in a series of 300 cases of general paresis (Fig. 753) (*cf* Adie's syndrome)

Foster Kennedy in an admirable brief address (Brooklyn Soc. of Int. Med.) summarized some of the clinical simulants of paresis as follows: effects of great fatigue, even to slowing of the pupils (during the First World War); lead intoxication; intestinal intoxications in middle life; arteriosclerosis. His suggestion that a test of the paretic is to require him to write not a line or two, but a *four-page letter* is most useful.

One cannot exclude paresis merely by the fact that the time interval between the chancre (if one had occurred) and the appearance of clinical signs is short, since true paresis may develop, as soon as eight months (Zeifert, 1939) or as long as thirty years (average fifteen years) after infection. Cheney (1933), however, found only less than 2 per cent of his cases developed after a latent period of less than five years. Fifty-seven per cent came on after a latency of ten to nineteen years and 6 per cent in over thirty years.

Trauma and General Paralysis.—The influence of trauma as a factor in syphilis is considered in Chapter I. Its importance in paresis (especially head injury) is discussed by Klauder and Solomon (page 15) and Merritt and Solomon (1943). Trauma may apparently incite to paretic manifestations a neurosyphilis that would otherwise have remained quiescent. The fact, now accepted, has important medicolegal and industrial liability bearings.

Fig. 753.

PUPILLARY CHANGES IN GENERAL PARESIS (AFTER JOFFROY)

	Per cent.
Altered light reflexes	73
Pupillary inequality	65
Lost light reflex	[illegible]
Irregular pupils	[illegible]
Diminished accommodation reflex	17
Mydriasis	13

Course of Paretic Neurosyphilis.—The course of paretic neurosyphilis varies remarkably in different patients. An acute *fulminating* or *galloping* form occurs, with an encephalitic picture and fever (Cestan and Riser) or with rapidly successive seizures or shocks, each leaving the patient more deteriorated than the preceding, and terminating *often* in the fatal convulsive state already mentioned. The excited type with flight of ideas, delusions, extreme irritability and outbursts of maniacal violence is contrasted with the silent, depressed and suicidally inclined patient, and with the slow deteriorative type which gradually declines into silliness, dementia, and amentia. The *mental characteristics which constitute the average conception of paretic* neurosyphilis belong simply to a median type whose euphoria, fabrication, and grandiose delusions during a physical decline unaccompanied by any consciousness of course or termination, is the medical apotheosis of an easy death. Less than three to six months, in extreme cases, three to five years in average cases, and five to thirty or more years in the unusual slowly deteriorative type (Galbraith, 1940) is an all-round prognostic scale.

Remission, a feature of paresis to which much interest attaches, is an as yet unexplained phenomenon. It consists in a spontaneous *temporary recovery* often of astonishing completeness, from all active symptoms of the disease. Remission occurs, according to various authors, in from 4 to 17 per cent of

untreated cases (Cotton, Gaupp, Kraepelin) Its duration may range from a few months to as long as twenty-two years in the extraordinary case observed by Tuczek, the average duration being from six months to a year

Four of Nonne 10 apparently cured cases in premalarial days turned out to be examples of long remissions. Remission, according to Kraepelin, is more common in the agitated and expansive types than in the depressed and demented forms. Improvement may be very sudden, but restoration to entire normality is rare. The patient may treat his past with certain degree of insight, but more often slurs over it, and tremor and speech defect residua may be detected on examination. The improvement in the flabby relaxed, and vacuous facies of the paretic and the restoration of crispness to the speech in remissions produced by treatment are most interesting to watch.

The possibility of remission complicates all decisions regarding the effect of treatment and the curability of the disease.

Paresis Sine Paresi.—Just as isolated pupillary signs may precede by years, and absolutely without other event, the appearance of general paresis, so the spinal fluid may during a long asymptomatic period, present the strongly positive Wassermann reaction on all concentrations, positive globulin, pleocytosis and first zone colloidal reaction of general paresis, in combination with positive blood serologic reactions. This serological forerunner of clinical paresis has been designated by Solomon "paresis sine paresi" and has been spoken of in an earlier chapter as the "red flag. (See also asymptomatic neurosyphilis.) While it does not have infallible prognostic value and while such fluids may appear early in neurorecurrence, and respond to treatment there is much reason to believe that the repeated serological findings of "paresis sine paresi" in successive examinations is of grave prognostic significance. *We have been inclined to limit the term to cases in which such fluid findings* withstand vigorous treatment, rather than to apply it on the outcome of one or two examinations.

Senile Paresis.—This is name applied to picture suggesting arteriosclerotic dementia which characterizes paresis beginning late in lif (Bennett, Riser and Gay). The condition makes no response to treatment and is rapidly fatal. Diagnosis depends mainly upon serological findings.

OTHER SYPHILITIC CEREBRAL SYNDROMES

Brain Gumma.—Brain gumma is not as specific a term as tradition supposes, and its symptomatology is, therefore, ill-defined. Miliary gummas if numerous give the symptomatology of diffuse neurosyphilis of an encephalitic type. Gummatous infiltration may also assume a diffuse form. Sharply defined solitary gummas may present the localizing signs of brain tumor if in an area from which such signs can arise. In the frontal lobes they may produce the entire range of mental symptoms given in Fig 752. Accompanied as they often are with meningeal thickening and inflammation, or originating in some cases in the meninges and invading the brain substance, they may present in addition to the pressure symptoms of brain tumor (headache, vomiting, and choked disk) the paralyses of ocular muscles and involvement of cranial nerves which assist in identifying a meningitis. Solitary gumma may exist without an abnormal lumbar spinal fluid, so that negative findings from this *angle do not necessarily exclude brain gumma from the diagnosis.* The blood serologic reactions may be, but are not necessarily positive A Wassermann test on the ventricular fluid, obtained at operation, may yield a positive finding, although the lumbar fluid may be negative.

Gumma of the hypophysis, especially of the anterior lobe, is stressed by Simmonds and Nonne as frequent in prenatal syphilis, and very responsive to treatment. Involvement of the infundibulum has also been recently illustrated by cases reported by Lhermitte and Kyriaco (narcolepsy diabetes insipidus, obesity amenorrhea) and by Louris (diabetes with pigmentation, enlarged liver and dysendocrinism), Brugsch, Lewi and Dresel (midbrain sclerosis with diabetic syndrome). We have seen amenorrhea and pituitary obesity in congenital syphilitic woman simulate pseudocyesis. The precaution taken in the preserological era, of invariably giving a course of potassium iodide to all suspected cases of brain tumor before the relief of pressure symptoms by trephine, if time permitted, deserves revival in the light of the inadequacy of the serologic test in this diagnostic field. Trephine does not necessarily come amiss in gumma with pronounced pressure symptoms, but the surgeon should restrain desire to go too far if signs of marked pachymeningitis are encountered.

Brain tumors of nonspecific origin may occasionally respond temporarily to modern syphilotherapy so that the diagnostic resort in the individual case must often be determined by the seriousness of the patient's condition and the presence of localizing signs which will direct an intelligent surgical intervention.

Acute Syphilitic Encephalitis.—Disseminated syphilitic encephalitis, an unusual and still debatable entity may be confused with lethargic encephalitis and with the hemorrhagic encephalopathy of arsenical reaction

The patient in Fig 436 came to his death in what may have been this fashion in the third year of his infection, after neurorecurrence which had apparently been brought under control by treatment. The infection in Barrett's case was only of seven months duration, and occurred in the prearsphenamine era. The onset is sudden, with clouding of consciousness, lapsing rapidly into stupor or for a brief period with noisy delirium and restive movements. Localizing signs do not at first appear but after the first twenty-four to forty-eight hours it may be possible to identify pupillary anomalies, beginning ocular muscle palsies, and peripheral paralytic changes. These seldom become marked before death occurs. In our patient, as in Barrett's, the cortical lesions were more marked than in the usual lethargic encephalitis. The spinal fluid and blood Wassermann reaction in our case were repeatedly negative. To assert that the condition in our patient is syphilitic merely on the basis of a history of syphilis and recent neurosyphilitic involvement does not, of course, bear critical examination. No spirochetes were found in the brain in Barrett case in subsequent examination, and none could be found in the brain, spleen, liver, or lymph nodes examined in our case. It is therefore entirely possible that the case was one of infectious encephalitis of nonsyphilitic origin. (Sugar in spinal fluid 0.15 Gm. per 100 cc.)

Subacute or Chronic Syphilitic Encephalitis.—That encephalitis in syphilis does not necessarily follow an acute course, as described above, is suggested by several cases we have been called upon to treat. Their symptoms on admission were stupor and disorientation, amounting almost to coma, but with no distinctive signs of a meningeal or vascular lesion. In one case the spinal fluid was negative in another strongly positive A third case at first supposed to be encephalitic subsequently developed hemiplegic accidents indicating vascular basis not at first recognized Recovery with psychic scar resulted in the first two, but the time under observation is, of course too short to determine their ultimate outcome. In one instance the presence of a weakly positive spinal fluid Wassermann reaction, in patient whose history and course were typical of postinfluenzal encephalitis, well illustrated the caution which must be used in interpreting encephalitis across which the suggestion of syphilis has been thrown either by history or signs. The encephalitic syndromes so frequently described since 1918 have greatly increased the possibility of confusion.

When an acute encephalitic picture in a neurosyphilitic follows upon an arsenical injection, the difficulty in deciding whether the condition is a therapeutic shock (Herxheimer) a hemorrhagic encephalopathy or a syphilitic encephalitis is considerable The attempt to give adrenalin in one such case as a therapeutic test provoked a violent exacerbation from which the patient fortunately recovered

Syphilitic Pseudoparesis and Nonparetic Syphilitic Dementia.—These terms apply to the borderland of paresis, and are in all probability variations on the symptomatic pictures of meningovascular brain syphilis which suggest paresis, but do not follow the classical course to fatal termination. Nonparetic dementia of syphilitic origin often has negative spinal fluid, and may well be product of cortical vascular changes. Kraepelin gave to nonparetic syndrome characterized by auditory hallucinosis, delusions of persecution, and peculiar suddenness of onset and remission the name *syphilitic paranoia*. The status of the disorder is uncertain according to Southard and Solomon, and not based on complete serological evidence.

Encephalomalacia in Syphilis.—Widespread degenerative and atrophic changes, *secondary to innumerable foci of atheromatous change affecting the* finer vessels of the brain, give rise to a clinical picture that may be interpreted either as meningovascular neurosyphilis, as an atypical paresis, or even as tumor of the cortex, though the latter is eliminated by the absence of pressure signs.

In a most striking example, this confusion in diagnosis was well illustrated by the contrast between the clinical diagnosis of vascular neurosyphilis on the basis of five years observation of repeated hemiparetic seizures with a negative spinal fluid, made in the Mayo Clinic and the equally insistent diagnosis of typical general paresis by asylum physicians based upon the terminal picture. The autopsy disclosed almost unbelievable encephalomalacia with profound arteriosclerotic changes in the basilar circulation.

SYPHILITIC SPINAL CORD SYNDROMES

Separate description of cord and cerebral lesions in neurosyphilis can be excused only on account of convenience, for the two processes are rarely sepa rated in fact. It is apparent from our account of the general symptomatology of neurosyphilis that cord symptoms come much more to the front in ordinary practice than do cerebral symptoms. This is readily accounted for by the *relatively large silent areas and larger tissue reserve of the brain, as contrasted* with the intense concentration of the transmitting and controlling mechanism of the cord. Certain it is that cord complaints outnumber cerebral complaints in the patient s story ten to one, and testify continually to the practical truth of the statement one of us (J H S.) has several times made, that neurosyphilis (*i. e* cord syphilis) is in reality the syphilis of internal medical practice, *for it is the source of innumerable and too often inexplicable symptoms* in gross examination.

Pathology—An important anatomic consideration influences the pathology and symptomatology of cord lesions in syphilis. The vascular distribution of *Spirochaeta pallida* deposits it, obviously in those parts of the tissue most directly supplied by the principal vessels of the arterial system. These are the posterior portions of the cord, including the posterior meninges, the sensory horns, and the posterior and lateral columns of the cord. The anterior or motor horns are much less frequently affected. Thus sensory rather than motor disturbances characterize large part of the symptomatology of spinal syphilis. Even those symptoms which appear clinically to be motor in character are often in reality due to disturbances of the sensory segment of the reflex arc. There are of course, exceptions in the myelitic pictures which will appear in due course

The cord and its meninges are subject to the same pathologic changes which characterize all syphilis of the nervous system—acute and chronic syphilitic inflammation, and the *meningeal, vascular gummatous, and parenchymatous degenerative lesions* previously described. Taken as whole the white matter is more frequently involved than is the gray matter of the cord (Nonne).

Vascular Syphilis of the Cord.—The principal syndrome is that of throm bosis of the anterior spinal artery (Spiller Margulis, Ornsteen *cf* S Berman

1940 below Merritt, 1940 and King, 1942) with apoplectiform onset, complete flaccid paralysis of trunk, arms and legs, and loss of deep reflexes when upper levels are affected. Absence of direct violent trauma, rapid progress, no prodromes, are important in diagnosis. A stationary is followed by a spastic stage

Fig. 734

EARLY SYMPTOMATOLOGY OF SYPHILITIC SPINAL MENINGEAL AND MENINGOMYELITIC LESIONS

Pain: In the neck, between the shoulders, in the back or lumbosacral region (backache, "sacro iliac strain, etc.")
Paresthesias and Pains in upper or lower extremities and buttocks.
Hyperesthesia in spots where pain is felt.
Tenderness on pressure in the hyperesthetic areas.
Muscular tension May reach the point of contracture.
Increased tendon reflexes.
Stiffening of the back Chiefly on rising Nocturnal pain not especially characteristic.
Secondary symptoms from spinal nerve involvement: Sensory changes, slight paralyses (may be "pseudo" due to fear of pain)
Early bladder disturbance: One of the earliest and most important myelitic symptoms.
Motor weakness, often interpreted as fatigue.
Spinal fluid: Strongly positive in all reactions, blood Wassermann usually positive.

Meningitis and Meningomyelitis.—Figure 734 presents the symptomatology of spinal irritation, the prodromal complex of many meningomyelitic lesions.

The advance of the process with the sharper definition of level signs brings out the *paraparesis and paraplegia of the upper or lower extremities*, the *dissociation of sensation*, in which pain and temperature senses are modified or lost first while other forms persist unchanged and *ankle clonus Babinski sign*, and *further exaggeration of tendon reflexes*

Fig 735.

SPECIAL SYMPTOMATOLOGY OF CERVICAL MENINGOMYELITIS

Paraparesis and spastic later flaccid paraplegia of all four extremities.
Signs of involvement of the brain, especially:
- **Headache and dizziness.**
- **Aphasia.**
- **Unilateral paresthesias** of the extremities.
- **Pupillary changes and extra-ocular paralyses.**
- **Optic neuritis.**

Cervical Sympathetic Symptoms Unilateral pupillary contraction, sweating, and redness of skin
Fluctuation in th extent and intensity of symptoms.

In lumbar cord involvement the development of a chronic myelitis results in the disappearance of reflexes and a flaccid paralysis ensues.

The picture of pachymeningitis hypertrophica cervicalis in syphilis is essentially as in Fig 735 The involvement of the upper extremities may be more marked than the lower and the cerebral symptoms less conspicuous.

This syndrome of chronic hypertrophic cervical pachymeningitis as well as that involving other levels of the spinal cord is well portrayed by Wilson, Bartle and Dean (1939) and by King

(1942). Wilson and his coworkers from study of 18 cases point out that no symptom or syndrome may be regarded as pathognomonic. From their cases syphilitic pachymeningitis, although showing an affinity for the cervical and dorsal regions, cannot often be regarded as an exclusively localized process, but rather as regional manifestation of usually more generalized meningovascular syphilis. In 10 of their 18 cases definite brain symptoms were clinically manifest.

Syphilitic Transverse Myelitis.—The pathologic changes involved in syphilitic transverse myelitis may include, in one and the same case, vascular inflammatory and gummatous processes. Acute and chronic forms are recognized The acute form is sudden in onset and within a few hours may reduce the patient to a helpless paraplegic. *Nonne gives the frequency in his practice* as 8 cases in 212 of spinal syphilis.

Acute accidents may occur in the course of a chronic myelitis. In this case they are preceded by prodromes similar to those in Fig 756 The bladder in such cases may show retention for a considerable period.

Nonne states that the appearance of paralytic signs from level different from that which the prodromal symptoms lead the observer to expect, is suggestive of syphilis. A fluctuating course is more suggestive of syphilis than of the nonspecific types. The suddenness with which

Fig. 756.

SYMPTOMATOLOGY OF SYPHILITIC ACUTE TRANSVERSE MYELITIS

Onset sudden, progress rapid.
Upper extremities rarely affected.
Total paralysis lower trunk and extremities.
Sensation totally lost or dissociated remnants may persist.
Total incontinence of bladder and bowel, or retention followed by incontinence. Pyelitis usually follows.
Edema of the extremities, occasional.
Decubitus, sacral, of fulminating onset.
Loss of tendon reflexes, if lesion is below the center
Exaggeration of tendon reflexes, if lesion is above the center
Rapidly fatal course, in most cases.
Spinal fluid and blood usually positive.

decubitus develops in these cases is sometimes almost unbelievable. Stokes has seen the sacrum and both trochanters virtually denuded of overlying soft tissues by huge slough within three or four days, in spite of every precaution; this in striking contrast to the ordinary infectious or toxic myelitis of his experience.

Acute syphilitic transverse myelitis in the early months of a syphilitic infection may have a more favorable prognosis than the late type. Cole has reported with bibliography a case occurring in the second month of the infection with recovery under treatment with mercury and arsphenamine and Stokes has seen a case also recovering under mercury and arsphenamine which occurred nine months after infection. Remains of the patient s grouped follicular secondary syphilid were still present.

S. Berman (1940) in well documented report of case notes that judging by the frequency of published reports acute syphilitic transverse myelitis is becoming rare. From 1924–1940 only 5 cases have been reported in this country

Syphilitic Spinal Paralysis (Erb s Syphilitic Spastic Paraplegia)—This syndrome has been a storm center of controversy since its description by Erb in 1892 The question is essentially whether the picture is not simply that of

a chronic incomplete dorsal myelitis as in the case reported with microscopical study by Collins and Taylor or that of a transverse myelitis. There is also question as to its invariably syphilitic character. Nonne compromises, after a summary of the literature, by saying that there is such a disease but that it may be the result either of lateral or combined sclerosis, or of myelitis. Spastic symptoms appear in various syphilitic syndromes, including general paralysis, and it is interesting to see one competent observer make a diagnosis of Erb's spastic paralysis while another simultaneously makes a diagnosis of paresis, the latter supported by the course and outcome. Many early paretics, before mental changes are well defined though recognizable exhibit the curious symptom of "spastic thumb" in which under examination tension they exhibit a "splayed" or hyperextended thumb and at times a positive Babinski and ankle clonus.

Peters (1941) studied the blood and cerebrospinal fluid serologic findings in 30 cases of Erb's syphilitic spinal spastic paraplegia. He found the blood serologic reactions for syphilis positive in 73.3 per cent of the cases, while the cerebrospinal fluid was normal in 23.3 per cent of the cases. (Type I 13.3 per cent, Type II 20 per cent and Type III in 36.6 per cent.) In only 3 patients was serologic evidence of syphilis completely lacking. King (1940) in his monograph on "Syphilis of the Spinal Cord" summarizes this condition as follows: "This syndrome is not common, it occurs five times more frequently in males and is sometimes a late complication of syphilis. Clinically the patients present a picture of slowly developing weakness, fatigue and stiffness of the legs, with little or no pain. Bladder disturbances are frequent. Examination reveals spastic paraplegia with evident lateral column damage but little or no sensory loss. At first there is paraplegia in extension, but this later may occasionally become paraplegia in flexion. There is no block in the subarachnoid space. The condition has to be differentiated from cord tumor, multiple sclerosis, other forms of cord involvement due to syphilis, and changes due to pernicious anemia. The blood and spinal fluid Wassermann reactions are frequently positive but may be negative. The process is very resistant to treatment and frequently progresses in spite of it."

Fig 737

SYMPTOMS OF ERB'S SYPHILITIC SPINAL PARALYSIS

Onset gradual, some years after infection.
Spastic paresis of the lower extremities.
Spastic gait.
Little true motor paralysis.
Little increase in muscle tonus.
Increased tendon reflexes.
Little or no sensory disturbance.
Slight or moderate bladder disturbance.
Pupils, cranial nerves, upper extremities, psyche and intelligence unaffected.

The obvious problems in differential diagnosis raised by the cord lesions of the anemias and multiple sclerosis can only be answered by the spinal fluid examination and complete study of the patient for other signs of syphilis.

Acute Ascending Spinal Paralysis (Landry).—Nonne and Spiller maintain that Landry's paralysis may be of syphilitic origin in some cases. The clinical features of the Landry type of spinal paralysis consist of ascending paralysis of the spinal and finally of the bulbar nerves, with preservation of sensation and electrical reaction but disappearance of reflexes. Care must be taken not to confuse the picture in some cases with that of syphilitic polyneuritis, in which, however, marked sensory changes and disturbance of electrical reactions do occur.

Amyotrophic Lateral Sclerosis.—Kalber has extensively discussed syphilis of the spinal cord manifesting itself in the clinical picture of amyotrophic lateral sclerosis. Stone rates syphilis as

the most common cause of chronic spinal progressive muscular atrophy of the atonic type. Early and vigorous antisyphilitic treatment may arrest the wasting and weakness.

Syphilitic Chronic Anterior Poliomyelitis.—Syphilitic involvement of the anterior horns, while uncommon, occurs either alone or occasionally in abortive form (upper extremities) in combination with tabetic changes in the lower cord.

The syphilitic factor in spinal muscular atrophies must be borne in mind even though the picture be not typical of anterior horn involvement.

Nonne discusses the literature with reference to amyotrophic lateral sclerosis and the Aran-Duchenne type of progressive muscular atrophy quoting among others, Dana (prESerological period, 1906) who found 25 per cent of such patients to have syphilitic histories. Spiller emphasized the importance of histologic findings in his cases.

Syringomyelic Syndromes.—Syphilitic meningomyelitis, with the production of compression symptoms and invasion of the cord by solitary gummatous infiltrates, may occasionally give rise to isolated paralyses with regional dissociation of sensation momentarily suggesting syringomyelia.

Brown-Séquard Syndrome.—This picture may be produced by gummas which invade the cord from the pia-arachnoid, causing unilateral lesions. The cases may be regarded clinically as cord tumors and may involve any portion of the cord. Nonne rates the lesion as rather-common one among the pure cord involvements, citing also Oppenheim and Mitchell Clark. The symp-

Fig. 736.

SYPHILITIC CHRONIC ANTERIOR POLIOMYELITIS

Pain, insistent and severe, in the affected extremities.
Weakness of the peripheral muscles.
Atrophy often beginning in the small muscles of the hand, sometimes selecting groups of muscles, sometimes the extremity in toto.
Fibrillary twitching of the affected muscles.
Changes in electrical reactions.
Preservation of sensation.
Isolated loss of reflexes.
Final complete paralysis and paralytic atrophy of the affected muscles.

tom complex consists of motor paresis or paralysis of one side of the body usually chiefly the lower extremity with loss of pain and temperature sense on the other side. The picture, when syphilis is responsible, is often imperfect, the patient having paraparesis with accentuation of the motor phase on the one side, and more marked sensory dissociation on the other, though both sides are somewhat affected by both types of changes. Signs such as pupillary abnormalities, suggestive of more extensive neurosyphilitic changes, may also be present. The therapeutic test may be of importance in differentiation.

The Combined Scleroses.—The vascular supply of the cord is such that a variety of combined column degenerations are possible, among which the combined sclerosis of the posterior and lateral columns is the most common and easily recognized. The clinical picture includes mixtures of varying proportions of tabes dorsalis and spastic paraplegia, so to speak. Abortive forms of tabes, with pupillary rigidity to light, optic atrophy extra-ocular muscle palsies, lightning pains and sensory disturbance, will be associated with increased instead of lost tendon reflexes, ankle-clonus, positive Babinski sign, and a slightly spastic gait becoming ataxic with the eyes closed. The preservation of sexual power in a patient with the eye signs and lightning pains of tabes should lead at once to a search for the earmarks of lateral column involvement. Pupillary changes may appear late instead of early

TABES DORSALIS

Fundamentally tabes dorsalis is a disease of the dorsal roots of the spinal nerves, with ascending degeneration of the posterior columns of the spinal cord (Goll and Burdach) Occasional muscle atrophy has been explained both as due to anterior horn cell and to parasympathetic involvement (Cadwalader 1932) The clinical symptomatology is directly derived from these facts, although the clinical variability of the sensory and subjective picture sometimes makes it difficult for either physician or patient to realize the unity of the process.

Whether or not tabes dorsalis, like paresis, is to be regarded as primary syphilis of the nervous system in the sense that syphilitic meningitis is a primary syphilitic process caused directly by *Spirochaeta pallida*, or whether it is to be regarded as secondary degenerative picture possibly of toxic origin (para or metasyphilis) cannot be discussed here, and is still the field of marked differences of opinion.

That tabes is not a disease of the sensory nerve roots and the spinal cord alone, but is, in reality a cerebrospinal process is evident not only from such symptoms as Argyll Robertson pupil, extra-ocular muscle palsies, and primary optic atrophy but also from the combinations which it presents with paretic neurosyphilis (taboparesis) While, therefore, we may describe for convenience a "typical tabes dorsalis," an uncomplicated picture will be anything but the rule in ordinary practice, and too much rigidity should be guarded against in diagnosis. On the other hand, if single symptom of tabes, such as pupillary rigidity to light, be selected as diagnostic, the field of tabes becomes almost synonymous with all of neurosyphilis, to say nothing of many nonsyphilitic neurological conditions. The student should therefore guard against making part of the picture stand for the whole.

Tabes as a Deficiency Disease.—*Because of its current influence* on treatment conceptions, the hypothesis that tabes is at least partially a nutritional or vitamin deficiency disease should be specially mentioned Much of the reasoning is based on the importance of avitaminoses, particularly A and B complex in conditions such as pernicious anemia, beri-beri and syndromes experimentally produced in animals but as yet without parallel in man, in which a degenerative type of change in nerve tissue and recovery under adequate diet or vitamin therapy are well recognized This subject has been well reviewed by Moore and Woods (1940) and Cochems and Kemp (1942) chiefly in conjunction with primary optic atrophy and lightning pains. Metildi (1939) used the work of Wintrobe Mitchell and Kolb (1938) as the basis for his introduction of thiamine chloride into the treatment of tabetic pains. Stone (1942) employed vitamins B and E intrathecally and cited Reese and Hodgson s (1939) preliminary feedings of the B complex to tabetics with ensuing improvement prior to antisyphilitic treatment. Conceptions of the role played by vitamin deficiency must be regarded as still in the formative stage and the multiplicity of action of such highly complex agents as the vitamin groups constantly kept in mind in interpreting mechanisms. When a vitamin group like B which relieves constipation, acts as an antiallergic, assists in controlling intestinal infection influences secretion of hydrochloric acid in *hypo- and achlorhydrica and so forth, is employed in therapy* interpretations of mechanism are hazardous. When the crystalline vitamins are employed, the results are less clear-cut (Cochems and Kemp, B) and it will be necessary to test out individually riboflavin pantothenic acid (calcium pantothenate), and pyridoxin at least in response to various suggestions as to which item or combination of items seems to be therapeutically useful.

Symptoms of Tabes Dorsalis.—The symptomatology of tabes dorsalis will

vary with the stage of the process in the material surveyed (Fig. 759) A num ber of them, especially of the sensory type, have been described as early symptoms of neurosyphilis.

The proportions of various symptoms are dictated to some extent by the stage of the disease in the material studied. Early cases show a lower propor tion of ataxia and rombergism and a higher proportion of pains and pares- thesia. No single symptom or sign of tabes is, of course, diagnostic, but groups of two or three taken together should arouse enough suspicion to lead to a search for the entire picture. The atypical character of tabes dorsalis in women is a point which has been of much value in clarifying our experience. The incomplete forms, especially with reflex eye disturbances, a few "rheumatic"

Fig. 759

IMPORTANT SYMPTOMS AND SIGNS OF TABES DORSALIS

Symptoms.	Per cent.
Lightning pains	73–90
Visual symptoms	44
Difficulty in urination	43–68
Trouble in starting.	
Dribbling afterward.	
Nocturnal frequency and "bed-wetting	
Paresthesias (numbness, prickling, girdle sensation, etc.)	40–58
Ataxia	57–87
Strabismus	18
Diplopia	11
Girdle sense	10–31
Visceral crises (gastric, rectal laryngeal)	10–22
Loss of libido and potentia	6–25
Failing vision	6
Ptosis	5–23
Vertigo	4–12
Deafness	1–4

Signs.	Per cent.
Argyll Robertson pupils	80
Reduced or absent lower cord reflexes	70–90
Romberg sign	43–86
Sensory disturbance and dissociation	40–68
Diminished pain.	
Diminished vibration sense (bone fork conduction).	
Diminished sense of motion and position.	
"Cord" (atonic) bladder	45
Trophic changes	12 19
Charcot joints.	
Malum perforans.	
Optic atrophy	6–9
Miscellaneous, including muscle trophy tabetic clubfoot, wrist and foot drop, hyperextensibility of joints (decreased muscle tone) mentioned by various authors.	

Combined from the statistics of Nonne, Lecke, and Stokes and Shafler aggregating approximately 1400 cases and descriptions by Cad alader (1928), Windelman (1936).

pains, and slight frequency or dysuria but no ataxia, should not be too readily accepted as an "arrested" or "burnt out" neurosyphilis, a constant temptation to the internist or general practitioner who minimizes syphilis in his experience. A spinal fluid test may indicate an active process.

On the other hand, the negative spinal fluid in progressive cases, especially with trophic changes and crises, is too commonly misinterpreted in general diagnosis, especially where a surgical issue seems to be involved Not only the blood serologic reaction (often negative) and spinal fluid examination, but a neurological study with examination of the eyegrounds and visual fields, and even observation over a period of several years for signs of unfavorable prog- ress, are essential to the correct interpretation of incomplete tabetic pictures.

Gastric and Visceral Crises.—Three types of gastric crises have long been

recognized the attack of pain without vomiting the attack of vomiting without pain and the most common type, combining both pain and vomiting. Simons (1930) emphasizes the pain and hyperalgesia of the abdominal wall, without true deep pain or rigidity in the splanchnic type of crisis. Many gradations from abortive to severe forms exist. As a rule, the attack comes on without warning, though patients occasionally say they have had premonitory sensations. Exhaustion, emotional stress, acute infections and treatment shocks, including lumbar puncture may serve as precipitating incidents but, more characteristically the attack comes on from a clear sky The pain is usually epigastric, though the patient often has difficulty in defining or localizing it. It may radiate into the neck and jaw the back, chest, shoulder sacrum (Simons) may be intermittent or continuous. Intense nausea may be the only symptom. It is of agonizing intensity grinding or spasmodic, and soon reduces the average patient to convulsive sobbing helplessness. The vomiting is uncontrollable, and continues long after stomach and even duodenum may be emptied. The most trying feature is the nervous collapse and disorganization that often ensues during the several days to a week or more that the attack may last, resembling more than anything else the state of nervous collapse of a hypersensitive woman in childbirth. The recovery is almost as striking. The pain and vomiting disappear within a few hours, and the pale, exhausted and disheveled patient usually rapidly regains composure and appetite. The weight loss may be extreme and, in combination with exhaustion and loss of morale, constitutes the chief background for a fatal issue.

Woltman, grouped crises in the abdomen as: (1) sympathetic, with marked pain, vomiting and hyperalgesia over the abdomen, (2) vagal, with little pain, but marked nausea and vomiting, with pain in the region of the larynx, ear or heart; and (3) phrenic crises, with abdominal pain, hiccough and pain over one or other shoulder The pain of crises even when severe is strikingly unaccompanied by tenderness to deep pressure, though the patient may complain bitterly of the weight of a sheet or ice-cap

Roentgenologically and in tracings, the stomach is seen in violent contraction during crises which may be shared by the entire gut but it is not proved which (pain or contraction) is cause which is effect.

Simons (1930) gives an excellent review of the classification of gastric crises and conceptions of their pathogenesis. H interprets the crisis with nausea, vomiting, gastric hypersecretion without pain as of vagus, probably nuclear origin; that with severe pain and hyperesthesia of the abdominal skin, as of splanchnic type (paravertebral sensory fibres). The third is a mixed type.

The most striking symptomatic characteristic of the majority of gastric and other visceral crises in tabes is their periodicity which is sometimes as perfect as that of the menstrual function or of cyclic vomiting The tendency of the attacks is to follow closer and closer upon one another in the lapse of months or years, so that the patient ultimately can no longer recover his physical equilibrium between them He may pass over into a distressing state of almost continuous nausea. Laryngeal crises are of course marked by spasm with symptoms of suffocation that may necessitate tracheotomy Rectal crises are occasionally seen Differential diagnosis depends not upon symptoms, but upon the signs of neurosyphilis elicited by examination with elimination of other possibilities. More often after repeated misdiagnosis as gallstone attacks, the periodicity without apparent exciting cause arouses suspicion of gastric crisis.

Celialgia.—Turner uses this term for sensations of twisting, burning or heaviness in the epigastrium without radiation or vomiting, though with salivation or constipation, and diar-

acteristically pain on pressure over the solar plexus. Relief as well as diagnosis is secured by therapeutic test.

Achlorhydria, Pylorospasm.—Symptoms arising from or associated with either of these conditions may be interpreted as gastric crisis rather too easily in patients with syphilis plus functional neurosis. Objective evidence of neurosyphilis of tabetic type is necessary to diagnosis, and tabetics may have gastric neurosis symptoms without crises.

Errors in Medical and Surgical Diagnosis Associated with the Symptomatology of Tabes Dorsalis.—The rich visceral symptomatology of neurosyphilis, and particularly that of tabes dorsalis with its sensory root pathology provides an admirable background for general diagnostic error which has been illustrated by previous case records. It may be said in general that the internist meets with difficulties chiefly in dealing with the cerebral syndromes which suggest neurasthenia, while the surgeon encounters them in the symptomatology of tabes. Incomplete examination and unfamiliarity with the outstanding facts of neurosyphilology account for most avoidable errors. A systematic study by Nuzum of surgical error based upon the records of 1000

cases of tabes dorsalis in the Cook County Hospital, Chicago, yielded a table (Fig 700) which outlines the main sources of error The proportion of tabetics subjected to useless operation amounted to 0 7 per cent.

Among the definite symptoms of tabes, visceral crises furnished 65 per cent of the occasions for diagnostic error Woltman found that crisis patients had received an average of two abdominal explorations each. Unbelievable persistence in error was well illustrated by a patient seen on our service in the Hospital of the University of Pennsylvania, whose abdomen carried five scars of laparotomies performed elsewhere, marking unsuccessful operations for gastric crises (Fig 701) We have never seen a surgeon who either makes an adequate examination himself, or acts upon the findings of a competent medical consultant, operate upon a case of gastric crisis under an erroneous diagnosis. If emphasis be placed upon the *signs* of tabes elicited in history and examination rather than upon the blood serologic reactions and spinal fluid examination both of which may be negative, this mistake will almost never occur

Taboparesis.—The syndrome of taboparesis is variously interpreted and in ordinary practice is earliest recognized as a combination of the objective signs of tabes with the spinal fluid and blood serology of paresis. This combination is particularly associated in our experience with primary optic atrophy and patients presenting it should have immediate field and visual

Fig. 701.—Pentalaparotomy for gastric crises.

This patient was first seen September 26, 1925 complaining of stomach pains of nine years duration occurring one to two times a week for which he had had four laparotomies. Primary lesion 1911 Previous treatment, 4 intravenous injections in 1921

Examination revealed irregular pupils which reacted very sluggishly to light and accommodation, and normal deep reflexes. Bladder tabetic in type but patient not incontinent. BWR negative CSF—strongly positive Wassermann increased globulin; 63 cells; and typical "tabetic curve After prolonged treatment with bismarsen, total of 67 injections, the abdominal pain was unrelieved.

CSF February 25 1928, Kolmer-Wassermann, 0134; increased globulin, 10 cells; mastic 4443210000.

Patient was lost sight of in 1928 and returned in September 1929 saying he had had an abdominal operation in an outside hospital.

In May 1939 patient was examined after ten years lapse. He had no gastro-intestinal complaints and the examiner stated that there seemed to have been "remarkable symptomatic improvement. Blood serologic reactions and spinal fluid examination negative

In May 1942, patient, now sixty-five years of age entered clinic looking and feeling well except for his old complaint pain in the stomach. This pain was worse after certain types of food. No changes in physical examination.

acuity studies and ophthalmoscopy of the fundi before any form of treatment is instituted Not uncommonly the mental degenerative features and symptomatology of paresis play the lesser role and with the onset of blindness, as Camp used to emphasize, the process comes to arrest without the typical paretic fatal termination.

SYPHILIS OF THE PERIPHERAL NERVES

Syphilitic neuritic disturbance if involvement of cranial nerves be excepted, is relatively rare form of syphilis of the nervous system. The following forms are well recognized:

Secondary Involvement of Nerves.—This is the result of pressure on nerves due to periostitis, or syphilitic osteitis of the vertebrae, and to gummatous processes involving lymph nodes, fasciae, and muscles. The diagnosis must be made through identification of the primary syphilitic cause

Syphilitic Root Neuritis.—This is rare condition, of which Nonne cites examples suggesting tumor of the cauda equina. The symptoms include paralyses of isolated muscles supplied by the involved nerves, pain, isolated reflex changes, weakness of the bladder and anal sphincter, and the spinal fluid findings if positive

Syphilitic Perineuritis.—This occasionally involves peripheral nerves and can be detected by beadlike thickenings, distortion of the trunk of the nerves, and more or less pain on pressure. The demonstration of syphilitic etiology must be by collateral factors. The nerves most commonly involved, according to Ehrmann, are the ulnar crural, and peroneal.

Syphilitic Neuralgia.—Nonne states that syphilitic neuralgias are most conspicuous in the early stages of the disease. Syphilitic trigeminal neuralgia presents no distinctive clinical features and can only be identified as syphilitic through general examination and history and its prompt response to treatment. Ornsteen has described isolated bilateral fifth nerve involvement. A case practically indistinguishable from tic douloureux, of nine years duration, associated with positive blood Wassermann and spinal fluid, with prompt response to treatment, is described by Vieta. Trigeminal neuralgia late in the course of syphilis is probably not of syphilitic origin though simulated occasionally by tabetic pains in this region and has usually required surgical treatment for relief although one of us (J. H. S.) has seen one striking exception. Cervical plexus neuralgia is likewise uncommon, though not rare. Intercostal neuralgia, with relapses and entire absence of other symptoms of neurosyphilis, may persist for years. Lumbosacral plexus neuralgia stands next in frequency to trigeminal neuralgia. Obstinate and severe sciatica may be one of the principal symptoms and nocturnal exacerbations are emphasized. The identification of the syphilitic cause for these conditions depends mainly upon serological and collateral clinical findings plus history of infection and response to treatment for syphilis. The almost invariable presence of tender point where the nerve emerges through the fascia, and the comparative lack or total absence of objective sensory changes in the course of the nerves are suggestive In one observed case the "sciatic pain disappeared permanently following hemiplegia, suggesting central factor

Syphilitic Neuritis and Polyneuritis.—The subjective symptoms of syphilitic types incline more toward paresthesia than toward actual severe pain. The attacks are rarely so prolonged or so severe as with other conditions. Neuromuscular hyperesthesia to pressure and spindle-like enlargements of the nerve trunk may be detected when the nerve runs superficial course. Motor paresis affects particularly the radial, ulnar and peroneal nerves. A variable degree of atrophy with diminution of the appropriate reflexes takes place. Involvement of nerve in the course of gumma may give rise to neuritic paralysis.

Polyneuritis is very much more common in syphilis than involvement of isolated nerves. A pure motor, sensory and pseudotabetic type have been described by Castan. An early acute form accompanying the cutaneous and osseous manifestations of the secondary stage clears up with extraordinary rapidity under mercurial and iodide treatment for syphilis, point of infallible differential value The extent of toxic versus direct spirochetal origin in this type has been argued as for all acute structural disease (syphilitic nephritis, hepatitis, etc.) in early syphilis. The occurrence of definite peripheral neuritis in an alcoholic patient receiving antisyphilitic treatment must not be confused with true syphilitic polyneuritis. The same applies to "foot-drop occasionally seen as complication of intra-arterial injection of heavy metal. A rare form of syphilitic root polyneuritis occurs in which cranial nerve paralyses and gradual extensive involvement of spinal nerves develops, which must be differentiated from the compression syndromes produced by syphilitic gummatous meningitis. The chief interest of syphilitic root neuritis lies in the simulation of tabes (Nonne).

DIFFERENTIATION OF NEUROSYPHILIS FROM OTHER NEUROLOGICAL CONDITIONS

Every neurological description properly emphasizes the fact that there is no specific cerebral or cord symptomatology in neurosyphilis if the items be taken individually A complete survey of the case must be made including the complete examination of the blood and spinal fluid and of the fundus and

Differentiation of multiple root neuritis and syphilitic polyneuritis is considered by Nonne (1921 edition).

fields of the eye and all the changes found must be taken into account. On the other hand, it may be said again that if the practicing physician can assemble a reasonable preponderance of ordinary clinical signs and convincing serological evidence in blood and spinal fluid for a syphilitic etiology he can usually proceed safely to treatment. The differential considerations here given apply to those pictures in which confusion is most likely to occur. Whenever ill-defined or doubtful cases in these types arise the inexperienced should seek advice.

Chronic alcoholism gives rise to conditions which *may easily be confused with neurosyphilis*. A history of total abstinence from alcohol eliminates them, but a collateral history of syphilis does not, since the two often coexist.

Pupillary irregularity and sluggishness, though not perhaps an absolute Argyll Robertson phenomenon, convulsions with a postconvulsive stupor, persistent amnesia, fabrications with euphoria ("liar dementia"), disturbance of reflexes, difficulty with test phrases, tremor, and writing disturbance, may all occur and differentiation from general paresis be possible only upon the finding of a negative blood and spinal fluid. It should be recalled that a gin debauch may lead to a temporarily negative blood serologic reaction. The dementias of chronic alcoholism and acute alcoholic symptoms occur in patients who, by virtue of their habits, may be expected to present higher incidence of syphilis than the average. For this reason the spinal fluid examination is particularly essential in all doubtful cases. The presence of cranial nerve palsies favors the diagnosis of syphilis. Signs of alcoholic polyneuritis may accompany the convulsions and mental disturbance (Korsakoff syndrome).

Alcoholic pachymeningitis can simulate pachymeningitis of the convexity, both giving rise to diffuse or localized headache, somnolence, and even to localized convulsions of the Jacksonian epileptic or general epileptic type with paralyses of the extremities.

Cerebral Arteriosclerosis.—The production of pupillary abnormalities and senile dementia by arteriosclerosis makes possible confusion with general paresis, on the one hand, and with abortive forms of tabes, on the other. The senile arteriosclerotic psychosis presents hemiplegic seizures, confusion, memory defect, deterioration of judgment, insomnia, and irritability. Southard and Solomon, who *describe very interesting* case in which the death of the patient who from general paralysis was the clue to the finding of a positive spinal fluid in the patient himself, state that small group of senile cases may present grandiose delusions. A high grade of frontal lobe trophy observed at autopsy as in a case of advanced cerebral arteriosclerosis seen on our service (myelomalacia) may suggest paresis on gross examination. Syphilitic arteritis and non-specific arteriosclerotic changes may produce an almost interchangeable clinical symptomatology associated with thrombosis of the basilar arteries. In such cases *only* combinations of the arterial process th signs of cerebral meningitis, positive blood and spinal findings, and collateral clinical evidence of syphilitic infection, can serve to distinguish the two. Nonne states that even Jacksonian convulsions and a *status epilepticus* may be simulated *by cerebral arteriosclerosis* in senile subject. The frequent failure of the spinal fluid in syphilitic vascular disease to show any distinctive reactions increases the difficulty of differentiation.

In spite of the foregoing considerations the student and practitioner should be cautioned *against too ready acceptance of marked grades of pupillary* abnormality in later life as merely arteriosclerotic in origin. They are much oftener suggestive of syphilis, and the specific possibility should be traced to the bottom.

Brain Tumor.—Opportunities for the confusion of brain tumor with cerebral syphilis are numerous in special practice, though fortunately brain tumor is much less common in ordinary practice. The first possibility arises in connection with headache, vomiting, and edema of the optic nerves as symptoms. It may be safely said that there is not single neurosyphilitic cerebral syndrome hich cannot be imitated by a properly localized brain tumor. Nonne emphasizes in discussing the psychic disturbances that the mentality of the brain tumor case is essentially torpor semisomnolent condition rather than the disturbances of consciousness observed in neurosyphilis. The possibility of confusing glioma of the frontal lobes with paresis in syphilitic patient is brought out in Fig. 774. Bilateral choked disk may of course develop purely as result of localized basilar meningitis, and in 1 case observed by Ayer† such picture had been produced by a *meningitis involving the chiasm*. The patient had undergone decompression for sup-

An elaborate differentiation of cerebral arteriosclerotic psychic disturbances from those of paresis is given by Weber (quoted by Nonne).

† Personal communication.

posed brain tumor (autopsy). Unilateral choked disk is more likely to be local meningeal phenomenon. Tumors of the base of the brain may be imitated by the hypophyseal syndrome of basilar meningeal neurosyphilis, including ocular nerve palsies and optic neuritis. The therapeutic test in distinguishing tumors from cerebral syphilis is not always reliable, for slow-growing sarcomas may show temporary improvement, optic neuritis may improve under mercury even though not of *syphilitic origin, and Fig. 774 likewise illustrates transient improvement of the* symptoms of cerebral gliosis. Nonne cites case in which convulsions following arsphenamine were interpreted as Herxheimer reaction in case of sarcoma. Under these circumstances only the ensemble of the evidence from history clinical findings, serological examination, and familial study can make an antemortem diagnosis possible. Exploration in patients with accessible localized lesions may be the best practice. It goes without saying that gummas of brain and meninges may themselves be brain tumors.

Brain Abscess.—Nonne insists that the confusion of syphilis and brain abscess will be largely prevented by withholding the latter diagnosis unless evidence of source of infection elsewhere in the body or of head injury can be found.

Dementia Praecox.—Very presentable imitations of the paranoid and catatonic types of dementia praecox can be produced by nonparetic neurosyphilis and by general paresis. Mention has been made of the occurrence of hallucinations and persecutory delusions in the latter condition, and the nonsensical flow of conversation of the paranoid dementia praecox may likewise occur in purely syphilitic psychosis. The physical signs may be insignificant, or the patient may seem entirely normal apart from his mental disturbance, yet the serological findings may be conclusive for neurosyphilis though not invariably for paresis. The symptoms disappear under treatment for syphilis. Nonne stated (1921) that he had seen no satisfactory examples of typical catatonia in neurosyphilis, but cites reported instances, and Southard and Solomon include in their series young woman of twenty-six (Case 66) who, following period of excitement and auditory hallucinosis, developed typical catatonia, resistiveness, and noncooperation. The positive spinal fluid and blood Wassermann findings were confirmed by autopsy at which a syphilitic encephalitis as found. In practice the differentiation must be made on the general picture and the serological findings. Nonne observed dementia praecox in patients with congenital syphilis, but sees no reason for ascribing direct syphilitic etiology to the condition. Healing with *defect, familiar in dementia praecox, occurs, of course, in neurosyphilis, as previously stated.*

Manic-depressive Psychosis.—The possibilities of confusion of cerebral neurosyphilis with manic-depressive psychosis are numerous and the differential diagnosis from variety of angles admirably discussed by Southard and Solomon. According to these authors laboratory tests furnish the final diagnostic criteria in most cases, but they of course, do not eliminate manic-depressive psychosis as complication of neurosyphilis. The depressive state appears to be the more difficult to differentiate, and no qualities seem to be wholly sufficient to distinguish the depression of general paresis from that of manic-depressive psychosis. Pupillary signs and speech defect if present are of great value, but may be absent even in advanced cases of cerebral neurosyphilis. A history of manic-depressive psychosis in the family and of previous alternating excited and depressed phases of conduct, in some cases antedating syphilitic infection, is of value. In the manic phase differentiation of the two types of disease may be equally difficult since identical delusions may occur in both. As Nonne says, only years of observation may decide the doubtful case. Under any circumstances, however treatment of syphilis in the presence of serological *evidence of its presence is imperative.*

Hysteria.—The tradition of an association of hysteria with syphilis has come down mainly through the French school in the writings of Charcot, Gilles de la Tourette, and Fournier. Whether or not true syphilitic hysteria exists cannot be stated with positiveness. In order to demonstrate the existence of such condition there should be evidence that the hysteria followed instead of preceded the syphilis, and that it responded to treatment for the disease. The variability of hysteria in its successive clinical outbreaks in given individual nearly parallels that of neurosyphilis. Southard and Solomon describe case in which recurrent dazed state suggested hysteric fugues, and this possibility should be by no means lost sight of where clinical signs of neurosyphilis are lacking or are confined mainly to sensory disturbance. The stigmata of hysteria (anesthesia of the conjunctiva, pharynx, nipples, etc., with hyperesthetic zones) are suggestive but not absolutely conclusive. The occurrence of opisthotonos in hysteric seizures (major type) may differentiate the convulsions at sight from those of noisy delirium in cerebral syphilis (Southard and Solomon, Case 67).

Nonne emphasizes the possibility of confusing the transient pareses of cerebral and spinal cord syphilis with hysteric paralyses. In some cases the serological finding may be the chief differential factor. In all doubtful cases spinal fluid examination is in order.

We have occasionally been impressed with the fact that extremely intensive treatment of syphilis, especially with arsphenamine, in predisposed subjects may bring on overtreatment syndrome" (described on p. 372), group of symptoms superficially suggesting a minor form of hysteria. The objective signs of hysteria are however, absent. Reassurance and a rest period usually clarify the situation. Nonne mentions a type of hysteria which he observed in a strenuous therapeutic test of an hysteric individual with supposed neurosyphilis.

Neurasthenia.—The differentiation of neurasthenia and simple nervous states assumes the greatest importance as an issue in preventive medicine, for not only is large part of the symptomatology of early and latent neurosyphilis classifiable under this head, but ith the improved therapeutic outlook of general paresis the period of preparetic neurasthenia becomes the ideal one in which to treat this form of the disease. Accordingly in any patient with even a suspicion of syphilis in his history a blood serologic test is essential and, in view of the numerous instances in which it is negative the properly performed spinal fluid examination may be urged. It should not be forgotten, however that the frankest statement of the necessity for the test and the possibilities of reaction is important in neurasthenic patients in order t prevent the occasional addition of traumatic neurosis ("punctured" spine) to true neurasthenic syndrome. True cerebral neurasthenia in syphilis is often the consequence of psychic shock and anxiety and must be carefully differentiated from the onset of true neurosyphilitic symptoms. Southard and Solomon give a very clear-cut picture of this differential problem (Case 9). After emphasizing the serological criteria they place next in order of importance pupillary and aphasic symptoms. Kraepelin remarks that the sudden occurrence of neurasthenic disorders in a male of middle age, without any evident cause therefor is always suspicious. Yet occasionally dizziness, slight speech defect, tremor of the tongue, and moderate increase of tendon reflexes do not possess any marked significance and may be produced by f tigue and tension. Clear insight and understanding of the nature of the disease phenomena, persistent search for recovery reasonableness in conversation, progressive improvement under appropriate treatment, speak for neurasthenia. Joffroy and Mignot state that the pure neurotic suffers great deal more than the patient who is destined to become a victim of paresis. The character change in neurasthenia does not amount to that entire transformation of personality (even to the performance of criminal acts) that we find in paretic neurosyphilis at the most the neurasthenic shows minor emotional disturbances and a certain pathologic egoism. Psychotherapy readily relieves the true neurotic of many of his fears and feelings. The sexual anesthesia of the preparetic is often preceded by stage of sexual overexcitement. (This may occur in true neurasthenia.) The finer clinical distinctions fade into insignificance beside the results obtained from laboratory tests.

Syphilophobia (previously described).—We have already emphasized in discussing treatment the unwisdom of treating too lightly the so-called "syphilophobic state in patient with undoubted syphilis. Such syphilophobias have too often in our experience been proved, after examination of the spinal fluid, to arise from true neurosyphilis, although the physician had already assured the patient, on the finding of a persistently negative blood serologic reaction, that his fears were imaginary The therapeutic test which acts with such extraordinary promptness in true syphilitic neurasthenia should not be begun without adequate evidence that the symptom complex is of syphilitic origin, for a syphilophobic responds with the greatest alacrity to the suggestive effect of a therapeutic test. The necessity for therapeutic test has largely disappeared with the improvement of laboratory diagnosis.

Encephalitis.—Some reference has already been made to the differential diagnosis of various forms of encephalitis. The lethargic type, with its prolonged course and extraordinary variety of symptoms, has become especially familiar since the influenza epidemic of 1917 18. The differentiation of lethargic encephalitis from syphilis depends almost exclusively upon laboratory criteria and the finding of collateral evidence of syphilitic infection. In the acute phase the pupillary abnormalities and paralyses of extra-ocular muscles which occur accompanied by stupor and paralytic lesions may be indistinguishable from those which may occur in syphilis. In the chronic phase the alterations of personality may simulate the irritable or depressed phases and conduct slump of paretic and nonparetic neurosyphilis. The spastic phenomena which develop later are perhaps more distinctive of lethargic encephalitis than any other feature of the clinical picture yet even these may be simulated in syphilis. In practice one is therefore obliged to rely upon the history and collateral evidence of syphilis and most of all upon the W sserman reaction on the blood and spinal fluid. False positive Wassermanns t least, undoubtedly occur. Other changes in the fluid are not distinctive unless it may be the increased sugar content in lethargic encephalitis. That the therapeutic test must be used with caution is illustrated by the rapid recovery of an undoubted case of early lethargic encephalitis which one of us (J H S) had the opportunity to treat with mercury succinimide. Remission and recovery may however.

be spontaneous. The parkinsonian syndrome may occasionally show slight improvement under arsphenamine therapy but not enough to be deceptive. The presence of a sugar content in the spinal fluid exceeding 80 mg. per 100 cc. is suggestive of lethargic encephalitis, although moderate increase is sometimes seen in neurosyphilis.

The differential problems presented by acute syphilitic encephalitis have been discussed in the description of the condition. A very vivid picture of the maniacal excitement of such patient is given in Southard and Solomon (Case 100). The more acute type may sink t once into stupor and somnolence suggesting encephalitis.

Lead encephalopathy must at times be distinguished from syphilitic encephalitis and the dementias of diffuse cerebral syphilis. Now that bismuth is coming into prominence in treatment, the occurrence of lead (e. g. bismuth) line in the gums cannot be given quite the previous diagnostic weight. The history blood picture and finding of lead in the urine are essential. Very interesting examples of the dementias and convulsive symptoms induced by lead have recently been afforded by the appearance of tetra-ethyl-lead poisoning as an industrial hazard. In the more chronic types lead neuritis with wrist-drop and foot-drop assist in the differentiation.

Uremia.—The differentiation of uremic headache, vomiting, epileptiform convulsions, and coma from neurosyphilis may at times be extremely difficult, especially if they appear in patient previously known to have neurosyphilis. The determination of the blood urea and the blood serologic and spinal fluid findings may be the turning points in diagnosis if the urinary abnormalities and other signs of nephritis are not pronounced. Examination of the fundus of the eye may disclose nephritic retinitis with characteristic hemorrhages. In retinal changes and visual damage as residues of hypertension (renal) and pregnancy intoxication in women who have syphilis, confusion may arise and unnecessary treatment be given.

Epilepsy.—Much of the current discussion of epileptic syndromes in syphilis bears evidence of an unformed opinion and highly theoretic approach. Jacksonian epilepsies present no features distinctive of syphilis and must be identified as such on serological and collateral clinical evidence. True epilepsy and generalized syphilitic epileptiform convulsions are likewise clinically indistinguishable in some cases. If following an apparently true epileptic convulsion, aphasia and pupillary abnormalities, cranial nerve, and other paralyses are found, syphilis is suggested and true epilepsy eliminated. It is apparently possible for true epilepsy to recur as manifestation of syphilis for many years (parasyphilitic epilepsy of Fournier) without any distinguishing signs. Nonne notes, however that the intelligence suffers much less in these cases than in true epilepsy and that long remissions and onset very late in the course of the disease are quite characteristic. The true epileptic seizure maintains more constant character over period of years than does that of neurosyphilis. Petit mal seizures may appear during intervals of seeming quiescence. Petit mal seizures may likewise appear in the course of cerebrospinal syphilis and after apparently effective treatment in paresis (especially juvenile) without major attacks and persist over period of years unaffected by treatment and without substantial change. Such symptoms may perhaps be the effect of microscopical healing in the brain. Serologically negative, but none the less syphilitic, epilepsy occurs and can sometimes be recognized by therapeutic test. It is, however decidedly rare and does not justify the wholesale application of such test to cases of apparently typical idiopathic epilepsy without satisfactory collateral evidence of syphilis.

Migraine.—Recurrent headaches in neurosyphilis may be interpreted as migraine, and *vice versa*, especially if accompanied by vomiting. The familial history of periodic headache and allergic background, the unilateral character in the typical case, and recurrence of the ttacks at regular intervals over period of years suffice for differentiating typical cases. On the other hand, the distinction is not always so easily drawn. In severe migraine accompanied by ophthalmoplegia, only full serological and clinical examination may eliminate syphilis. Stokes has personally observed patient in whom the severity of the gastro-intestinal phase of the migrainous attack and the mildness of the headache had led to mistaken diagnosis of gastric crises. In the severe cases, accompanying headache, blindness, aphasia, in the attack, and the family history assist in differentiation. Wolfman mentions women with both tabetic crises and abdominal migraine.

Diabetic Syndromes.—Polyuria, polydipsia, and occasionally glycosuria may lead to the ascribing of diabetic origin to neurosyphilitic cerebral and basilar meningeal disturbances. Lesions in the chiasm produce, according to Nonne, the characteristic sequence of basilar cranial nerve paralysis, polydipsia, and hemianopsia, with or without hemiplegia. x-Ray examination of the skull may show deepening of the sella turcica or changes in the clinoid processes which may be gummatous in origin. Diabetic pseudoparesis may suggest general paresis in its onset, and the differentiation only be made by serological findings. Pupillary abnormalities are rare in diabetes, but when they occur in association with peripheral neuritis they produce the picture of diabetic pseudotabes with loss of reflexes and lightning (neuritic) pains. The neuritis of diabetes is es-

sentially polyneuritis, and involvement of other nerves with polyneuritic atrophic changes and absence of evidence for syphilis must be the diagnostic resorts. The occurrence of a *false positive* blood serologic reaction in diabetes can, in the light of recent investigations, be practically dismissed in differential study.

Multiple Sclerosis.—*This differentiation,* constituting in many respects the most difficult confronting the neurosyphilologist in the pre-Wassermann era, has been greatly simplified by spinal fluid examination. Syphilis may produce multiple areas of sclerosis in the nervous system; and similarly suitably placed sclerotic changes in multiple sclerosis may give rise to pictures indistinguishable from neurosyphilis. The *familiar* earmarks of multiple sclerosis, including nystagmus, optic nerve atrophy, intention tremor, and scanning speech, are not by any means invariably present and more confusing symptoms such as ocular muscle palsies, hemiplegic attacks, bladder disturbances, and spastic paraplegia may make clinical *differentiation* difficult or impossible. Mental changes have been shown to occur in multiple sclerosis, and mental confusion, maniacal states, and grandiose delusions are recognized. Sclerosis of the posterior spinal roots may give rise to lightning pains. Nonne has observed the Brown-Séquard syndrome in multiple sclerosis.

Furthermore, some cases of multiple sclerosis respond definitely to treatment for syphilis, especially with the arsphenamines, although spontaneous remission must be thought of. The effect is by no means so great as in neurosyphilis of a similar clinical type. *In fact,* marked delay and small returns in a therapeutic test for an atypical neurosyphilitic syndrome with negative spinal fluid Wassermann should, *if other evidence for syphilis is scanty,* arouse some suspicion of multiple sclerosis.

The characteristic spinal fluid findings of the two conditions are usually sufficient to make the diagnosis. In multiple sclerosis the spinal fluid Wassermann is negative even to large amounts; there is rarely any increase in globulin, but there may be pleocytosis, usually slight. The first zone or paretic curve is present in perhaps 40 per cent. This combination of paretic curve with negative blood and spinal fluid Wassermann rarely fails to establish or confirm the diagnosis.

Infectious Cerebrospinal Meningitis.—The differentiation of acute infectious cerebrospinal meningitis, whether due to the meningococcus or streptococcus, calls for culture and microscopical examination of smears from the spinal fluid sediment. This should be done routinely in connection with all spinal punctures in acute disease of the nervous system. The occurrence of fever, leukocytosis, and of polymorphonuclear cells in the cytological examination cannot be accepted as diagnostic, for they may occur in syphilis. The *identification* of a *focus* of infection, such as mastoiditis, is, of course, contributory *evidence.* In all cases of doubt it is wiser to give antimeningitic serum coincidentally with the diagnostic spinal puncture than to postpone it until the results of bacteriological examination are received. This precaution we learned from several cases in which a delay due to overcaution seemed responsible for the unfavorable result. Blood culture sometimes contributes to the identification of a nonspecific infectious factor where the patient is known or suspected to have syphilis. Southard and Solomon cite a case of taboparetic neurosyphilis in which the terminal picture was that of typhoid meningitis without other clinical symptoms of typhoid fever.

Tuberculous and Other Forms of Meningitis.—The differential diagnostic problem arises more frequently in tuberculous than in more acute *forms* of meningitis. The diagnosis frequently depends upon the serologic negativity of the blood and spinal fluid and the finding of tubercle bacilli on microscopical examination of the spinal fluid sediment and guinea-pig inoculation. Weak positive serologic reactions sometimes appear in the spinal fluid as in other meningitides. The formation of a clot in association with a low sugar (18 to 40 mg.) and chloride content is practically diagnostic of tuberculous meningitis. Localized tuberculous meningo-encephalitis may, according to Nonne, produce symptoms indistinguishable from those of gummatous meningitis. The general habitus of the case and the serologic reaction on blood and spinal fluid, which may, however, sometimes be negative, must be relied upon to distinguish these cases. In solitary tubercle of the pons the symptoms may simulate those of syphilitic thrombosis of the basilar arteries or gumma, or focal syphilitic meningitis as described by Southard and Solomon (Case 6).

Cysticercus and actinomycotic meningitis are identified by the spinal fluid findings. Tularemic meningitis (recall tularemic "chancre"), torulosis (Stiles and Curtiss, 1931) and blastomycosis must be kept in mind.

Cord Tumor.—The differential diagnosis of spinal cord tumor is growing in importance. Since syphilitic meningeal gummatous involvement can produce symptoms indistinguishable from cord tumor, it is obvious that there must be some cases in which the diagnosis will depend entirely on laboratory findings and collateral clinical evidence. In old fibrous sclerotic gummas all criteria may fail and the nature of the process be discovered only at operation. Gummatous

invasion of the cord itself (localized gummatous myelitis) may likewise produce symptoms of cord tumor The serologic reaction is practically the only distinctive differential criterion in these cases. There is nothing distinctive in the cellular content, and the compression syndrome with xanthochromia may appear in a cord tumor of syphilitic origin precisely as under other circumstances.

Cerebral Symptoms and Cord Changes of Pernicious Anemia.—The patient with primary anemia of the addisonian type may exhibit mental symptoms (Woltman) of the infection-exhaustion type, or alterations of personality The former may include delirium, delusion, hallucination, paranoid states, and dementia, the latter ranges from mild indifference or abnormal affability and gentleness to shallow confusion, torpor and dream states. The most distinctive objective early sign of the cord changes, according to Woltman, is from the posterior columns as in tabes, and includes loss of vibratory sense and sense of motion and position. Pain, tactile and temperature sense are preserved almost intact. Knee jerks may be lost if the posterior columns are affected and a positive Babinski test may indicate the changes in the lateral columns. The patients suffer from paresthesias, numbness, prickling and "silk-glove" sensations, but rarely have pains, which assists in distinguishing the picture from serologically negative tabes, in which pains are often present. Optic atrophy and the Argyll Robertson pupil accompany tabes, but not primary anemia, while retinitis of the anemic type is a very common feature of primary anemia (90 per cent) The differentiation is not difficult if the blood and spinal fluid are positive, but in those patients in whom cord changes appear before the blood picture of addisonian anemia is clearly defined, or during a blood remission, as well as those in whom a false positive blood Wassermann reaction may be present, the differentiation may momentarily present something of a problem. Patients with tabes rarely develop a degree or type of anemia which is likely to be regarded as primary The completion of the case, as a whole, here as in other differential problems, is the only safe guide. The response of primary anemia to arsphenamine should not be forgotten in attempting a therapeutic test.

THE TREATMENT OF NEUROSYPHILIS

The Recent Changes.—As one surveys the field of the treatment of neurosyphilis during recent years, one observes, as in the field of cardiovascular syphilis, a gratifying trend toward more rational and better-grounded interpretation and toward the conquest of the more resistant manifestations.

What might be called localizing or topical methods of attacking syphilis of the nervous system as, for example, intraspinal and intraventricular therapy are losing ground with the advent of three notable advances: (*a*) the more thoroughgoing and systematic systemic treatment of early syphilis; (*b*) the use of drugs with high penetrating power for the nervous system, particularly pentavalent arsenicals; (*c*) the employment of nonspecific stimulation of the defence mechanism, including fever and nonspecific protein therapy

The Objectives of Treatment.—The first aim of treatment in neurosyphilis is to restore a sick man to effectiveness, to make him act and feel better It is not, of course, to reverse a serological reaction or even to reduce a single symptom to absolute zero at the cost of physical collapse or economic ruin for the rest of the man. In the evaluation of treatment results the restoration of economic status and the replacement of the disabled individual in the niche in the social scheme which he occupied before the disease produced its destructive effects, is assuming increasing importance both as a fact and as a method of mensuration of treatment effect. It will deserve increasingly critical analysis in the future as we watch the return of treated general paralysis with its dangerous potentialities for individual, family and social life to the community at large. A second aim of treatment is to make the benefit obtained by therapeutic procedure as nearly permanent as possible. Inevitably the evaluations in this field will be a matter of years and decades rather than months, and almost no information as yet available equals or transcends the first ten-year period since the adoption of the most effective

special methods. A third aim, negatively speaking, must be the avoidance of therapeutic hobbies and the employment in the individual case of each and all the methods that may seem, under skilled judgment, to be applicable to the particular problems presented. The fourth aim is an inevitable corollary of the third—the treatment of neurosyphilis in the later years becomes in the highest degree a matter of individualization as contrasted with the essential use of vigorous routine in the earliest years of the infection.

STANDARD OR PRACTITIONERS' METHODS IN THE TREATMENT OF NEUROSYPHILIS

The Prevention of Late Neurosyphilis.—Despite the fact that there still remain unsettled questions in regard to the comparative evolution of untreated and treated asymptomatic neurosyphilis, there is no longer any reasonable doubt of the worth of thoroughgoing treatment of early syphilis in the prevention of late neurosyphilis. The treatment of early syphilis, in this country especially, is a practitioner's problem. There can be therefore no escaping the fact that the prevention of late neurosyphilis is his responsibility. To the extent that he is able to put into effect the standards for early treatment described in Chapter XIV, the consequences of syphilis in the neurological field will disappear from the clinical scene. Inasmuch as we have several times emphasized the large place held by neurosyphilis in the clinical symptomatology of internal medicine with respect to the disease, the real meaning of such a reduction in morbidity and mortality can be imagined.

The preventive management of early neurosyphilis has been reviewed on page 673 and summarized in Fig. 445. The practitioner can be bolstered in his determination to see the issue through in the individual case by the figures summarized below.

Keidel and Moore found that after 12 or less doses of arsphenamine with courses of mercury the spinal fluid showed abnormalities in 21.4 per cent of cases, while after 13 or more doses of arsphenamine with mercury the proportion dropped to 8.7 per cent. The striking effects of energetic early treatment on the prevention of asymptomatic neurosyphilis is again shown in Zurhelle and Krechel's results in Hoffmann's clinic (Fig. 725). The Cooperative Clinical Group, it will be recalled, including tryparsamide and malarial therapy results in their statistics, found that only 6.8 per cent of the abnormal spinal fluids observed in their large series proved irreversible by treatment. Relatively little treatment by modern methods readily reduces slight abnormalities to normal. Marked abnormalities, on the other hand, are less responsive from every standpoint and the presence of a positive Wassermann reaction in the spinal fluid particularly, even though not in conjunction with a typical paretic formula, demands intensification of treatment (see p. 120) and prolongation over at least an additional two years from the time the abnormality is discovered. The later in the course of effective treatment such abnormalities are identified, the more serious they are. The more recent demonstration by Padget (1940) of the prophylactic effect of treatment of early syphilis against the development of neurosyphilis should be recalled. The incidence of neurosyphilis dropped from 11.3 per cent in patients who received 1 to 3 doses of 606 during the first 3 months of treatment to 9.9 per cent after 4 to 6 doses and 7.6 per cent after 7 to 9 doses.

The "red flag" formula or the "paretic" spinal fluid (Type III) is the practitioner's warning of grave danger for his patient. In the Cooperative Clinical Group study this particular formula proved to be at least twice as difficult to reverse to normal as any other markedly abnormal spinal fluid. When such a formula is recognized, therefore, there should be no delay in shifting not only to the intensified methods of standard treatment but to the use of tryparsamide and fever therapy if a prompt response is not secured. It is here precisely that our greatest weakness has lain. If the

spinal fluid was examined at all in the past decade, treatment by routine weekly injections of neoarsphenamine was continued over months and sometimes over years with the gradual decline of the patient and a total lack of significant therapeutic effect.

The importance, from the preventive standpoint, of the institution of treatment at the earliest possible moment in the course of a syphilitic infec-

Fig. 702.

WHEN NEUROSYPHILIS APPEARS AS A COMPLICATION WHETHER ON FIRST OR SUBSEQUENT EXAMINATION OR IN THE COURSE OF TREATMENT

1. There is no occasion for hopelessness or panic. Treatment results are good.
2. Secure base-line physical general and neurological survey for present and future reference (Chapter II).
3. Have fundus, vision and fields examined if possible at once
4. Detect intercurrent disease and identify all forms of syphilitic involvement, especially cardiovascular
5. Consider tolerance for various treatment possibilities, in advance of trouble, not after it.
6 Weigh acuteness and rapid progression signs. Cataclysmic methods may give catastrophic results.
7 Recall the dangers of therapeutic shock and prepare practically all cases with iodide and heavy metal.
8. Remember the patient as whole has syphilis—not just one part of him, and treat him accordingly
9 Value system for the average early case and the young patient, insist on it.
10. Individualize th acute, the late case the "wreck.
11 Never "hammer" the aged, the arrested, the quiescent patient.
12. At each interview look first at th patient; then at his record.
13. Refuse hurry reject stampede, avoid fads, check overenthusiasm, resist routinized thinking, especially in treatment decisions involving methods. A living dog is better than a dead lion.
14 But value youth, resistance, clear-cut early warning of grave dangers ahead (e. g "the red flag syndrome") and strike full force (e. g., malaria) when necessary—no trifling with half measures.
15. In other than paretic and acute or critical localized forms of neurosyphilis, be conservative, persistent, even leisurely—results take eeks, months, years, and involve the whole resistance and constitution of the patient, not merely spirillicides and serological test.
16. Place clinical improvement first among objectives and criteria.
17 Make serological negativity an intelligent treatment aim but not fanatic obsession.
18. Maintain but don't overdo spinal fluid control, only examining the fluid when the next move depends on it, not as mere routine.
19. Value rest—"The boatman reacheth the landing, partly by pulling, partly by letting go.
20. But never prescribe therapeutic inactivity merely from laziness.
21. Let treatment results determine further treatment and prognosis.
22. Have a heart as well as head. Help the patient with the personal problem of his disease.
23. Study the family and examine the marital partner of every neurosyphilitic patient.

tion stood out clearly in the Cooperative Clinical Group investigation and deserves reemphasis here. Irreversibly positive spinal fluids were twice as frequent when treatment was begun in early secondary syphilis (1.3 per cent) as when treatment was begun in seronegative primary syphilis (0.6 per cent).

The General Principles of Treatment of Established Asymptomatic and Symptomatic Neurosyphilis.—All treatment problems in neurosyphilis have

certain elements in common and we have accordingly attempted in Fig 787 to summarize a number of considerations that should apply when neurosyphilis appears or is recognized as a complication in the management of any given case whether the occasion be that of first or subsequent examinations or in the course of treatment.

Between the pessimism of the older generation and the prearsphenamine era and the stampede toward fever therapy the really distinguished merits of systematic routine treatment with the arsenicals, mercury bismuth, and the iodides, are at times in danger of being discounted or overlooked

A medical examination of the patient before treatment is begun should detect evidence of renal insufficiency and disturbance of excretory function, so common especially in old tabetics. The cardiovascular system may present lesions which positively contraindicate massive treatment, at least at the outset. It may present warning of a cardiovascular lesion that may progress after treatment for the neurosyphilis, especially fever is completed. Similarly with the advent of fever therapy the eligibility of the case for this method of treatment should be considered from the start and not after it is found that every other resource has been exhausted without effect. The general principles for the avoidance of complications are often especially important in late neurosyphilitics. The examination of the eye (item 4) should be undertaken before arsphenamine is begun, to detect warnings of impending primary optic atrophy including pallor of the disks to detect damage done by the disease before treatment is instituted as a matter of medicolegal as well as purely medical protection and to assist in deciding whether tryparsamide may be counted among the eligible procedures. The detection of intercurrent disease is extremely important and death from diabetes (Osborne) and from the activation of tuberculosis, or the complications of pregnancy has occurred from neglect of this consideration. Acuteness and [illegible] of rapid progression of a process in the central nervous system demand an adequate preparation, though the technic need not be robbed of effectiveness by this consideration. As our personal experience with the unexpected increased, our caution in the matter has grown [illegible]. Even though the infection does not seem extremely active, we now believe that practically all patients should receive preparatory treatment, before the institution of arsphenamine or special treatment methods. After all, many patients with seemingly active and even symptomatically grave neurosyphilis, to say nothing of paper syphilis, have lived effective and not-too-troubled lives on minimal treatment or even no treatment at all. A lengthening experience tends to temper therapeutic furore In the baseline neurological summary special attention should be paid to items which may show improvement under treatment, including the size and distribution of the areas of sensory change and subjective symptoms such as paresthesia, pain, visual disturbance and so forth. Focal infection, especially in the patient with many subjective complaints and much debility deserves careful study and may be the clue to an entire situation that obstinately refuses to yield to therapeutic bombardment. The tonsils and teeth, the sinuses, the gallbladder, and appendix less often, the colon more often, the bladder and prostate and the uterine cervix may be contributing to the exaggeration of the clinical picture, as we have indicated in the general discussion of treatment.

Value and Use of System.—Average neurosyphilis, if the fundamentals of protection from explosive reaction at the outset, avoidance of toxic complications and positive contraindications be kept in mind stands routinization well and "system greatly promotes the confidence of the patient in his treatment and his ability to adjust himself to the demands of a thorough-going cure. If the patient is told at the outset that eight or ten weeks of concentrated treatment, then four months of virtual self-treatment and rest will be followed by a similar course three to five times in succession, he makes arrangements inspired by the definiteness of his outlook which in our experience are better adhered to than those which follow a vague statement that treatment may continue an indefinite period. The patient must of course be told that decisions are modifiable by the course of his case but it is better here as elsewhere to plan a maximum rather than a minimum

Many times patients have expressed to us their personal appreciation of organization in method and definiteness in program as factors in their rehabilitation. On the other hand, worship of system by the physician himself if it blinds him t the fact that given case has achieved the best possible result in less than regulation time, is misguided, and ultimately damages the patient cause.

Acute and Very Late Cases Individualized.—The acute case and the very late case call for those indefinable juggleries of method which only experience can suggest. An acute case in general is marked by a high spinal fluid cell count, objective evidence of an acute process, as an encephalitis or myelitis, a rapid advance of symptoms, such as pains, bladder disturbance, ataxia, failing vision, palsies of cranial nerves, cerebral accidents, and choked disk. For the large majority of such cases we have found nothing superior as preparation to the soluble mercurial salt intramuscularly provided the patient is not greatly emaciated. The severely debilitated patient may do better on inunctions. The best effects of medication by mouth, and, in fact, almost the only field for it is in the late case in which a gain in weight is especially desired.

Therapeutic Shock (Herxheimer).—The therapeutic shock is as real in all types of even moderately intensive treatment for neurosyphilis as in early secondary eruptions (see Chapter VII) The clinical increase in symptoms during the first few weeks is something of which the patient may well be warned and which may be interpreted to him as a favorable rather than an unfavorable sign. In patients exhibiting mental symptoms it must be provided for in advance, lest an attempt at suicide or an act of violence terminate the case Genuinely unfavorable progress of a patient and a merely transient Herxheimer reaction may be confused In general, we have found the less significant Herxheimer reaction to affect subjective sensory disturbances, while the more serious symptoms of unfavorable progress include the objective signs of increasing ataxia, bladder paresis, and vascular accidents or convulsions. Numbness of the extremities has, however sometimes appeared as a subjective sign of genuinely unfavorable progress.

Discipline and Cooperation.—Among the general principles of management we consider it mark of the experienced therapist to refuse to be hurried, and to maintain discipline in his patient' case, so to speak, by insisting on adherence to regimen devoid of uncalled-for temperamental variations. The patient who will not keep treatment appointments, refuses reasonable checks upon his condition, and insists on relying solely on his feelings and business convenience, as in all aspects of the disease, is sometimes unpredictably successful in escaping consequences, but is usually the first to blame the physician for an unfavorable turn of affairs. For this reason it is important to appraise the patient from this standpoint at the first interview if possible. There is, however certain amount of adjustment of the patient treatment to his personal situation which should be made in all possible cases. The less it galls him, the better his response and the better adjusted t his economic situation, the longer he will continue it; point of much significance in the late neurosyphilitic whose means have often been spent in futile search for health, and whose earning capacity t best is below par

Help with Personal Problems.—Helping the patient with the personal problems consists first in determined reassurance wherever such is even faintly justifiable. The response of the neurosyphilitic to reassurance sometimes surpasses the effect of antispecific medication if it comes from a trusted and experienced source and as the result of a full consideration of the case. Neurosyphilis so often comes as a complete surprise that adjustment of family relations and the informing of the marital partner (see Chapter XXI) are essential to clear the way for really effective treatment.

Indefinable Personal Impressions of the Patient.—The injunction to look at the patient first and his record later seems trite, but is a real problem of the busy consultant and practitioner. The asymmetry of the face in a beginning hemiparesis, the "flabby" expression, the changes in speech, in gait, in consciousness and insight, in weight, complexion, lustre of hair, color of sclerae, and even the identification of the faint odor of urine, all at times outrank in importance anything to be found in the laboratory reports. "He doesn't look good" is sometimes the only justification, but a perfectly proper one for a change of methods.

The Value of Rest.—There can be no doubt that there is a very close relation between the recuperative or rest period and the "cure" of the case. The effect of treatment on neurosyphilis is slow, comparatively speaking, and cumulative, so that it may not be until weeks or months have elapsed and during a period of suspension of treatment that the patient begins to rally to the physician's satisfaction and his own.

A definite reduction in the scale of energy output of intense personalities is desirable, yet complete inhibition of their activity may throw them into a depression and introspection whose effects are worse than those of overtreatment. An excellent practical device for the busy patient is the breaking of the day in the middle by an hour['s] rest with a nap, a scheme which is life-saving in many aspects of medicine. The "fishing trip," if of the Izaak Walton or the "dry" type, has come to be a familiar phrase for the recuperative period.

Examination of Conjugal Partner.—The frequency of conjugal neurosyphilis is such that every marital or sexual partner of a neurosyphilitic is suspect, and should have a full study if possible, including a spinal fluid examination when the spouse was married within the infectious period of the patient's disease. It is theoretically desirable perhaps to make the rule invariable for all cases, but we rarely urge it if marriage took place later than ten years after infection and there are no collateral confirming or suspicious signs. The children of every neurosyphilitic patient should be clinically examined, and those who show signs of syphilis should have spinal fluid examinations in addition to the usual tests.

The Standard Drugs in Neurosyphilis: the Arsenicals.—Arsphenamine (606) has the right to priority on the score of its general greater therapeutic effectiveness. It is proper to say, however, that much Continental practice, particularly in France, has centered around the use of neoarsphenamine in the treatment of neurosyphilis by technics employing small dosage and frequent injection with apparently satisfactory results in all but the specially refractory conditions. The problem of treating symptomatic neurosyphilis other than paresis is not in general one of overwhelming the disease with an enormous mass of treatment. For this reason we have incorporated in the unit courses of technic two very serviceable plans, one relatively intensive and one tonic, which exhibit the general principle of shortened intervals, longer courses, and a closer amalgamation with the heavy-metal phase which is now known to increase the effectiveness of neoarsphenamine therapy. Sicard has reported excellent results in tabes dorsalis from the intramuscular use of neoarsphenamine in long series beginning with minute doses.

The Arsenoxides (Mapharsen, Dichlorophenarsine).—While not yet clearly evaluated in neurosyphilis, there is a disposition to replace the arsphenamines by the arsenoxides that cannot be gainsaid. If this is done they

should be given not less than twice weekly or for maximum effect 3 times weekly in doses of 60 mg or more per injection for from eight to twelve weeks, with bismuth concomitantly (subsalicylate, weekly) somewhat as in the Eagle-Hogan intensified technic for early syphilis (Chapter XIV)

Bismarsen is useful as tonic or mild type of treatment and secures reversals of the less serious spinal fluid changes in 60 per cent of cases in series of 40 injections or more. It has good symptomatic effect on tabetic pains and meningeal headaches in debilitated patients.

Bismuth is notably effective in securing the relief of subjective symptoms in tabetic neurosyphilis. It is therefore an essential element in all treatment schemes and with the development of better penetrating compounds will probably assume an increasingly important rôle. The iodobismuthite (Iodobismutol) despite controversy on its penetrating powers is an effective and useful drug if its technic of administration is mastered In patients subject to risk of complications from the use of arsenical bismuth is particularly valuable and well tolerated

The mercurials in neurosyphilis deserve a higher place than the growing ascendancy and popularity of bismuth will probably allow them. Recent experimental work tends in an interesting way to explain the genuine and deserved popularity of the massive mercurial inunction in the long-run treatment of neurosyphilis, as for instance by the Aachen technic. Hoff found that in dogs it was possible to demonstrate mercury in the central nervous system, usually within eight hours following mercurial inunction, though following the succinimide the results were less definitive or negative. He found also that large doses of iodide hastened excretion of mercury but small doses apparently delayed excretion in dogs. To mercury therefore we would assign an important place in the treatment of neurosyphilis as in the unit courses of Fig 763 where mercury by inunction is a major interim feature of one of the systems. From a long experience both with the soluble mercurial salt (succinimide) and the massive mercurial inunction, we feel that they are as yet irreplaceable in the determined assault upon an intrenched neurosyphilitic process other than paresis. It is our impression that the intramuscular use of a mercurial in conjunction with tryparsamide materially increases the effectiveness of that arsenical likewise, this being a feature of the Lorenz Loevenhart technic.

Iodide in neurosyphilis occupies an undoubtedly important but not technically well-defined position. W have based our interpretations on Osborne observations. The enormous increase in iodine content of the spinal fluid by the use of sodium iodide intravenously while brief and often conditioned by meningeal involvement has genuine therapeutic merits. The intravenous use of sodium iodide is not, however advocated particularly for the elderly quiescent case, liberal doses by mouth being preferred. The use of sodium iodide intravenously alone is sometimes an excellent preparatory treatment and occasionally gives quite striking results, but combination with heavy metal and particularly with mercury rather than bismuth is preferred. A preliminary trial of iodide by mouth, to test tolerance, is essential for patients who are to receive iodides intravenously

Stampede and Fadism *versus* Overconservative Delay —Much of the wisdom accumulated by prolonged experience tends inevitably toward conservatism. One learns, and not alone through progressive senile endocrine

deficiency or arteriosclerotic change in himself the singular virtue in many situations of doing relatively little of avoiding strenuosity and of invoking the resolving power of time in a genuinely masterly inactivity Aphoristically stated, we may fall back upon Ochsner's famous dictum "Leave something to God" and accept a partial result in a living patient as preferable to an attempted cure with a fatal outcome, on the principle that a living dog is better than a dead lion. Thus, one will sometimes mistakenly but often wisely withhold malaria in a conservative interpretation of a situation in late neurosyphilis. On the other hand a routine or pigheaded conservatism is an abomination and a consistent setback to progress. As rapidly as clear cut good results *justify the taking of special risks or as the margin of special risk* is reduced by extending experience promptitude in radical or intensive methods becomes more important even than the methods themselves. Thus, in the early utilization of the advantages and assumption of the risks of malarial therapy while a relatively unimpaired (asymptomatic) nervous system and good physical resources in the patient give us every advantage,

Fig. 703.

UNIT COURSES OF STANDARD TREATMENT IN NEUROSYPHILIS
PREPARATORY UNIT (1 and 2 are alternatives.)

1 Mercury and iodide.
   (a) Hg succinimide or bichloride intramuscularly ⅙ to ¼ grain, three to five times a week for 20 to 30 injections.
   (b) Potassium iodide by mouth, 50 to 100 grains three times a day
2. Bismuth intramuscularly (water-soluble sodium tartrate liposoluble camphocarboxylate, salicylate iodobismuthate) once to three times weekly depending on the salt, for 10 (insoluble) to 20 (soluble) injections.

Discussion

(a) The mercury-iodide preparatory unit is preferred in very acute or rapidly advancing lesions, or in the presence of vascular or visceral complications.
(b) A mercurial or bismuth unit may be used simultaneously with, in preparation for or as interim treatment between arsphenamine or neoarsphenamine courses.
(c) The iodide may be used with the bismuth, or an iodobismuth salt employed.
(d) A mouth prophylaxis and preliminary iodine tolerance test are necessary

is a demand of rather than a concession to progress. The young preparetic recognized as such by his spinal fluid findings or by the earliest symptoms of the disorder is the candidate *par excellence* for the life-saving virtues of malarial therapy

Standard Treatment. —By this term is meant conventional arsenical and heavy metal therapy as outlined for example in Fig. 704. The question as to whether standard treatment est right wast time hen neurosyphilis with type III (preparetic) spinal fluid is recognized, is not fully resolved. It is conservative, and we do not believe it wastes time to give the unit course of Fig 704 if there are no urgent or deteriorative symptoms, and the patient has had no previous standard treatment Each case must be decided on its merits.

The "Unit Course. —In Figs. 703 and 704 are outlined several preparatory and several arsenical-heavy metal unit courses which may be conceived as constituting the building blocks from which a standard treatment regimen may be built up. While such a group of seemingly standardized procedures may appear to fly in the face of the proposed individualization,

such is not in reality the case. The use of treatment units will give to the management of the large majority of patients the touch of system whose value has already been emphasized. Some of the combinations are suggested in discussion of the outlines.

A Scheme for Treatment in Neurosyphilis.—While the individual specially difficult and particularly late case may require consultant assistance in individualization, it is possible to summarize current trends of reasonable but not ultraconservative practice in the treatment of neurosyphilis in a way

Fig. 764.

UNIT COURSES OF STANDARD TREATMENT IN NEUROSYPHILIS

Arsphenamine-Heavy Metal Unit.

(1, 2, and 3 are alternative types.)

1. Arsphenamine 606 intravenously preferred in uncomplicated cases; 6 to 10 injections, 0.3 to 0.5 Gm. each, weekly intervals, followed by bismuth intramuscularly (salicylate, liposoluble camphocarboxylate, iodobismuthite) in full adult dosage for 8 to 10 injections.
   (a) Arsphenamine 606 intravenously with coincident mercury succinimide or bichloride as in preparatory unit (Fig. 765)
   (b) Arsphenamine 606 intravenously 6 to 10 injections followed by 40 single or double (4 or 8 Gm.) 50 per cent mercurial inunctions (5 or 6 each week) and one month rest.
2. Neoarsphenamine 914 intravenously 0.45 to 0.6 Gm. every three to five days for 10 to 14 injections with ½ dose of bismuth (see No. 1) coincidently intramuscularly for 20 injections, the bismuth being continued beyond the neoarsphenamine course with full adult doses when given alone.
3. Neoarsphenamine "tonic (nonintensive) unit"; 8 to 12 intravenous injections beginning 0.15, 0.3, 0.45, and 0.45 or 0.6 Gm., etc., weekly alternating with (a) mercury succinimide unit or (b) 20 injections of iodobismitol twice weekly
4. Mapharsen or equivalent arsenoxide, 20 to 25 injections 2 or 3 a week, 60 mg. average dose per injection, with weekly injections (8 to 10) of bismuth subsalicylate 0.2 Gm. per injection.

Discussion

(a) The arsenical together with the heavy metal which follows or is given with it, constitutes the unit.
(b) Units may be combined into alternating continuous treatment or rest periods may be allowed after the heavy-metal part of a unit, but not after an arsenical.
(c) When mercury is employed, rest periods are more necessary
(d) The tonic unit is appropriate only to late and badly debilitated cases.
(e) Neoarsphenamine is preferred if there are coincident cardiovascular lesions.

that has been attempted in Fig. 765 It will be noted that practically every type of case is subjected to preparatory treatment, even to the advanced and deteriorated paretic who is given preparatory treatment for the purpose of appraising his treatment tolerance before putting him to the life-and death test of malarial or even tryparsamide therapy The necessity or desirability of preparatory treatment as a preliminary to malarial therapy has been emphasized by Jacobs and Vohwinkel, Kerl Mulzer Jadassohn O Leary and Osborne. In the use of routine or unit courses it must be emphasized that the arsphenamine and the heavy metal are indispensable to each other and that the course should terminate with a heavy metal. Overlapping, or staggered, intermittent, and continuous systems may be compounded of

deficiency or arteriosclerotic change in himself the singular virtue in many situations of doing relatively little, of avoiding strenuosity and of invoking the resolving power of time in a genuinely masterly inactivity Aphoristically stated we may fall back upon Ochsner's famous dictum "Leave something to God and accept a partial result in a living patient as preferable to an attempted cure with a fatal outcome, on the principle that a living dog is better than a dead lion Thus, one will sometimes mistakenly but often wisely withhold malaria in a conservative interpretation of a situation in late neurosyphilis. On the other hand a routine or pigheaded conservatism is an abomination and a consistent setback to progress. As rapidly as clear cut good results justify the taking of special risks or as the margin of special risk is reduced by extending experience, promptitude in radical or intensive methods becomes more important even than the methods themselves. Thus, in the early utilization of the advantages and assumption of the risks of malarial therapy while a relatively unimpaired (asymptomatic) nervous system and good physical resources in the patient give us every advantage,

(*d*) A mouth prophylaxis and preliminary iodin tolerance test are necessary

is a demand of rather than a concession to progress. The young preparetic recognized as such by his spinal fluid findings or by the earliest symptoms of the disorder is the candidate *par excellence* for the life-saving virtues of malarial therapy

Standard T eatment —*By this term is* meant conventional arsenical and heavy metal therapy as outlined for example in Fig. 704. The question as to hether standard treatment set right extra time when neurosyphilis with type III (preparetic) spinal fluid is recognized, is not fully resolved It is conservative and we do not believe it wastes time to give the unit course of Fig 61 I there are no urgent or deteriorative symptoms, and the patient has had no previous "standard treatment. *Each case must be decided on its merits.*

The 'Unit Course "—In Figs 703 and 704 are outlined several preparatory and several arsenical heavy metal unit courses which may be conceived as con tituting the building blocks from which a standard treatment regimen may be built up. While such a group of seemingly standardized procedures may appear to fly in the face of the proposed individualization,

sultation, for the protection both of physician and patient, precisely as in decisions involving major operations. In preparation for such decisions, adequate serological data are indispensable and are more often used in final judgment than the mere evidence of clinical improvement, though the latter is the ultimate at least at the present day of a favorable outcome. Good and complete tests on the spinal fluid are especially important. In a patient who has been for some time under routine measures without adequate serological response, a physical and neurological reappraisal as well as merely paper findings will be essential to a decision. The impressions of the family and particularly of the wife or husband on subtle changes, such as nocturnal petit mal attacks, altered disposition and "conduct slump," may be very important. A general enthusiasm for a method should never be substituted for the most painstaking consideration of specific indications and contraindi cations in each and every case

Value of Prolonged Treatment.—In summarizing the schemes applicable to the various types of neurosyphilis where reliance is placed largely on unit courses of standard treatment, emphasis should be on the prolongation of the treatment until a result is achieved In the subsequently reported results of standard treatment obtained by Shaffer and Stokes the average number of courses approximating the unit type with or without intraspinal therapy required to produce the results presented was three three to five courses are therefore made the average expectancy Only 30 per cent of our cases required four or more courses. The question as to how long one shall keep "pecking away" in the effort to wear down a serologically or symptomatically resistant case can never be given a general answer If the patient takes treatment without embarrassment and shows nothing to suggest a preparetic or paretic tendency five courses over a period of three years is the rough maximum.

W have discussed among ourselves number of times conception of periodic courses throughout life, but have always ended by opposing them on the belief based on experience, that some of the worst wrecks, physically and mentally in the general field of syphilis are the victims of the subcurative treatment habit. The question as to how far one shall try first this, then that, stepping up the intensity till nothing remains but malaria and tryparsamide for patient who at the outset showed no indications calling for either of these procedures, is problem susceptible of decision only after the fullest study of the individual case. In general, intensification in the absence of contraindications is preferable to long-drawn prolongation both from the standpoint of the patient morale and his finances—but the potential risks outweigh in decision, all told, both morale and finances.

Intraspinal Treatment Phase.—The restricted usefulness of intraspinal therapy as means of attacking localized processes, such as lower cord tabes with lightning pains, an apparently isolated meningeal lesion, or seemingly focal process such as primary optic trophy is apparent in the table. Special equipment and experience are essential in using intraspinal therapy and its present limited field does not justify its use under unfavorable working conditions as desperation measure Kierland and O'Leary (1941) revival of this procedure will be mentioned later (see p. 1049) and Viets believes that intracisternal Swift Ellis treatment may be reduced to the simplicity and status of an office procedure. If the complexion of the case is favorable, t to three or t most ten to twenty treatments should, except in primary optic trophy show definit therapeutic results. In no case have we felt disposed to use the long series of intraspinal treatments (forty or more), hich have occasionally been employed. The usual intraspinal course consist of four or five treatments at bi-weekly intervals, repeated in three to four months. In primary optic atrophy the treatment should be prolonged.

In only [illegible] per cent of our meningeal cases of neurosyphilis was any resort to intraspinal therapy necessary to secure permanent good result within the t to seven years of our observation. In only 10 per cent ere series of twenty or more such treatments given. In cerebrospinal syphilis intraspinal therapy was found necessary in [illegible] per cent and series of twenty or

these unit courses to meet individual situations. Intensification begins with the substitution of arsphenamine (606) for neoarsphenamine (914) With the advent of tryparsamide and fever therapy the method of doubling the

Fig. 763

SOME RECOGNIZED COMBINATIONS IN AMERICAN PRACTICE IN THE THERAPY OF NEUROSYPHILIS

1 Standard treatment alone (see Fig. 764) Indicated in first year to eighteen months of most infections and in rapidly advancing acute local processes with marked therapeutic shock risks (N III, N VII, meningitis, low tabes)

2. Standard treatment plus intraspinal Swift Ellis treatment in 5 injection courses for 8 to 20 treatments.
   Indicated especially in low tabes with marked ataxia, severe lightning pains, early optic atrophy

3. Standard treatment *for six months to one year followed by tryparsamide either* (*a*) in 10 injection courses with coincident mercury salicylate and four to six weeks' rest between courses; or (*b*) one to two years or more periodic combination with mercury or bismuth. *Spinal fluid examination every six months.*
   Indicated (1) As a conservative course in late latent or resistant neurosyphilis, including the "paretic formula"; (2) in the presence of malarial contraindications (3) in the presence of other active forms of syphilis; (4) in the first two *to three years of the* disease as protection against relapse, infectiousness, progression in other structures, (5) where institutional management is inaccessible.

4. Standard treatment 1 to 2 courses, malaria 12 to 15 chills, quinine and *standard treatment* 1 to 3 courses, or neoarsphenamine alone. Spinal fluid examination every six to twelve months.
   Indicated Robust young preparetics ("red flag"), and early paretics, especially *after* the fourth to sixth year of the infection, avoiding tryparsamide risks to vision. Viennese type of course.

5. Standard treatment, 1 to 2 courses, malaria 12 to 15 chills, quinine; tryparsamide either in courses or continuously one to t o years or more.
   Indicated Where well-defined symptoms of paresis have ppeared, or the patient has serious neurosyphilis, asymptomatic or symptomatic, and ill soon pass out of the optimum age period for malarial therapy

6. Tryparsamide from the start in moderate doses, 10 to 20 injections, followed by malaria, 4 to 8 chills, quinine neoarsphenamine, malaria repeated, standard treatment or tryparsamide.
   Indicated In the debilitated paretic (Poole) The broken malarial course is coddling device the initial tryparsamide for tonic effect.

7 Malaria without preparation, followed by quinine and neoarsphenamine (8 to 5 injections), then tryparsamide
   Indicated A standard institutional type of course for robust paretics.

8. Systems 4, 5 6 and 7 followed by (*a*) malarial reinoculation or (if immune) by typhoid vaccine fever cabinet.
   Indicated In clinical (not necessarily serological) failures.

9 Standard treatment combined with ( ) typhoid vaccine or hot baths.
   Indicated ( ) where equipment for other method here is lacking, or special facilities exist (diathermy) (*b*) here malaria is contraindicated, tryparsamide refused or non-cooperation makes it risky ( ) for special symptoms in neuro- and late syphilis, *e.g.* lightning pains, crises, malignant tertiarism, obstinate bone and eye lesions, serologically f st cases.

arsphenamine and heavy-metal dose (inunctions) and halving the interval in the treatment of paresis, may now be regarded as superseded.

The Decision to Intensify Treatment.—*The* decision to intensify by a shift to a treatment method involving greater risk whether to eyesight (tryparsamide) or t life (pyrexial therapy) may often be the basis for con-

syphilis, tryparsamide and intradural therapy are about equally effective and both much more so than routine treatment (3) that malaria is much

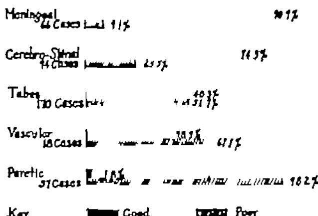

Fig. 706.—Results in treatment of neurosyphilis without tryparsamide or malarial therapy (Stokes and Shaffer)

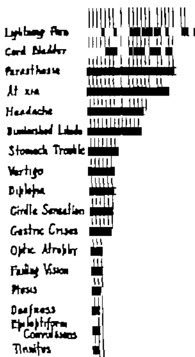

Fig. 707.—Relative frequency of common symptoms in neurosyphilis as major complaint. One space equals 5 cases.

the best treatment for paresis and taboparesis (4) that malaria and tryparsamide are more effective in tabes than routine treatment (5) and that primary optic atrophy may be arrested in numerous cases by intraspinal

therapy after all other methods have failed. Moore's further studies (1942) have led him to prefer malaria.

Response of Specific Symptoms of Neurosyphilis to Standard Treatment.—The results obtained by the Mayo Clinic service as summarized by Shaffer and Stokes, are still, in spite of the newer treatment agents, fairly representative of what may be expected in behalf of the individual patient. In Fig. 767 the relative frequency of common symptoms in neurosyphilis as chief complaint is presented, and in Fig. 768 the percentage of good clinical response. Special methods of dealing with individual refractory complaints are considered in subsequent section.

Location and Accessibility of Lesions, in Relation to Therapeutic Response.—In general it may be said that the recovery of the neurosyphilitic patient appears to depend upon the ratio of active inflammatory process to

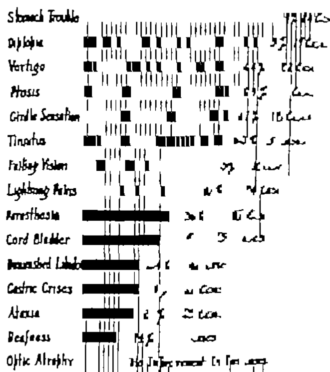

Fig. 768.—Percentage of good clinical response secured in various symptoms of late neurosyphilis. One space equals 2 per cent.

degeneration at the time treatment is begun. It is dependent, too upon the location of the lesion and its accessibility to local or circulatory approach. The approachability of the base of the brain and the meninges through their rich blood supply makes for the ready response of headache, diplopia, and ptosis and of the various paresthesias which express irritation of the spinal roots. The relatively poor prognosis of chronic anterior poliomyelitis of neurosyphilitic origin as compared with tabes dorsalis is a consequence of the direct attack of the disease upon the parenchyma of the nervous system (motor neuron) in the former and the somewhat less direct approach via the meninges, in the latter. Thus, too, a recovery of light reaction in an Argyll Robertson pupil or of absent knee-jerks in a myelitis will depend upon the location and the inflammatory character of the lesion. Both Spiller and

Stokes have seen the Argyll Robertson pupil recover and they regard this as evidence that the lesion is peripheral and not nuclear. Healing changes may as in the cardiovascular system, leave a symptom unchanged or accentuated, or as in the development of cortical epilepsy following the healing of pachymeningitis, substitute a new one for it. Many of the conflicting statements made regarding the outlook of optic atrophies, due to failure to distinguish the primary degenerative lesion of tabes from the secondary degeneration following optic neuritis in other forms of neurosyphilis, require critical revision. The outlook of secondary atrophy is proportional to the degree of neuritis still present when treatment is begun, and is often surprisingly good. The outlook of the primary degenerative type is, of course far more grave.

Serological Responses in Neurosyphilis Under Treatment.—In dealing with the more benign forms of neurosyphilis reduction of the spinal fluid and blood abnormalities to normal, side by side with symptomatic improvement, is common observation. It is also well known that clinical relapse is forewarned or accompanied by serological relapse. This marked parallelism in serological results cannot, however in the present state of knowledge, be carried over full force into the interpretation of serological as compared with clinical improvement in general paralysis. Practically all observers are agreed that while striking remission and even clinical cure as determined by economic rehabilitation criteria, may take place in the first year of general paralysis under treatment, the reduction of serological tests to normal requires from two to five years with an average of approximately four years from the institution of treatment, granted that it occurs at all.

The current statistics such as those of the CCG (Kierland, O'Leary and Vandoren 1942) must be quoted in their entirety to show the trends and even then seem to contain sources of statistical error such as nonexamination after fluid once becomes normal, no data of deaths and lapses, which permit only the general statement that the spinal fluids of tabes and taboparesis are the most resistant, those of meningeal and meningovascular syphilis the least resistant. Tabes occupies middle ground, the percentage of reversals ranging from 33.8 to 60 per cent in gradually ascending see-saw scale. It was clear in this study as in others, that serologic improvement or complete reversal does not necessarily go hand in hand with good clinical results. In the published material, the shortness of the period of observation in the larger groups of cases greatly weakens the ultimate conclusions.

The Fever Committee of the Cooperative Clinical Group (J.A.M.A. 115 677 1940) reported the following:

SEROLOGIC RESULTS

1 Reversal rates for originally positive spinal fluid and blood increased as the duration of treatment-observation increased.

2. Positive blood reversed more rapidly though not in greater proportion than positive spinal fluid. The degree of spinal fluid abnormality on beginning fever therapy influenced the proportion of expected reversals.

3. In patients treated with fever plus chemotherapy the annual rates of spinal fluid as well as blood reversal were consistently higher with malaria than with artificial fever but this difference was assumed to be due to the greater amount of chemotherapy (17 per cent more) administered to the malaria patients. Without the use of auxiliary chemotherapy there were no differences between the spinal fluid and blood reversal rates of patients treated with malaria and those treated with artificial fever

4 Blood as well as spinal fluid reversal rates were at least twice as great with as without the use of auxiliary chemotherapy Among patients not treated with auxiliary chemotherapy 46 per cent of all spinal fluid reversals subsequently relapsed as contrasted with only 24 per cent spinal fluid relapses among patients treated with auxiliary chemotherapy

5. Two thirds of all the relapses from spinal fluid reversal occurred within one year following the original reversal.

6. Negative blood serologic reaction did not indicate the status of the spinal fluid, but persistently positive blood serologic reaction was indicative of positive spinal fluid reaction.

RELATION OF CLINICAL TO SEROLOGIC RESULTS

1. Reversals of both blood and spinal fluid were associated more than twice as frequently with clinical success as with clinical failure. However, since clinical success was not accompanied by complete reversal (blood and spinal fluid) in 42 per cent of the cases it follows that clinical success was not necessarily dependent on serological reversal.

2. Reversal of the spinal fluid was more important than reversal of the blood in indicating the chances of complete clinical recovery.

3. In three fourths of the cases with clinical as well as serologic recoveries, the clinical remission preceded or occurred during the same year as the serologic reversal. When the clinical remission preceded the serologic reversal, it did so by an average difference of from two to three years. In the remaining fourth of the cases in which serologic recovery occurred first, an average of from two to three years elapsed before clinical remission was obtained.

Even, however, while we concede the lack of harmony between serological and clinical results in this special field of neurosyphilis, there is still reason to look forward to and to seek serological improvement in the paretic under malarial or tryparsamide therapy by analogy with the parallelism of clinical and serological results in benign forms of neurosyphilis. Such response should be looked for and an examination of the spinal fluid not less frequently than once in twelve months, and preferably once in six months, is a necessary part of the control of treatment in all forms of neurosyphilis.

In the majority of cases showing improvement, the spinal fluid cell count, the hyperalbuminosis, the colloidal tests, tend to subside toward normal with treatment, and the spinal fluid Wassermann becomes weaker, positive only in larger and larger amounts of fluid until it becomes negative in the generally accepted quantitative procedure. A persistently positive Wassermann reaction in the spinal fluid, as in the blood, suggests a resistant case, and should not be lightly dismissed as of little moment, though it may be perfectly proper, after a reasonable amount of treatment, to allow a more or less prolonged rest interval to decide whether the finding is significant or not. In all Wassermann testing of the spinal fluid for therapeutic purposes a quantitative procedure measuring grades of positiveness is of great help. We have seen repeatedly relapse occurring in patients whose tests were negative on smaller concentrations such as 0.3 or 0.4 cc. and who later remained normal for long periods when the test became negative on 1 cc. with a cholesterinized antigen. The fact that the lumbar fluid is not always an index of the condition of the entire nervous system must be borne in mind, of course.

Behavior of Cell Count.—Cell count under treatment tends to increase with unfavorable progress or rises in an unknown proportion of cases as a temporary flare-up of the Herxheimer reaction. It is unusual indeed to see in early cases persistently normal cell counts and persistent strongly positive findings in the other three tests. On the other hand, in late cases this combination is not uncommon. A few patients with long-standing processes never seem entirely to regain a normal count, and hover about 4 to 8 cells without, however, being any the worse for it within the period of our observation. The more pronounced abnormalities have, however, seemed to us important for observation at least. We have watched slight and even moderate degrees of spinal fluid abnormality, heralded by slight rises in cell count, sometimes even with a paretic trend, resist the utmost resources of treatment and persist over a period as long as ten years without advance of symptoms.

On the other hand we have seen to our regret, cases in which with Grade III spinal fluids at the outset, we have allowed a quick reduction to a mild grade of abnormality to lead us into withholding the utmost resources of treatment (fever) The result was a slow degeneration and symptomatic progression under a mask of serologic benignity maintained by repeated but always inadequate treatment.

Blalock and Hinsie (1936) found that the earliest serologic changes in paretic spinal fluids occur in the cell count, and Maletz and Solomon (1937) found the cell count normal at the end of one year in 80 per cent of their cases of paresis treated with malaria and tryparsamide. They noted that once the count was normal it rarely became abnormal again. A sharp rise in cell count on reexamination is referred to as meningeal relapse, and its repetition time after time is to us an earmark of resistant neurosyphilis. Stokes and Shaffer found that 9 per cent of their early meningeal, 5 per cent of cerebrospinal, and 20 per cent of their paretic cases, showed such relapses. While the symptomatic significance of the cell count is sometimes denied, we have had too many patients of reasonable intelligence able to predict, from the revival of their symptoms, almost the exact count of their fluids, not to accept this warning as sign of relapse. It is not, however, invariably accompanied by symptoms, and again may precede by months or years the ultimate appearance of definite paretic changes. The irreducible or see-saw cell count (Fig. 780) is, in our experience, an unfavorable sign.

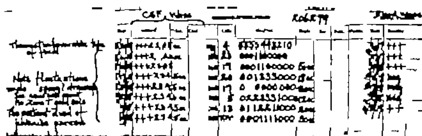

Fig. 780 —The least responsive type of spinal fluid, Wassermann strongly positive to 0.2 cc., low cell count (before treatment) and first zone gold sol.

The question as to whether the cell count is invalidated by local reaction following repeated lumbar puncture can in general be answered for our experience in the negative, provided not more than 10 cc. be removed each time and the interval be not less than week.

Colloidal Tests.—The colloidal tests must not be too closely read during treatment or minor variations given unjustified significance While colloidal reactions tend to subside toward normality as the patient improves, and a first zone test may change to a second zone and finally become negative entirely the margin of technical error is large enough especially in the gold sol, to require repetition to confirm any particular finding A reported reading below 5 from our laboratory in the first tube of the colloidal mastic test (as 3555543100) has repeatedly accompanied taboparesis with primary optic atrophy A first zone curve may gradually develop in a series which was at the outset of second zone type, and intervals of second zone tests may separate first zone tests which in view of the outcome of the case, more truly expressed a tendency toward paresis.

The colloidal test according to many observers since 1919 (summarized by Maletz and Solomon, 1937), and Moore (Text 1943) is the last of the tests to become negative (preceded by cell count, protein and Wassermann in order named). W concur in the general order but believe the Wassermann equally resistant, and the slightly elevated cell count sometimes likewise, in some individual cases.

Stokes and Baughn reached the conclusion that even though blood serum had been introduced into the canal by intraspinal treatment two weeks before, a strongly paretic fluid still retained its characteristics, and a nonparetic fluid was not in general made to yield a paretic gold sol unjustifiably. The colloidal benzoin and mastic tests, while less delicate, seem to be more constant in their expression of cerebral involvement than the gold sol.

Fig. 770.

PROGNOSIS OF HIGH AND LOW CELL COUNTS WITH FIRST AND SECOND ZONE GOLD SOL CURVES. (Stokes and Baughn.)

	Cell count.	Cases.	Improved, per cent.	Not improved, per cent.
Zone I.	High	51	38	62*
	Low	16	19	81
Zone II	High	49	65	35
	Low	19	63	37

No data in 3 cases.

Unfavorable Combinations.—The combination of cell count and colloidal test was studied by Stokes and Baughn as a result of the impression that low cell counts and first zone gold sol reactions tended to indicate an unfavorable prognosis. While their series was small, such a tendency seemed definitely apparent, and is expressed in Fig. 770.

Fig. 771.—Response of an abnormal spinal fluid to treatment, with ultimate return to serological normality. The rise in cell count following spinal puncture is a curiosity in our experience. The patient was a child with juvenile tabes who made a complete recovery. Under observation five years. Twelve intraspinal treatments.

From this figure it is apparent that the patient who has a low cell count with a first zone colloidal test and the usual accompanying strongly positive blood and spinal Wassermann reaction, has the poorest outlook therapeutically while patients with second zone colloidal tests have a very much better prognosis.

Globulin Test.—The importance of increased globulin must be largely redetermined in the light of more exact total protein estimations. Ayer

Solomon, and others have suggested their value as an index of return to normal.

Maletz and Solomon (1937) noted that gradual reduction in the amount of total protein in the spinal fluid occurs under malarial and tryparsamide treatment so that at the end of one year the total protein reached normal level in one third of their cases. But after five or even ten years, 40 per cent of the cases showed elevated total protein. They noted that to some extent the height of the total protein was an index of the final figures and concluded that the higher the initial level, the smaller is the likelihood that it will become normal. Blalock and Illness (1936) *felt also that the decrease to normal of the protein occurred less frequently than the cell count.*

Blood Serological Tests.—In the more benign forms of neurosyphilis, the blood serological tests should be comparatively easy to reverse if positive Even in the more severe forms reversal may occur in the majority of cases in about five years after treatment is instituted Their predisposition toward the negative in vascular neurosyphilis should be recalled. A persistent positive serological reaction in neurosyphilis suggests either paresis, a cardiovascular or a visceral lesion The use of the Kahn and Kline precipitation

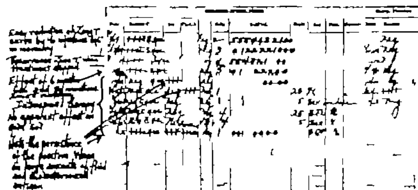

Fig 772.—An illustration of the importance of the quantitative Wassermann test on the spinal fluid, and of the ease with which first zone gold sol test may sometimes be "reduced" to negative by treatment.

procedures and their presumptive or sensitized modifications in the evaluation of the treatment of neurosyphilis is not as yet worked out.

Value of Repetition of Tests.—Spinal fluid findings gain meaning from repetition, and, in fact, can rarely be safely judged from single tests. It is the long series of tests in a single case, covering a period of years, which is really informative and yet which must never be disproportionately valued

Special Treatment Methods in Neurosyphilis

Indications, Contraindications, Technic, Results.—In beginning this discussion of the most recent advances in neurosyphilotherapy let it again be recalled that there are no exclusive methods in the field. Each and every method has its zone of particular effectiveness and two or more methods are more usually appropriate in an individual case than exclusive adherence to one alone

The rationale of the various methods here discussed has been taken up to some extent in connection with the general principles of the treatment of

syphilis and in the discussion of the various drugs and technical procedures, including nonspecific therapy

Spinal Drainage, Intraspinal and Cistern Therapy.—We believe that the controversy over the relative merits of spinal drainage and intraspinal therapy may be said to have resolved itself into approximately the following residue: Spinal drainage may be employed in treating neurosyphilis by standard methods but has very restricted field of usefulness and should not be employed as a substitute for the newer methods in refractory cases or in those showing a preparetic or paretic tendency In the main it is less effective than Swift Ellis intraspinal ther

Blood and Pus in Urine Still Ignored.
Re-examined 1918. Spinal Fluid Negative
Re-examined 1919. Trace of blood and pus in urine.
Patient at last sent to urologist.
Urine: Albumin, moderate amount. Microscopic blood (trace). Much pus.
Phenolphthalein Excretion 10 per cent.
Blood Urea: 61 mg per 100 c.c.
Residual Urine 32 ounces.

Patient refused to see urologist and returned home.

Six weeks later physician wired that he was seriously ill with vomiting and hiccup, urin very cloudy much albumin. Patient died in coma.

DISCUSSION

The diagnosis is obviously in retrospect, terminal uremia. Note that the arrest of this patient tabes was complete.

Urinary retention due to atonic ("cord") bladder is exactly as serious *factor* **in the** life expectancy of the tabetic patient as in the patient with prostatic hypertrophy It should be similarly managed.

Th **functional tests should be done early in every tabetic, and infected bladders and** retention properly treated by instruction and, if necessary catheterization and irrigation.

Catheterized *functional* **tests only are** *reliable in these cases.*

The *life* **of an arrested tabetic may** *depend* **on his bladder.**

apy as, for example, in the material studied by Osborne nd Stokes. In carrying out spinal drainage quantities of fluid ranging from 20 to 60 cc. over and above the amounts required for ordinary test purposes may be withdrawn. The patient should lie on his side and no attempt should be made t aspirate fluid. Drainages may be repeated weekly or once in two weeks, though intervals as long as six eeks have been employed, probably without material effect. Complications are rare even headaches not being any more frequent, if as frequent as after ordinary lumbar puncture Reports of precipitation of generalized neurosyphilitic manifestations are rare (Jahnel, Handbuch) Of the various intraspinal procedures available including the introduction of arsenic in the form of arsphenamine, neoarsphenamine, arsphenaminized serum reinforced with arsphenamine (Ogilvie modification) and tryparsamide, we believe that opinion has pretty well simmered down t the use of the Swift Ellis auto-arsphenaminized serum to the exclusion of the

This case, despite its ancient date-line, is retained as one of the eternal verities.

Fig. 774.

CEREBRAL GLIOMA WITH FATAL TERMINATION IN A PATIENT WITH SYPHILIS. EPILEPTIFORM ONSET CONFUSION WITH NEUROSYPHILIS. TRANSIENT IMPROVEMENT UNDER ANTISYPHILITIC TREATMENT

Male, aged thirty-five, clergyman.

Date Examined May 9, 1919
Chief Complaint Swollen knee.
History: The early history of this case is given in Chapter XV to illustrat the impor tance of taking blood Wassermann tests in synovitis before operative interference The patient remained under treatment for four years and during that time his case underwent the following developments
Synovitis of the Knee: Given 9 arsphenamin injections and 40 inunctions. Disappeared from observation.
Returns eighteen months later complaining of dizziness and convulsions.
Neurologic examination two years before had been negative, with negative spinal fluid.
Pupils now slightly retarded and unequal. K. J. slightly increased, hypogastric decreased -ray of head negative; no aura.
Indeterminate diagnosis Grand mal (?)
Returned fifteen months later Series of arsphenamin injections elsewhere less than one month go. Convulsions disappeared, but now has severe bilateral frontal headaches and failing memory; involuntary bowel movements occasionally; will not talk; walks slowly; slight staggering; voice normal; 20 pounds weight loss; has never been right mentally since last arsphenamin injection given when he had fever of 101 F Patient drowsy all the time. Spinal fluid negative.
Neurologic Examination Left eye deviates on convergence. Pupils slower than on previous examination. Bladder control much reduced. Biceps and patellar reflexes increased Cremaster and bulbocavernous reflexes decreased. Marked tremor; slurred speech and difficulty with speech tests. Slight sensory disturbances in perineal region.
Neurologic diagnosis before spinal fluid examination was "dementia paralytica or severe meningo-vascular syphilis. After negative spinal fluid examination diagnosis of paresis unlikely May have neurosyphilis, but cannot be certain. Incontinence hard to interpret, as objective findings are almost all over sacral distribution.
Later neurologic opinion under hospital bservation "Essentially an encephalitis, but whether syphilitic or otherwise we cannot say May have softening of the silent area due to thrombosis in addition to old findings. Nothing especially characteristic of epidemic encephalitis. Would have to place question mark after any C. N. S. diagnosis made. Would treat him for lues if any other findings indicate.
Placed on treatment for syphilis, given 40 injections mercury succinimid grain ⅙; 30 injections sodium iodid, 10 grams daily 5 injections arsphenamin 2 to 4 decigrams.
Result, marked improvement Became well oriented, remembers present and past events, but his speech is slow and tremor of lips persists. Headache disappeared.
Neurologic comment, "Would continue to treat as for lues. This patient may have brain tumor but lues seems undoubted. Get fundus examination. Examination fundus—hyperemia and edema of disks (1 diopter right, 2 diopters left); apparently choked disk.
Neurologic examination five days later—frontal lobe syndrome. Gradual deterioration, death two weeks later.
Postmortem examination—glioma of frontal lobes of cerebrum with gliosis Syphilitic aortitis with advanced arteriosclerosis cardiac hypertrophy ith moderate dilatation.

Discussion

The neurologic comments show in the clearest possible way the difficulty in distinguishing objectively between syphilis and frontal lobe tumor.

Note especially the repeated improvement in the patient neurologic symptoms under treatment for syphilis.

The negative spinal fluid is compatible with vascular syphilis of the brain and has been repeatedly seen in patients who at autopsy show incontestable evidence of vascular cerebral syphilis.

The negative spinal fluid practically eliminates general paresis.

Note that in all the numerous physical examinations to which this patient was subjected in the period of four years, not once was his cardiovascular condition (advanced aortitis and arteriosclerosis) ever suspected.

His blood-pressure was repeatedly found to be within normal limits, 120/80, and no murmur was ever recognized.

Non-specific effects of treatment for syphilis must be guarded against in the therapeutic test with arsphenamin, mercury or iodid in an effort to differentiate cerebral vascular syphilis from encephalitis and frontal lobe tumor

other enumerated methods. There seems no reason for introducing nonspirillicidal drugs such as tryparsamide into the spinal canal, and much of the action of mercurials, for example, must be that of exciting aseptic meningitis (cf Kierland and O'Leary 1941).

In administering intraspinal therapy in present practice, the indications include (1) moderate resistiveness, especially of the meningeal phase of early meningovascular neurosyphilis (2) low tabes with bladder and sexual disturbances and marked lightning pains and ataxia (3) basilar meningitic lesions, including isolated cranial nerve involvement in which the technic should be that of Gennerich the patient being kept with the buttocks high and head low for some time after the performance of the intraspinal injection (4) primary optic atrophy (Moore contra, 1942)

Among the contraindications should be included (1) especially rapidly advancing bladder sphincter difficulties (2) acute cerebral processes with increased intracranial pressure (choked disk) (3) rapidly progressive ataxia and advanced tabes dorsalis (4) patients in whom reactions from the treatment are more severe than those resulting from ordinary lumbar puncture (Kierland and O Leary 1941 with which our experience is not entirely in accord since we have almost no reactions to puncture and some leg pains after Swift Ellis) Gastric crises in general are not particularly responsive to intraspinal therapy and severe attacks may be precipitated by the procedure. Inexperience with the method is always a contraindication to its use for it is distinctly the province of experts.

Intracisternal and intraventricular therapy was extensively employed in the treatment of paresis and primary optic atrophy but has been largely superseded both because of its technical difficulties and its risk. If employed, the Swift Ellis procedure is the only one we consider even reasonably safe and we believe equally good results can be obtained by the Trendelenburg posture in intraspinal therapy or by the Gennerich double-puncture technic (page 328) Moore speaks of the intracisternal route as probably" valuable in primary optic atrophy

Tryparsamide Therapy of Neurosyphilis

Therapeutic Use of Tryparsamide in Man.—Tryparsamide in syphilology at the present day is a one-purpose drug. Its field of effectiveness is limited to neurosyphilis and conspicuously to early and active paresis. Moore, Robinson, Keidel, and Lyman (1924) showed conclusively that the drug is entirely ineffective in all other aspects of systemic syphilis except that of the nervous system and that its use even in early neurosyphilis associated with secondary cutaneous and mucosal lesions without reinforcement by other forms of treatment may be associated with recurrence continuance of active lesions and even some forms of relapse There is no evidence that the drug has any preventive effect in the control of late neurosyphilis, but this question has not had systematic investigation

The drug has, incidentally marked tonic properties and eight gains are to be expected. Not infrequently it is necessary for the patient to be completely retailored, if in poor condition at the outset. There are also definitely stimulative effects pon the sexual centers observable in even comparatively normal individuals, but this should not be taken as endorsing it to the public as an aphrodisiac

Methods of Administration and Dosage.—Tryparsamide is administered intravenously the therapeutic dose being dissolved in 5 to 10 cc. of water

prepared under all the precautions appropriate to arsphenamine. Jamot describes its subcutaneous use in trypanosomiasis with occasional abscess formation only. The method, however, is not advocated. The crystalline drug can be dissolved in ampule by a technic similar to that for any of the more easily soluble arsphenamines, the large ampule favoring this use. The dosage of the drug comes as a distinct shock to one accustomed to an arsphenamine scale, ranging as it does from 1.0 Gm. to 5.0 or even, on rare occasions, to 7.0 Gm. with an optimum adult dose of 3.0 Gm. (0.04 Gm. per kilogram of body weight). Lorenz and Reese, whose experience is enormous, particularly caution against the use of doses less than 1 Gm., stating that they are definitely irritative and hasten the progress of the disease. The total amount of the drug given in successful cases ranges from 48 to 1500 Gm. (Lorenz).

Prolonged Treatment.—Tryparsamide makes no impression, or an actually unfavorable one when given as a scattering of injections or a single short course. The best clinical and serological results all observers agree, do not appear until after 70 to 100 injections. It is a matter not as yet definitely settled whether these should be given in broken courses or continuously, but either technic may be accepted as satisfactory according to the circumstances and individual indications. Cady and Alvis believe that high dosages and long series tend to favor eye complications, but while too large preliminary dosage may be important, there is much evidence that eye complications are most frequent during the first ten injections and that thereafter a series may be indefinitely continued with little risk of trouble from this particular complication. Vigilance should not, however, be completely relaxed after the tenth injection since a patient on our service had tryparsamide visual disturbances on the eighty-second injection (Beerman and Shaffer, 1940). Others have noted similar cases. Downs and his associates (1941) found that 31 per cent of the objective visual disturbances among their 223 patients occurred late in the course of treatment, one case after 113 injections. Reese (1940) insists, however, that tryparsamide must be used week after week for a period of years. Tryparsamide treatment is not an exclusive form of therapy. It may be used to advantage in alternation with courses of standard treatment if indicated by the general status of the syphilitic infection, or in alternation with fever therapy or as a sequel to it if indicated by the status of the neurosyphilis. The original Lorenz Loevenhart technic prescribed the use of mercury salicylate in 1-grain doses weekly, and many observers still continue this synchronous use of the mercurial. Bismuth may likewise be thus employed, either between the individual tryparsamide injections or simultaneously with them.

Complications in Man.—Tryparsamide, aside from its optic nerve damage, was considered to be so reactionless that Lichtenstein rated its innocuousness ironically as a positive drawback to the popularization of the drug. Recently there has, however, been an apparent increase in the observed frequency and severity of various reactions (Moore, 1939; Traenkle and Dalce, 1939; Hinrichsen, 1939; Beerman and Shaffer, 1940; Kopp and Solomon, 1940; Downs, McDermott and Webster, 1941). There has perhaps been a tendency to overemphasize the minor ones.

The reactions produced by the drug are summarized in Fig. 775.

Downs and coworkers found that 80 per cent of the nitritoid reactions (their most frequent reaction) occurred late in the course of treatment and repeated reactions necessitated stopping therapy in 42.2 per cent of their

223 cases Kopp and Solomon (1943) found that the use of tryparsamide immediately following fever does not increase the amount of liver damage or delay repair The Cooperative Clinical Group in an experience of 19,964 injections noted 0 35 cases of jaundice per 1000 injections.* The incidence of crustaceous dermatitis from tryparsamide is according to the Cooperative Clinical Group, 0 15 per 1000 injections. Epstein (1941) found in a comparison of the various arsenical antisyphilitic drugs that in regard to total skin reactions mapharsen was apparently second only to tryparsamide in relative freedom from paratherapeutic cutaneous complications. While it is generally safe to use tryparsamide when indicated in a patient who has recovered from trivalent arsenical dermatitis, the possibility of polyvalent sensitivity previously mentioned should be recalled.

Our material (Beerman and Shaffer 115 cases) contained 10 patients who sustained one or more systemic reactions to tryparsamide. There were no

Fig 775.

COMPLICATIONS OF TRYPARSAMIDE THERAPY

1 Local slight burning, no necrosis.
2 Abscess: subcutaneous use 1.6 per hundred cases. Method not recommended.
3. Dermatitis occasional, mild. The drug may occasionally be used after trivalent arsenical dermatitis.
4 Fixed exanthem (rare) Urticaria (rare) Herpes Zoster (occasionally)
5 Nausea, vomiting, diarrhea, cramps.
6. J undice and hepatitis mild incidence 1 to 10 per cent of cases. (3.8 per cent Kopp and Solomon.)
7 Nitritoid crisis, dizziness, sickness. (Nitritoid reaction may occur after much tryparsamide therapy Kopp and Solomon.)
8. Possible slight irritation of abnormal kidneys.
9 Neuritis (rare)
10. Idiosyncratic intolerance: loss of weight, increased irritability confusion, coma.
11 Therapeutic flare-up (Herxheimer) del yed to fourth t eighth eek may require incarceration of disturbed patients.
12. Eye complications: toxic trophy or amblyopia.

TRYPARSAMIDE TREATMENT IS TONIC;
USUALLY UNEVENTFUL AND UNSPECTACULAR

local reactions. The reactions we observed included loss of weight (2 cases) severe nitritoid crisis (4 cases) nausea and vomiting (7 cases) itching or patchy dermatitis (4 cases) headaches (1 case) jaundice (1 case) nervousness (1 case) neuralgic pains (1 case)

Occasional patients show what might be regarded as idiosyncratic reactions to tryparsamide. That is, without apparent reason they tolerate the drug poorly lose weight become nervous and restless and confused a prompt improvement ensuing when the drug is stopped In such cases it is best to discontinue its use entirely

Therapeutic Shock Effects from Tryparsamide.—An earlier suspicion has grown into certainty on this point. There can be no reasonable question that the drug produces symptomatic exacerbation in neurosyphilis which is especially disturbing and vexatious in the first six to ten weeks of the treatment of the disturbed patient This evidence that therapeutic flare-up occurs

Gastrointestinal reactions ere encountered in 7 1 per cent of Kopp and Solomon s patients.

has led to reduction in the initial dose and to increasing it gradually We believe with Cady and Alvis also that this measure, together with intensive preliminary preparatory treatment by the use of mercury bismuth, and the

Fig 778.

THE EYE COMPLICATIONS OF TRYPARSAMIDE

1. Comparatively frequent at the outset, they are still too common t the hands of the inexperienced and careless physician who does not apply ophthalmologic control.
2. The injury is presumed to be as with atoxyl, to the third neurone of the optic tract. The effect is an optic atrophy with visual loss first, disk changes later
3. Complications more frequent in abnormal than normal eyes (Cady and Alvis, 1.5 per cent vs. 37 per cent Hinrichsen, 2.9 vs. 22.7 per cent).
4. Primary optic atrophy however is not an absolute, though relative contraindication (Woods and Moore, Cady and Alvis)
5. Choroiditis is not a contraindication (Stokes and Wilhelm, Hadden and Wilson). (Especially if vitamins used, Muncy)
6. Two types of symptoms subjective, followed by objective.
7 Two types of outcome transient with recovery; permanent impairment, partial or complete. The former is much the more common. Vision may ultimately even improve over outset.
8. Subjective symptoms include dimming of vision, grayness, ground glass effect, dazzling (as of sunlight on snow), an appearance as of clouds or "waves approaching from the periphery of the visual field, and uncertainties in gait suggesting poor vision.
9 Objective symptoms include: mild cases with reduced visual acuity concentric or sector contraction of visual fields, unilateral or bilateral, partial or complet recovery; severe cases, total amblyopia with ultimate complet optic atrophy
10. Risk of eye complications decreases rapidly after the first course nd is negligible, *though not completely nil* after the tenth injection.
11. Suspension of treatment for month following subjective symptoms may make continuance of the drug possible (Cady and Alvis) but is not without risk.
12. Preventive measures:
    - (a) Insist on the proper ophthalmological control and complet eye examination before visual acuity tests and perimetric fields (not rough tests) *during* the first series of 10 injections. Check before each injection (fundus examination alone not trustworthy).
    - (b) Enlist patient cooperation if condition permits and protect yourself by explaining risks and symptoms and obtaining consent (some therapists disapprove).
    - (c) If cooperation of patient not obtainable, risk is much increased.
    - (d) Begin with moderate doses (1 Gm.) and have preparatory treatment with "606" and bismuth if possible.
    - (e) Question the patient each time before injection.
    - (f) Have the ophthalmological report at hand before each injection up t the sixth or tenth. Unnecessary except occasionally thereafter.
    - (g) Stop treatment immediately if subjective symptoms appear Do not wait for objective changes.
    - (h) Do not treat pregnant women with tryparsamide W have no knowledge of the effect on the child' eyes.
    - (i) Caston has suggested "forced" spinal drainage as treatment.
    - (j) Vitamins especially the B complex (Muncy) and B_1 (Boley and Albers). (Experimentally suggested by work of McDermott et al.)

arsenicals tends to reduce both the risk of therapeutic shock and eye complications.

Tryparsamide and the Optic Tract.—This group of complications has been extensively studied, beginning with the observations of Woods and Moore, Lillie, Young and Loevenhart and subsequently of Cady and Alvis. The principal facts thus far known regarding the eye complications are sum

marized in Fig 776 The average incidence based upon a compilation of the result in the literature to date involving approximately 7500 cases is about 9.8 per cent, and the frequency diminishes with the size of the series and the experience of the therapist.

Much has been written recently on the safety as well as risks of using tryparsamide in patients with impaired eyes. Regardless of the suggestions pro or con Hinrichsen, in her invaluable review has demonstrated from the reports published from 1928 to 1938 that tryparsamide causes about eight times as many permanent ocular complications in patients with damaged eyes before treatment as it does in those with normal eyes before treatment. She found that the average amount of permanent injury to the optic nerve in cases where there was no involvement prior to tryparsamide treatment amounted to 2 9 per cent, whereas in cases with optic atrophy which were treated with this drug there was an average incidence of 22.7 per cent of permanent optic damage

The irreducible minimum of eye complications with present experience seems to range about 1 to 2 per cent. Great emphasis should be laid in prevention on the use of subjective symptoms as guides to the cessation of treatment. If for any reason the patient is unable to cooperate, either in giving account of these symptoms at each injection or in carrying through the visual acuity and perimetric field tests, the risk from tryparsamide therapy is notably increased We have never been able to reach the point, in an estimation of the innocuousness of the drug at which we are willing to give up the practice of fully explaining the situation to patients or relatives and securing from them at least a verbal assent implied by their acceptance of a letter stating the facts. Some careful observers, however have thought that this procedure increased the subjectivity of the patient and have given it up. Our most serious early mistakes arose from reliance on the fundus *examination as distinguished from visual and perimetric tests and from* failure closely to question and observe the patient

The Abuse of Tryparsamide.—The usefulness of tryparsamide is being curtailed by the unnecessary and indeed shockingly negligent occurrence of tubular vision and amblyopia in patients whose treatment was begun or carried on without ocular checks, or persisted in after their complaints clearly indicated the need to stop The drug is also misused in the treatment of early syphilis with some unsupported notion of the prevention of paresis in mind (no spinal fluid abnormalities) and in the treatment of aspects of syphilis in which no benefit can be expected (primary and secondaries)

The medicolegal responsibility of the physician in cases of amblyopia due to tryparsamide has been affirmed by a decision of the Supreme Court of Appeals of Virginia (J.A.M.A. 1941) in which it was ruled that tryparsamide is a potent drug which should be administered only under ocular control.

The Indications and Contraindications for Tryparsamide Therapy—In Fig 7— are summarized in parallel columns the indications and contraindications for the use of tryparsamide in neurosyphilis. The atmosphere of controversy which inevitably surrounds various methods of treatment within the first few years of their introduction produces an effect of pitting tryparsamide against pyrexial therapy and especially malarial inoculation. Such comparisons have their good and bad points, the latter particularly evident when prejudice leads to the use of one method to the exclusion of another where both would be applicable Even though both tryparsamide and fever therapy

are planned for a given case, the sequence inevitably involves elements of decision as to money time and energy to say nothing of appropriateness to social and other conditions. Figure 777 (tryparsamide therapy) may therefore be compared with Fig 153 (malarial therapy) for indications and con traindications.

Fig. 777

TRYPARSAMIDE THERAPY

Indications	Contraindications
1 When prolonged ambulatory treatment of noniscapacitating character in resistant neurosyphilis is possible or essential. A practitioner' method.	1 When disease of the optic nerve is present (not the vascular mechanism)
2. When expertly managed malarial therapy is inaccessible because of location, local or economic conditions.	2. When eye warning symptoms follow properly (ophthalmologically) controlled trial (1 to 10 injections)
3. Asymptomatic nonparetic neurosyphilis, when serologically resistant to 2 or 3 courses of standard treatment.	3. In paresis and preparesis when every condition favors malarial therapy
4 Paresis and preparesis, early enough to allow trial of both methods (tryparsamide and fever) if either fails.	4 When the patient responds poorly or is reactive to it.
5 Where the patient prefers eye risk to mortality risk.	5. When serological or clinical improvement is delayed more than one year and the patient is eligible for malaria.
6. I certain of the contraindications to malarial and fever therapy; especially old age, marked cardiovascular disease, active tuberculosis, diabetes, obesity severe debility (a) As preparation for malaria in debilitated patients.	6. When the patient is near the age limit or is threatened ith complications that might by delay lose him his choice of malaria as resort if tryparsamide fails.
7 As an adjunct and sequel to successful malarial or other fever therapy	7 When the patient or his family rejects eye risks.
8. Where malaria has failed to "take or the results were unsatisfactory	8. Pregnancy (effect on NII in the fetus)
9 A "last ditch resort in gastric crises.	9 Presence in patient of other active forms of syphilis (to tryparsamide alone).
	10. Marked arsenical intolerance or hepatic insufficiency?

Discussion

1 **Advantages of tryparsamide** Permits ambulatory inconspicuous, nonstigmatizing treatment, equal or only slightly inferior to fever therapy without interfering with occupation (unless patient is of irritable or disturbed type); few serious complications of NII, almost no reactions; practically no mortality as such marked toxic effect; vailable through home physician; usable where malaria may be contraindicated.

2. **Disadvantages of tryparsamide** A definite risk to vision varying with experience of physician, selection of case and control, totaling between 1 and 9 per cent (most visual disturbance temporary blindness rare) slow action, prolonged treatment necessary; therapeutic flare-up may force institutional care after all, delay if drug not effective may cost patient the chance for or full benefit of malaria.

Treatment of Tryparsamide Complications.—The management of tryparsamide complications follows the general principles described for the trivalent arsenicals. Stopping the drug in time necessitates an inquiry at each treat ment session, as to the effect of the previous injection. Since complications other than the idiosyncratic and the ocular tend to occur late after many

treatments have been given, it is usually best to give the drug up entirely rather than to take needless risks. Two months rest and a resumption at a lower dosage scale is sometimes effective While we have the impression that more patients who have had prolonged tryparsamide therapy have enlarged livers than in similar groups under ordinary treatment, Kopp and Solomon whose experience is very large, have apparently discounted this risk on the basis of functional tests.

Ocular complications are at present dealt with (1) by *stopping treatment in time* and keeping it stopped (2) by repeated forced spinal drainage (Kubie, Casten) with the administration by mouth, subcutaneously and intravenously of large amounts of hypotonic fluid (0 45 per cent Na Cl (3) the intravenous administration of thiamine chloride 50 to 100 mg at first

Fig. 778.

RESULTS OF TRYPARSAMIDE THERAPY IN NEUROSYPHILIS

Type of Neurosyphilis	Clinical Remissions: Range of Percentage	Clinical Remissions: Average Percentage
Early General Paresis	12 to 70	49 7
Advanced General Paresis	0 0 to 30	[illegible]
Taboparesis	0 0 to 80	[illegible]
Tabes	Few remissions (20 to 75 improvement)	(43 8 improvement)
Meningovascular Neurosyphilis		44 0

[1] Lorenz series restudied by Reese, 1933 includes paresis, taboparesis, asymptomatic paresis, meningovascular syphilis and a small proportion of tabes. The 135 cases which had recovered had been under observation for at least five years and represent 87 per cent of a group of 155 cases which had shown an initial favorable response to tryparsamide therapy five years previously As will be seen from Fig. 778, the drug is notably useful in tabes and taboparesis as well as meningovascular syphilis, but without any comparison with standard intensive treatment, which is considered later (Solomon and CCG results).

Based on a summary of the literature by Hinrichsen, 1939

daily later 3 times a week for considerable periods. Intelligent patients have insisted that they experienced improvement in visual acuity even though fields remained unchanged under B_1 B complex, and A vitamin therapy We have observed field improvement in one case in which atrophic change seemed to have come to a standstill on thiamine chloride intravenously but such interpretations are risky If and when a general arsenic eliminant becomes available ocular complications will probably respond to a degree proportionate to the promptitude of their recognition.

Results from Tryparsamide Therapy —In spite of the obvious difficulties in evaluating a question of this sort we have in Fig. 778 prepared a tabular condensation from Hinrichsen s paper (1939) to summarize a group of carefully controlled series and resumés in which the tabular classification was applicable to the data given While such comparisons, lacking a standard of

agreement as to what shall constitute complete and partial remission and within the limits of elapsed time, cannot be completely satisfactory it is apparent that in its chief field of effectiveness, namely general paralysis, the drug is capable of securing complete remission with economic rehabilitation in approximately one half of the early cases remission in one fourth of the later cases.

Aldarsone as Substitute for Tryparsamide.—Previously described in Chapter VII, this drug, a pentavalent arsenical synthesized by Raiziss and coworkers, has according to the observations of Kamman (1938) and Spiegel, Leifer and Sarason (1941), totalling 186 cases, practically no complications of any sort, including ocular damage, and the drug was used with actual improvement in patients whose fields showed contraction. The serologic and clinical results were promising and deserve further study especially when tryparsamide is contraindicated.

Results of Fever Therapy in General Paresis (Induced Malaria and Artificial Fever).—The statement of the accomplishments of pyrexial therapy in this field can now be reduced to quite definite percentages, thanks to the shake-downs in definition and interpretation produced by the long experience of a number of individual observers plus the evaluations of such groups as the Committee on Non-Specific Therapy of Syphilis sponsored by the United States Public Health Service. Best expressed in the words of this group (J.A.M.A., 115 677 1940) are the now generally accepted terms for outcome, as follows

The term paresis in this study refers to the symptom complex caused by syphilitic meningo-encephalitis, characterized by distinctive psychiatric, neurologic, serologic and spinal fluid abnormalities.

All patients were classified by degree of involvement on beginning treatment with fever therapy The following subdivisions were maintained throughout the evaluation:

( ) Mild: Relatively free from signs of deterioration, with mental symptoms, usually transitory

(b) Intermediate Symptoms of manic excitement, depression or other psychiatric syndromes, in addition to evidence of moderate deterioration

(c) Severe: Evidence of advanced deterioration.

The clinical results of therapy were defined as:

(a) Remission Sufficient clinical recovery to permit the patient to return to his former socio-economic status.

(b) Improved: Complete or partial disappearance of clinical manifestations without corresponding improvement in the capacity to return to the former socio-economic status.

( ) Unimproved: N detectable clinical evidence of change in the course of the disease.

(d) Progressed Clinical condition less satisfactory after therapy than before.

(e) Death: Treatment deaths during therapy or deaths regardless of cause, occurring during or within three months subsequent to therapy

Occasionally further grouping of the cases in terms of clinical results was necessary in order to effect additional comparisons. These groups were

(a) Clinical success: Remission.

(b) Clinical failure· Unimproved, progressed, death.

(c) Relapse: Reversal from clinically successful result to clinical failure.

The serologic results of therapy as determined by spinal fluid and blood tests, were classed as·

( ) Positive (which includes cases with doubtful reactions).

(b) Negative.

(c) Not done.

The various degrees of abnormality of the spinal fluids were classed as Groups I, II and III previously described (p. 120).

Figure 779 presents the clinical results of malaria and artificial fever in the three grades of clinical paresis. Throughout the table artificial fever has somewhat the advantage in remissions secured (58 per cent malarial *versus* 59 per cent artificial in mild cases for example) The differences we are inclined to believe are within the margin of error due to material, selection and interpretation and *do not conclusively prove superiorities or deficiencies.* The mortality figures, however also favor artificial fever

Ewalt and Ebaugh (1941) directed attention to this interpretative factor in statistical material, and rated an intensive fever therapy-chemotherapy routine as beneficial to from 60 to 70 per cent of patients with paresis.

Figure 780 brings Fig 155 p 345 up to date for the purpose of showing again the shake-down to a range of 25 to 35 per cent of good remissions to be expected of malarial therapy with improvement in 25 to 40 per cent.

From J A M A [illegible]

The duration and degree of fever necessary to obtain such results as the Committee reports is given on p 345 Kopp and Solomon (1939) in a one- to thirteen year observation material (309 cases, 189 with general paresis) found that significant statistical differences did not exist between the groups reaching levels of 104 105 and 106 degrees with respect to clinical results The best results were obtained when more than 150 hours at 100° F were experienced Less than 10 paroxysms were definitely less effective than more than 10 The frequency of paroxysms and length of malarial incubation period made no difference

Serological Effect of Malarial and Artificial Fever Therapy—It is now quite generally accepted that clinical improvement and serological improvement under fever therapy in general, and in fact under all the indirect or systemic methods of treating neurosyphilis, do not necessarily go hand in hand (see above)

According to Hinton and Blalock, the cell count of the spinal fluid following fever therapy is the first factor to show improvement and the colloidal test is particularly resistant in the first two years Thereafter however the ultimate proportion of negative colloidal tests is larger

than of any of the other reactions, the Wassermann reaction on the blood being the most resistant to change and the spinal fluid Wassermann reaction intermediate between the two. Osborne estimates that the maximum improvement will be established between the second and the fourth years. O'Leary and Brunsting, examining the status of patients three to five years after treatment, found the spinal fluid completely negative in 58 per cent of 60 cases, and markedly improved *in an additional 20 per cent. Of 36 patients who had been in complete remission*, 73 per cent had attained completely negative reactions i the blood and spinal fluid. In the taboparetic as distinguished from the paretic group, the results were less satisfactory Osborne reported negative blood Wassermann reactions in 35 per cent and negative spinal fluids in 29 per cent of approximately 400 mixed cases of neurosyphilis. Hinsie and Blalock, in 197 patients treated with malaria between 1923 and 1928, some in combination with tryparsamide, and evaluated in 1932, found 78 per cent had obtained negative blood Wassermann reactions

and 83.1 per cent negative spinal fluid Wassermann reactions. The colloidal gold curve was negative in 69.7 per cent of these patients. They could recognize no close parallelism between the clinical and the laboratory status of their cases. According to later paper by Blalock and Hinsie (1936) in paresis, the best serologic results occurred if the patient received fever therapy followed by chemotherapy but Kierland, O'Leary and Vandorea (1942) found intraspinal ther apy the most effective means of reversing the spinal fluid in all forms of symptomatic neurosyphilis. Malaria therapy however proved most effective in obtaining marked clinical improvement and in preventing progression.

It is evident, then, that while a return to serological normality may be expected in a rather large proportion of malarially treated patients, serological normal'ty is neither a prompt, a necessary nor a significant concomitant of clinical improvement. While in general it is desirable to attain

it, present knowledge of its significance is hardly sufficient to allow us to overstress it.

Comparisons of Tryparsamide and Fever and Other Methods.—Here again, tabular summaries best present the evidence for the current conclusions (*Figs* 781 782, 783)

Due to treatment	2.3%	2.5%	

Relative Response of Various Types of Paresis.—In Fig. 784 quoted *from Hinsie and Blalock are summarized the outcomes of various types of* paresis under exclusive malarial or tryparsamide therapy and combinations of the two. As in the literature in general it is apparent that expansive types make the best response, and that euphoria and grandiosity argue a favorable rather than an unfavorable outcome.

General Comparative Summary.—The situation, then, we think, may be *summarized approximately in these terms, which no doubt will not please* the enthusiasts on either side. The choice of mode of treatment must be individual, not routine. The general situation may perhaps best be defined by saying that the young, robust paretic or preparetic with definite though

early symptoms or signs, who can afford hospitalization who is likely to become uncontrollable under ambulatory conditions if the process is stirred up by any form of treatment who must rapidly achieve a result before his own funds or those of his backers are exhausted or who is approaching the age of increasing risk (say forty-five years and over) is wisest to take malarial therapy as a first choice. On the other hand there does not seem at the moment, in view of the excellent tryparsamide results reported and the steadily decreasing risk of eye complications under better technical management, particularly strong reason why asymptomatic neurosyphilis, even with a preparetic or "red flag" formula should be subjected forthwith on recognition to fever therapy Particularly does the method seem inappropriate in such a situation when unsupported by general systemic treatment though the same statement applies to tryparsamide Six months or a year's trial of tryparsamide, or even two years of tryparsamide can frequently be carried by these patients without difficulty or embarrassment, while they remain at work as effective members of the community Where age debility and nonsyphilitic complications and contraindications to malaria are factors, tryparsamide also deserves first choice. With the growing comprehension of the advantages and possibilities of combined treatment precedence may remain an issue for decision but exclusion will tend to disappear

The important rôle played by chemotherapy in conjunction with all forms of fever and especially tryparsamide therapy is brought out by Simpson, Kendell and Rose's critical review of the larger part of existing material (1942) It is further emphasized in a somewhat unexpected fashion, by Solomon and Epstein's report (1036) of the tryparsamide-induced fever sequence, which our own limited observation confirms that malaria after prolonged use of tryparsamide without reversal of serologic findings, results in a sudden and surprising drop to normal. Evidently there is an effect of preparation for a good fever result, produced by preliminary chemotherapy as well as an accentuation of chemotherapeutic effect by fever

Postmalarial Use of Mapharsen.—Dattner and Thomas (1942) have carried over with intensification the Viennese practice of employing a trivalent arsenical after malaria, using mapharsen instead of neoarsphenamine, believing that the literature does not support the superiority of the pentavalent arsenicals as postfever routine They administer 10 daily intravenous injections of mapharsen, 60 milligrams each immediately following the last malarial fever The spinal fluids were not examined until six months later and the results have been stated to be satisfactory They do not approve the prolonged use of any arsenical after fever and do not continue routine weekly injections for more than six months, unless the fluid shows increased cells and protein at the end of this time

What then, in General May Be Expected of Existing Forms of Treatment?

1 Malaria and induced fever run neck and neck, with slight advantage to induced fever in early cases and a lower mortality in severe cases.

2. Intraspinal therapy produces the better serologic results, malaria the better clinical results and malaria is the better preventive of progression.

3. Tryparsamide, prolonged, can practically equal malaria, in paresis.

4 Fever and tryparsamide, employed as early as possible is the treatment of choice in the vast majority of cases.

5. Routine intravenous and intramuscular therapy still holds a place in tabes and as a brief preparation for more resistant (paretic) neurosyphilis.

Treatment Combinations in Neurosyphilotherapy

It must be apparent that from the various methods described, an almost unlimited number of commutations and permutations designed to meet individual indications can be devised. This individualization is eminently desirable up to a certain point, but thoroughly confusing where other than expert guidance must be relied on. We have accordingly in Fig 785 skeleton ized the situation for American practice at the time of this revision, omitting mention of methods exclusively used abroad or those still in their experimental stages, except in dealing with the difficult problem of special symptoms.

Treatment of Special Groups of Cases, Types, and Symptoms

Response of Individual Symptoms to Standard Treatment.—For purposes of comparison and review the general symptomatology of neurosyphilis as shown in Fig 750 should be compared with the percentage of good clinical responses secured by standard methods, including intraspinal therapy as shown in Fig 768. It will be apparent that the frequency of a symptom is by no means closely coordinated with its susceptibility to relief by treatment.

Furthermore there is an element of uncertainty at the outset as to whether a patient will fall into the category of easy arrest with routine standard treat ment symptomatic without corresponding serologic response easy serologic response with inadequate symptomatic relief temporary response with easy relapse of symptoms, serology or signs or progression in spite of or following treatment, with or without negative serologic signs, initially or as a result of treatment. The effort to clarify these often puzzling situations has been made by such authors as O'Leary using the CCG material, and Dattner and Thomas using the Bellevue Hospital material. Their views may well be summarized in advance of our own.

O'Leary (1936) view can be summarized as follows. He believes that response in neurosyphilis is conditioned primarily by the state of the defense mechanism, and that once routine spirillicidal types of treatment have done what they can, further progress in the individual case is determined by the responsiveness of the non-specific mechanisms. T determine whether patient has an active defense mechanism, observe the behavior under treatment. Rapid early response to mild types of treatment indicates permanent type of improvement, while clinical and serologic responses that require resort to intensive measures and supplemental therapy over period of three or four years, denote incomplete and often temporary improvement. The char acter or type of the spinal fluid is guide to intensity of the process. Low grade abnormality (as in Type I, we assume) responds more quickly than high grade abnormality (Type III). Serologic findings on the blood are untrustworthy guides t treatment in neurosyphilis. Clinical responses such as gain in weight, increased hemoglobin, decreased fatigue and irritability and improvement in memory may be more significant for an eventual good outcome, than relief of crises or pains. Treatment begun early (before the fifth year) while the patient is organizing his defense and nonappearance of spinal fluid involvement by the fifth year are both prognostically favorable circumstances. Patients who have received no previous treatment respond more rapidly and the response is more likely to be permanent than in those who have received previous treatment. The presence of intercurrent disease such as tuberculosis, nephritis, colitis etc reduces the effectiveness of treatment. On the other hand complications of syphilis such as cardiovascular disease and osseous syphilis do not influence the results of treatment unless they interfere with the use of intensive methods. The value of nonspecific therapy in the form of malaria or fever induced by the hypertherm or some other machine, or vaccines, lies probably in biologic changes rather than in any sterilizing effect of the fever. Accordingly the response both clinical and serologic which follows course of fever therapy is a favorable indication of an improvement in the status of the defense mechanisms.

O'Leary CCG figures supporting his contention that neurosyphilis is largely taken care of in the biologic course of the disease are worth special quotation. Thirty-three per cent of patients who had untreated neurosyphilis of less than one year duration were positive in the spinal fluid;

Fig. 785

A SCHEMA OF TREATMENT IN NEUROSYPHILIS

Number	Type.	Preparatory* unit course.	Routine† unit course.	Intensification.	Tryparsamide.	Nonspecific fever.	Special.
1	Asymptomatic meningeal and meningovascular	(1) [illegible] mercury [illegible], [illegible] to [illegible] grain, [illegible] injections weekly or (2) bismuth 10 to 20 injections every three to seven days.	Eight to 10 injections [illegible] (weekly) or 10 to 14 neoarsphenamine,‡ 1 injection every four to five days, alternating with [illegible] metal.	Three to five more units plus sodium iodide intravenously 20 to 40 injections or large doses by mouth.	Not needed.	Not needed.	Not needed.
2	Asymptomatic parenchymatous [illegible].	As in (1).	Three to five courses as above depending on response.	Sodium iodide intravenously or large doses by mouth.	Replaces arsphenamine after 2 unit courses if unresponsive.	Malaria may be given to robust young adults, 10 to 16 chills.	Intraspinal, 6 to 10 injections.
3	Asymptomatic preparetic.	Continue preparatory and first unit course.	One or two units, then examine CSF	Shift to tryparsamide or fever	(1) T[illegible] courses with mercury or bismuth (2) (preferred) weekly injections for one to two years.	Pretryparsamide malaria preferred if young and uncomplicated.	
4	Symptomatic neurorecurrence.	Succinimide mercury and iodide intravenously preferred.	Two courses and CSF examination. If not responsive give [illegible]	Three to five more units or manage as preparesis.	Only if preparesis.	Not needed unless preparesis.	Intraspinal.
	Symptomatic cerebrospinal.	Bismuth preparatory as in (1b).	Three to five unit courses.	Rarely needed. Iodide.	Only if resistant.	Rarely needed. [illegible]	Intraspinal 6 to 10 injections.
6	Symptomatic early tabes.	Mercury or bismuth with iodide as in (1).	Three to five unit courses.	Intraspinal.	If resistant.	Not especially effective and often inadvisable.	Intraspinal 5 to 15 injections.
7	Symptomatic late tabes.	Low dosage bismuth or [illegible] (oral or [illegible]).	Small dosage neoarsphenamine 6 to 15 injections.	Rarely advisable.	If resistant.	Rarely advisable.	Chronic eliminative, dietary, anti-infection.
	Optic atrophy	Small dosage, bismuth 10 injections.	Bismuth preferred.		Contraindicated.	Malaria probably more effective than intraspinal.	Swift-Ellis valuable method.
	Gastric crises.	All methods equally uncertain. For suggestions see text.					

* See Fig. 783. † See Fig. 784. ‡ The status of [illegible] and [illegible] is as yet undetermined.

Fig. 785 (Continued)

A SCHEMA OF TREATMENT IN NEUROSYPHILIS (Continued)

Number	Type.	Preparatory* unit course.	Routine† unit course.	Intensification.	Tryparsamide.	Nonspecific fever	Special.
10	Early paresis, uncomplicated.	Combine preparatory with first unit course.	One to two units if no urgent indications for immediate fever		Follow malaria.	Malaria first preferred.	
11	Active paresis.	None or one course.	None, or 1 unit if tryparsamide used.		Follow malaria if no contraindication.	Malaria first always unless unobtainable or contraindicated.	
12	Deteriorated late paresis.	Preparatory treatment for supposed purposes.	One to two units may precede or follow malaria.		Precede or follow malaria.	Malaria or milder measures if not contraindicated.	
13	Complicated paresis.	One course.	Two units.		If not contraindicated.	Depends on case and complications.	
14	Vascular neurosyphilis.	Bismuth or mercury and iodide.	Small dosage arsphenamine or avoid entirely		Useless.	Dangerous.	
15	Local inflammatory lesions.	Mercury and iodide or bismuth, as in ( ).	Two to three unit courses.	Iodide by mouth and intravenously	Only if serology demands.	Rarely needed.	Intraspinal or intracisternal.

* See Fig. 783. † See Fig. 784.

through repeated sieges of lightning pains and the overload on his excretory and defense mechanism which can be produced by dental foci, for example, which are scarcely detectable by the roentgen-ray. We have repeatedly seen the chase for a focus of infection with successive periods of temporary relief following each new discovery and removal, run the gamut of a roentgenologically-negative and dentally-approved molar, a foreign body in the upper jaw, a chronically infected prostate, a fistula in ano, and an atonic infected colon. It is wise, therefore, not to permit dental expediency and the limitations of roentgen-ray visualization to allow the tabetic to retain devitalized and suspicious teeth. Infected tonsils have seemed even less directly responsible for trouble. Colonic irrigation, though easily overdone, and a carefully selected diet, low particularly on the carbohydrate side, assist in the control of intestinal infection. Flooding the patient with well-soured milk (at least 3 pints daily) between meals as in dealing with the Kendall syndrome of intestinal carbohydrate intolerance may be helpful. The lowering of the pH of the intestinal tract by dilute hydrochloric acid by mouth, and at times the intestinal antiseptic virtues of mercury with chalk deserve more or less empirical trial. Plying the patient with mineral oil which leeches him of his provitamin A, and routinized cathartieism are poor substitutes for good judgment. In the atonic intestinal disturbances of the tabetic in which the gut seems to act as a focus for lightning pain etc., the vitamin B complex is especially useful.

Care of the Urinary System.—One of the first duties of the physician when a tabetic comes under medical care is to inquire into renal and bladder function. The blood urea nitrogen content, phenolphthalein functional tests, examination of the urine for evidences of infection, and an estimation of the degree of urinary retention are minimal requirements. "Every tabetic is a potential uremic" is a maxim that should be constantly kept in mind. In all but the earliest and mildest cases, catheterization of the bladder may be required, and this should be undertaken only with the most rigid precautions against infection, and should never be performed except by an expert urologist if the patient has been leaking and dribbling for some time and undergone thereby definite renal functional impairment. The catheterization of such a bladder precisely as in retention due to prostatic hypertrophy may precipitate the patient, without warning, into uremic coma.

The symptomatic inquiry in these patients is important. Slight signs of involvement of the mechanism of the bladder include dribbling, difficulty in starting the stream, difficulty in stopping, nocturnal bedwetting. It is unpardonable for the physician to catheterize repeatedly any patient without at least a survey for signs of neurosyphilis. Even postpartum retention may have sometimes a tabetic and not an obstetrical origin. It is well first of all to realize that dribbling is more apt to be a symptom of a distended and paralyzed bladder than of a deficient sphincter control. The question of whether such a distended bladder should be evacuated by catheter has no categorical answer. If the patient shows uremic symptoms or has a high blood urea, a retention catheter may be introduced and slow prolonged drainage performed as in cases of prostatic hypertrophy. In some instances suprapubic stab drainage has been life-saving. If the urine is uninfected (no pus or bacteria) and the renal function and blood urea are normal catheterization, even to obtain an exact phenolsulphonephthalein return may well be avoided. If expert urological consultation is available at this time catheter

drainage may be performed. On the other hand, if there is evidence of only moderate retention and no infection, the patient should be put under treatment for syphilis and systematically drilled in the evacuation of his own bladder. Most patients manage to strike a posture, as in prostatic cases, in which they can secure an evacuation. They may empty the bladder completely with the bowel movement. They may empty it in the warm bath, or at the sound of running water or with heat, cold, or pressure over the lower abdomen. In this way many patients can be trained to empty and keep the bladder uninfected and renal function normal. On the other hand, if there is evidence of marked residual urine (bladder percussed after evacuation, and so forth) catheterization by the physician with complete evacuation of the residual urine three times a week, accompanied by reeducational efforts, and treatment for neurosyphilis, often results in surprising gains. A residual urine of 22 ounces may be reduced to one-half ounce in the course of a year. If there is evidence of marked infection, appropriate irrigation of the bladder under direction of the urologist will be desirable. Every possible effort should be made to avoid introducing the patient to catheter life—although Stokes has seen at least one surprising instance of longevity under such circumstances, good health and comparatively little bladder infection 20 years after the institution of exclusive catheter evacuation.

The periodic rechecking of phenolsulphonphthalein excretion and blood urea, quite as much as the ordinary urine examination, are essential parts of the reexamination and observational control of the neurosyphilitic patient whose bladder function has once shown signs of impairment. In elderly patients the possibility of complicating prostatic hypertrophy should not be lost sight of. The success of these measures is, according to Stokes' experience with 73 cases studied with the help of the Section of Urology of the Mayo Clinic, dependent largely upon the grade of involvement when treatment is begun. Mild and moderate degrees of cord bladder show excellent and good results in approximately 70 per cent of cases. In severe grades of involvement, good results were only obtained in approximately 15 per cent. The aggregate shows 11 per cent excellent, 20 per cent good, 29 per cent fair and 40 per cent slight or no results.

A field is developing for the use of parasympathicomimetic drugs such as mecholyl in improving the function of atonic or "cord" bladders. Bauer, Lipton and Altschule (1943) especially commend "Furmethide" (SKF) for this purpose in a study controlled by cystometric measurements.

In the acute myelitic bladder paralysis, it cannot be overemphasized that the care with which catheterization is done may make all the difference between recovery and death from complicating pyelitis. In such cases hexamethylene or hexylresorcinol should be used as prophylaxis.

Libido and Potentia.—Sexual impairment in tabetics seldom makes a striking improvement, probably because of the complexity of the various factors involved in the psychic state, the neurogenous damage and acquired genito-urinary disease. In 24 per cent of Stokes and Shaffer's patients the response was good, in 21 per cent fair and in 54 per cent slight or none. Testosterone as the propionate intramuscularly (10 to 25 mg. daily) followed by methyl testosterone by mouth (30 to 40 mg. daily) may be tried. An intensive vitamin therapy by improving general health may be useful. Reassurance and psychotherapy are essential, and as in psychogenic impotence the suggestion of Owen and Wortis (1942) on conjoint use of mecholyl as in anxiety states may be tried.

Control of Paresthesias and Lightning Pains.—The control of these symptoms, while quite largely dependent upon treatment and often responsive to relatively mild measures, such as single course of bismuth or

bismuth arsphenamine sulphonate, is in the long run rather difficult matter It is in this connection as well as in the raising of the general level of well-being of the tabetic that rest, change to a warm winter climate, avoidance of overstrenuous exertion, and the occasional judicious use of mild stimulants (benzedrine) and sedatives and analgesics becomes an art. Emphasis should be placed upon the undesirable effect of making a barbiturate addict out of a tabetic whose symptoms could ordinarily be controlled by aspirin and acet phenetidin. The usefulness of alcohol as an analgesic cannot be denied in some cases, but its general effect on the tabetic in the amounts he tends to use it, is not good Hard liquor which gives him the most relief is particularly undesirable the glass of sherry after dinner often a valuable sedative Occasional courses of colon irrigation a dose of castor oil careful instruction in anticonstipation regimen irradiation with ultraviolet light, and sheer encouraging talk, play their part from widely varying angles. The physician in charge of such a patient should not depend too exclusively on antisyphilitic measures but should first carefully canvass the field of possible causes and nonspecific methods of relief The vitamin therapy of tabes has been discussed on p. 1010 in conjunction with vitamin deficiency aspects. Thiamine chloride alone is of little use in lightning pains, but the B complex in large doses of an active preparation is of undoubted service, partly perhaps by its effect on a bowel infection focus and atonic constipation A patient seen jointly by Stokes and Moore believed calcium pantothenate and the pyridoxin fraction were most effective to judge by experiments on himself When antisyphilitic measures are resorted to for this group of symptoms, especially in the sallow cachectic, and debilitated patient, a tonic procedure as distinguished from a treatment for arrest is often indicated The essentials of tonic therapy include small doses of neoarsphenamine (0 45 Gm once a week for six to ten weeks), mapharsen (0 04 to 0 06 Gm once a week for six to ten weeks) or bismuth arsphenamine sulphonate (0 1 Gm intramuscularly every fourth day for 15 to 20 injections) Several such courses at intervals of three or four months may be sufficient to place the tabetic "wreck" on his feet and maintain him in reasonable comfort for a long period

The adoption of fever therapy should be carefully weighed with consultation if possible Early in the course of a tabes fever therapy may be quite effective, but the furious exacerbations that accompany the fever bouts may be uncontrollable and unendurable, and force discontinuance of the treatment. Neurosurgical measures (cordotomy) are for desperate situations only and avail little or hasten the end

The Casual Use of Morphine for the Relief of Any of the Painful Symptoms of Tabes, Including Crises, Cannot Be too Vigorously Condemned.—This is one of the most unfortunate residua of old-school medical practice The combination of tabes and morphinism is a therapeutically impossible one and inevitably leads to deterioration The impulse to give a hypodermic for the relief of pain should be drilled out of instead of into medical students. Morphine is only rarely a necessity in dealing with the painful complications of neurosyphilis if the methods of procedure here described be given their proper place

Salicylates and other coal tar derivatives are useful and usually adequate even in dealing with the typical "shower or exacerbation of lancinating pains An excellent prescription includes 5 grains each of acetphenetidin and acetylsalicylic acid and 5 grains of sodium bromide in powder or tablets

Certain of the proprietaries are excellent, and the barbital derivatives may be administered at the same time for their sedative and anxiety reducing effects. A shower of lightning pains, like a gastric crisis, may occasionally be stopped abruptly by an intramuscular injection of 10 to 15 minims of one to one thousand epinephrine solution (Sicard and Lermoyez) Heat is usually not welcome, though some patients may obtain relief in the hot bath. The close connection between pains and stasis conditions in the gastro-intestinal tract is evidenced by the quick response in many cases to a cathartic. Intercurrent infections should be sedulously avoided where possible by patients subject to lightning pains. Exposure to ultraviolet light in moderate doses is helpful.

The more radical procedure of Rajka and Radnai, involving sharp repeated erythema doses ith intramuscular injections of the patient own whole blood, may be employed. Not more than 30 lamp exposures and 60 whole-blood injections divided into two courses should be given, the blood being drawn half an hour after the lamp exposure (10 cc.) and the quartz lamp exposures being given three times ek. This method, however, is still in the experimental stage, though we have known its less intensive use to be followed by marked benefit. Periarterial sympathectomy has been without effect.

By standard methods of treatment lightning pains respond with excellent results in 16 per cent, good results in 31 per cent, and fair results in 26 per cent, aggregating 73 per cent improvement. The notorious persistence of this symptom after the apparent arrest of the degenerative process, and the achievement of serological negativity is a particularly trying feature of late tabes. Intraspinal introduction of lipiodol recommended by Forestier (1935) has not been fully evaluated and we have had no experience with it. Neurosurgery in the form of cordotomy is a last resort indeed, and in our observation more often leaves a deplorable wreck than a materially benefited patient. Kahn and Barney (1937) however report superior results with anterolateral cordotomy For the obstinate case free from other contraindications, malarial therapy may be considered but in the so-called "burned-out" type is rated by Sterner as ineffective. The presence of an infected genito-urinary tract is regarded by most observers, particularly Moore, as a sharp contraindication to the attempt to deal with late tabetic symptoms by malarial therapy Ebaugh Schamberg and Greenbaum and particularly Ebaugh had, in contrast to the discouraging Continental results (Dreyfus) approximately 30 per cent im provement in lancinating pains following the malarial siege. Wile obtained general symptomatic improvement in 53 per cent, increased to 67 per cent on observation, but mentions no symptoms specifically Hot baths seemed to Mehrtens and Pouppirt particularly effective in dealing with lancinating pains.

Treatment of Ataxia.—The treatment of such a symptom is, of course dependent upon the cause. The spastic ataxic case seems, in our experience, to be made worse at times by the use of arsphenamine and obtains little relief from other forms of treatment. The tabetic type likewise gives a low proportion of lasting good results with standard treatment, only 5 per cent in the aggregate being rated excellent, 16 per cent good, 28 per cent fair and 51 per cent slight or none. The acute early types in comparatively young patients may however be transformed by treatment. In six months they may change from a state in which they can barely flop about the office, to one in which they walk so well that they are not recognized by their friends. A careful iodide and mercury preparation without too early use of arsphenamine has seemed

to us to contribute to this good result, and the impulse to employ malaria should not necessarily be substituted for it. The tabetic ataxic patient responds to fever therapy according to Steiner (mild cases) Ebaugh, and Wile. If no response has been secured in one to two years of standard treatment, including tryparsamide when serologically indicated, malarial therapy may be tried. Moore's patients, however were made worse by it.

The tabetic ataxic patient who fails to respond can be taught to substitute his eyesight for his sense of motion and position, and to practice muscle reeducation and balance by drill in placing his feet on painted foot marks, looking at them or keeping them "in the corner of his eye" as he walks. This reeducation of the tabetic was developed to its fullest extent by Fraenkel through systematic gymnastic training. The psychic factor in ataxia is quite apparent to any considerable experience and reassurance plays no small part in recovery of control. The patient who flounders in one's presence may make a much better showing in a crowded street, where he loses his self-consciousness. Patients with marked ataxia should not in general be subjected to avoidable spinal puncture, for in occasional cases there seems to be increased difficulty afterwards.

Treatment of Gastric Crises.—This commonest form of visceral crisis presents a discouraging but by no means hopeless therapeutic problem. With standard methods of treatment marked amelioration of symptoms is possible in 24 per cent, the usual response consisting in a reduction in severity and length of attacks with or without an increase of intervals between them. This degree of relief may restore an incapacitated person to self-support. The addition of tryparsamide in resistant cases slightly increases the good result. Fever therapy and especially malaria often afford striking temporary relief and the response may even be prolonged. There are no clear-cut indications or contraindications for it other than those generally applicable to the use of fever therapy in tabes, and the method is essentially one of trial and error following the failure of simpler and less hazardous methods. McGrath, Rudolf Driver Gammel and Karnosh, and Ebaugh, report relief in cases previously subjected to prolonged treatment by other methods.

The Cooperative Clinical Group results are more encouraging—48 per cent of patients completely relieved, an additional 23 per cent benefited. Routine standard treatment was more effective than fever and tryparsamide or intraspinal methods.

The combating of the neurosis, the panic, fear and hopelessness which seem to be a psychic accompaniment of gastric crises is often as difficult as any phase of the treatment. Here, too the cardinal error of the profession is the administration of morphine. As Steiner says most patients thus treated die of their addiction rather than their disease. If the practicing physician could be induced never to give a hypodermic injection of morphine for abdominal pain until he had noted the pupillary reactions and knee-jerks there would be an improvement worth while in the outlook of the average patient with gastric crises.

Symptomatic relief in the attack may be secured in the following varied and sometimes surprising ways. Simons (1930) has compiled most of the literature on this subject.

Bending the standing patient backward over the foot of his bed until his feet fly from the floor has been know to stop an attack. Intramuscular injection of epinephrine will stop some cases. Magnesium sulphat intramuscularly 5 cc. of 20 per cent sterile solution. Il quiet the patient temporarily nd Marinesco, Sager and Façon employ the drug intraspinally 1 to 2 cc of a 25 per cent solution. Recall the risk of magnesium poisoning, and have calcium gluconat t hand.

The most widely recommended method (Simons, 1930) is that developed on the Mayo Clinic service by McFarland (1923) consisting of the intrarectal use of 40 grains each of chloral and sodium bromide in an ounce of water If the room be darkened and the buttocks of the patient elevated, relief follows in few minutes even in quite severe cases, and in an hour the patient may fall asleep. In 75 per cent of cases the response lasted two to five hours. No habituation develops and solution of the two drugs may even be given to the intelligent patient for self administration. On one occasion chloral delirium developed, but disappeared on suspension of the drug. Alajouanine and Horowitz (1932) found atropine sulphate, intravenously in 1 to 3 mg. doses, effective in 30 cases. In 2 morphine addicts this treatment failed. Other drugs recommended include: sodium and potassium nitrit orally (Bouchard) 1 drop of tincture of iodine, in 15 cc. water every thirty minutes to check the vomiting (Holmes) alkalies or hydrochloric acid, depending on the gastric acidity· sodium luminal 0.3 Gm. in saline solution intravenously (Farnell, 1936); hypertonic glucose intravenously (25 per cent solution, 10 cc. every two days) (Farago, 1930)· hypertonic saline solution (Alajouanine *et al.*, 1930); 5 to 10 units of insulin, typhoid vaccine dissolved in neoarsphenamine and given intravenously; octinum (Nagel, 1937); various drugs including cerium oxalate, extract of cannabis indica, chloroform codeine and cocaine by mouth. Snake venom may be tried. Simons (1930) suggests 0 015 to 0.03 Gm. phenobarbital three times day for its effect on the patient morale.

Measures directed to the stomach are usually ineffective, though repeated washing sometimes shortens the attack, especially if there is evidence of gastric distention. Intravertebral injection of the splanchnic nerves ith 0.5 per cent cocaine solution was relatively ineffective, is inaccessible, and has been rated by Steiner and ourselves as of little avail.

Dehydration and acidosis must be dealt with by subcutaneous and intravenous administration of fluids, glucose, etc.

The surgical treatment of gastric crises is still in the experimental stage. Wertheimer Foerster and others, have sectioned the dorsal communicating branches of the posterior root, sometimes with good and sometimes with no results. Section of the lateral spinothalamic tract has relieved some patients. Section of the vagi is dangerous, owing to the anesthesia of the larynx. Resection of the celiac ganglion and Sicard-Robineau cordotomy (cutting of Gower' bundles and the lateral tracts of the posterior column) are as yet unaccepted methods. The whole surgical field for relief in gastric crises is at best matter of last and desperate resort.

The victim of gastric crises must be systematically encouraged to mak up the weight loss which occurs during an attack for only in this way can he be kept far enough ahead of the threatening cachexia and exhaustion for treatment to take ultimate effect. He should be told that his stomach trouble has nothing to do with his stomach, that he must gorge himself with food just short of dyspepsia in the intervals between attacks, the most nourishing foods being taken in bundance. I occasional cases in which the crisis becomes an almost continual affair of morning vomiting, feeding with the duodenal tube during the free interval of the day has produced gain in weight sufficient to turn the tide for the time being. Attacks may be brought on by nervous strain and by both intravenous arsphenamine injection, lumbar puncture, and intraspinal and fever therapy

The vitamin therapy of gastric crises is that of tabes in general (see above) Thiamine chloride intravenously or intraspinally in conjunction with wheat germ oil by mouth (Stone, 1942) should be added to the list of trial possibilities.

Other forms of visceral crisis must be dealt with by the same general methods. The laryngeal crisis should, if possible, be managed in hospital, on account of the danger of asphyxia, especially hen treatment for syphilis is begun.

Management of Primary Optic Atrophy.—Management in this condition is too often practically the only applicable term Primary optic atrophy is fortunately relatively uncommon with the inevitable disadvantage that few bservers have had the opportunity of studying and treating more than a very limited number of cases. When thus viewed from the isolated case standpoint, it must be said that practically all favorable or quasi favorable results can be matched with failure or rapid decline in vision or even an actual disaster following the use of what appear to be identical methods of treatment.

It has become increasingly clear that little but conflict of opinion develops from the publication of statistically nadequate material and small groups of cases, or the use of the "I had a case basis for reaching conclusions about the

treatment or outcome of primary optic atrophy. For this reason the publications of Moore and his associates on this subject are specially to be commended and have practically replaced in the minds of experts, a vast and heterogeneous mass of previous literature. On the other hand, it cannot be said as was pointed out in connection with the discussion of prognosis in neurosyphilis in general, that no individual judgment need be exercised about a particular case or that any one method is as yet so good as to exclude or even invariably to take precedence over all others as witness the reversal within a decade, of the Moore group's own views on the relative merits of intraspinal therapy and malaria. In dealing with small numbers of cases, a "run" of bad luck or poor results from unknown causes may reverse without justification in the long run some very positive but premature decisions. It seems wisest here therefore to quote the conclusions of Moore's group in an admirable summary at about the midpoint of their experience with the problem (Moore, Woods Hopkins and Sloan J.A.M.A. 111 385 1938) and to say that the enlargement of their case material from 191 patients to 250 cases (Moore Hahn Woods and Sloan 1942) has not apparently resulted in any other change than a more complete espousal of malarial therapy as the method of choice and a rejection of their form of intraspinal Swift Ellis therapy as involving too great risks of loss of vision. With the median type of statement allowing both methods their place, our experience is more in accord.

1 Untreated primary optic atrophy always becomes bilateral and leads to permanent and complete blindness in practically every instance within 7 years after the onset of symptoms.

"2. Inadequate routine antisyphilitic therapy apparently neither hastens, delays nor prevents the development of blindness.

"3. Adequate routine antisyphilitic therapy seems to delay the development of blindness to some extent and permanently to arrest the atrophic process in an occasional case.

4. Subdural treatment by the Swift-Ellis technic brings about permanent arrest of optic atrophy in about half the patients adequately treated, though it carries a risk of sudden extinguishment of vision in about 10 per cent of those treated. The observation periods in arrested cases ranges from 2 to 20 years.

5. Malaria therapy brings about permanent arrest of optic atrophy even more frequently (in our small material, apparently in about 85 per cent) and for observation periods ranging from 1 to 9 years.

"6. If treatment is begun while optic atrophy is unilateral, involvement of the normal eye may be prevented in a high proportion (in our material 70 per cent) of cases.

"7 The initial form of treatment of syphilitic primary optic atrophy should be induced malaria because its observed results are superior to and it is less dangerous to vision than subdural treatment. If visual failure progresses in spite of malaria, subdural treatment should always be tried. Either of these special forms of treatment should be followed by intensive and prolonged routine antisyphilitic treatment with trivalent arsenical drugs, bismuth compounds and mercury

In an earlier publication Moore suggested as a prognostic guide vision of 20/40 in the better eye as offering a favorable prognosis in about 44 per cent by intraspinal therapy

The CCG (O'Leary *et al.* 1938) found 13 per cent of patients with primary optic atrophy experiencing improvement in vision and progressive loss of vision arrested in 36 per cent. There were fewer cases of loss of vision after malarial therapy than after any of the other therapeutic procedures, perhaps because the patients received much routine therapy prior to the fever. Intraspinal therapy was the next most effective method.

Moore and associates, and we ourselves, consider tryparsamide absolutely contraindicated in the presence of, or in treatment for primary optic atrophy. Cady and Alvis have employed it, however even with improvement, and Lees (1937) believed the results with tryparsamide and bismuth equal to those by any other method.

Without intent to introduce anticlimax but the matter it is important to induce patients threatened with primary optic atrophy if possible, to learn Braille and if possible to prepare themselves occupationally for the complete extinction of vision. Their unpreachable optimism, however sometimes makes it difficult to secure cooperation in anticipation of *the event.*

General Management and Control of the Paretic Patient.—A few practical considerations, apart from the previously discussed syphilotherapeutic technics, are of importance in dealing with the potential or actual paretic patient. An early conference with relatives is highly desirable, and a responsible person should be kept informed step by step of the intended and actual treatment and the possibilities of complications. The patient's business affairs should at the earliest possible moment be gotten into safe hands and persuasion will sometimes secure a power of attorney where commitment might otherwise seem to be unavoidable. In general, commitment leaves a certain amount of psychic scar in a recovered patient, and injures his social and business status materially so that it should not be thoughtlessly or rashly carried out, either before or after fever therapy. Sequestration in a private hospital or sanatorium is often possible without actual legal formalities and records. Remission should be mentioned to the relatives as a possibility and they should also be warned of the probability of a flare-up of symptoms in the more excited type of case when treatment is first instituted. If excitement is very definite on first examination, hospitalization is practically unavoidable. If the patient is depressed, suicide constitutes a serious risk. Little should be said about prognosis, and this should be especially guarded if convulsive, hemiplegic or aphasic accidents have been noted or hebetude, sullenness and depression are conspicuous symptoms. The family must be warned of the risk of violent outbreaks. The excessive and indiscriminate sexual activities of the excited paretic must be controlled even to the point of sequestration. Our personal observation is in favor of a preliminary course of standard treatment before other therapeutic measures are adopted, thus, of course, provided the patient is in reasonably good condition mentally. The writers believe that this reduces the severity of therapeutic shock manifestations. The old or senile paretic is an unfavorable risk, despite the fact that expert handling of tryparsamide and fever therapy may enable an occasional case to achieve a therapeutic result.

Some Paretic After Effects.[*]—It is a matter of much importance and deserving of not a little reflection that modern methods of treating paresis produce a relatively large group of cases fitted, at least in the opinion of institutional authorities, to leave the custodial care of the institution and to be returned to family and community life. Personally we have had occasion several times to react very critically toward the judgment exercised by the *controlling authorities in this regard. There is moreover a residue of unfit* individuals, victims of psychic scar who require careful occupational placement, are a serious problem to wives, families and business associates and may require lifelong *supervision and even custodial care.*

A paretic in remission, even though fitted to take up gainful occupation, is not cured. Too often the striking symptomatic response in speech and appearance merely covers fundamental defects in the moral background and conduct mechanism which present themselves *as sometimes serious complications* when the patient takes up ordinary *life. Thus bigamous* marriages, financial difficulties, occasional crimes of violence, and peccadilloes such as dead-beat proclivities in the payment of bills, the passing of worthless checks, stinginess, chronic suspiciousness bursting out occasionally in paranoid manifestations, may all come to light to the discomfiture or actual injury of the family or social group which has received a supposedly cured paretic discharged from an institution into its midst.

Much more thought should be given to the development of an appropriate parole mechanism for paretic patients discharged after modern therapeutic procedures than has appeared in the literature or in practice thus far

CHAPTER XXI

FAMILIAL AND PRENATAL SYPHILIS ("CONGENITAL" OR "HEREDOSYPHILIS")

Even though the study of familial and prenatal syphilis has a poorer animal experimental background than any other aspect of the disease, it offers some of the most effective possibilities in modern preventive medicine. The fact that proper treatment of the syphilitic pregnant woman could virtually eliminate from practical consideration within a very few years the whole field of congenital syphilis has, for the last decade, made the attack on this aspect of the problem one of the fundamental popular approaches, if not the groundwork, of the public health movement to control this disease.

The basic psychology underlying this premise is found in the fact that (1) most communities are further advanced in their development of facilities to care for maternal and child health than they are in the management of the broader aspects of the venereal disease problem and (2) most privately supported organizations and the general public are much more willing to expend effort and funds toward the control of a disease which is innocently acquired in marriage and transmitted to the helpless and defenseless offspring before birth, than they are to contribute to the control of the more sordid aspects of this problem which too often embrace the whole field of sex behavior maladjustment at home, prostitution and sexual promiscuity.

Once progress has been made in any community or organization in the control of prenatal syphilis, it then becomes an easy matter to expand into a comprehensive program which will embrace the many public health and social implications of infectious early and symptomatic late syphilis. Within the last few years a veritable wave of premarital and prenatal examination laws directed toward the control of syphilis in the family has swept the country. The private practitioner, the obstetrician and the pediatrician have been placed in an unparalleled position of responsibility which they will live up to only after they have subjected themselves to a complete reappraisal of their knowledge of the control of syphilis in marriage, in pregnancy and in early infancy.

If, moreover, the all inclusiveness of this subject, which embraces in miniature every aspect of the disease, is fully realized, the problem of familial and prenatal syphilis assumes, for every physician confronted with it, an unusual piquancy and significance. When it is considered, that just a few treatments in the latter months of gestation will make the difference between a syphilitic and a healthy infant, that the whole problem of congenital syphilis can be largely solved by just a few weeks of competent medical supervision for this disease in late pregnancy with an adequate medical follow-up of the newborn child, it is hard to find anywhere in present day medicine a more effective demonstration of disease prevention or, in public health, a field more likely to show dramatically satisfactory results in reduction of disease incidence and prevalence in so short a period of time as in the field of congenital syphilis.

SYPHILIS AND MARRIAGE

Source of Syphilis in Marriage.—The responsibility for syphilis in marriage can be squarely placed upon antemarital sexual exposure of young men and women, and points directly to the treatment and suppression of the prostitute, toward attention to a study of the sex adjustment of the family the by-effects of the kaleidoscopic changes of present day living and the education of young men and women in the home and in the schools as the most fundamental form of attack on this problem.

Fournier found that 67 per cent of 208 women were infected by men who acquired the disease before marriage. Bulkley found that 88 per cent of his syphilitic women patients were married; Blaisdel (Boston), 79 per cent; Solomon, 76 per cent. Fournier analysis showed that 73 per cent of his syphilitic married women acquired the disease from their husbands. The Solomons, from critical examination of their experience, estimate that 80 to 90 per cent of the husbands acquired syphilis before marriage. Our own experience with a rural American clientele indicates that more than 90 per cent of sexual exposure in men is antemarital and that this is the source of familial infection. O'Leary and Williams (1940) have brought the observations on the Mayo Clinic conjugal syphilis material up to date by an examination of the records of 1175 married couples. Of the group in which one partner only was infected it was noted that three times as many men as women had the disease.

The more recent literature gives an increasing importance t the infection of the woman prior to marriage but does not invalidate the foregoing figures as to the responsibility of the male element, because of the difficulties, not to say impossibility of determining, in clinical study the importance of sex relations before marriage between those who subsequently obtain legal status. Brunet and Salberg (1939), in performing premarital examinations for syphilis on 913 women of the so-called lower middle class, found that of 796 single patients 4 per cent had had one pregnancy or more, which was usually terminated in abortion, and 6 per cent were pregnant at the time of examination. Of 500 patients who admitted sexual contact, 350 had had intercourse with their fiancés and 142 with other men. On vaginal examination it was found that only 177 (19 per cent) had intact hymens and in 736 patients bivalve specula were easily passed.

Decker (1934) found that among 576 families in which at least one marital partner had syphilis, 60 infected husbands and 96 infected wives had nonsyphilitic partners. Klingbell and Clark (1941) studying the question of conjugal syphilis in 236 couples, about equally divided between Negro and white, state that among the whites, the husband infected the wife in 30.2 per cent cases and the wif the husband in 13.1 per cent. Among the Negroes, the percentages were 33.3 per cent and 4.4 per cent respectively In 56.6 per cent of the white and 62.3 per cent of the colored it was impossible to determine which was the source. Among the white patients 38 per cent of the men and 7 per cent of the women admitted extramarital sexual intercourse and among the Negroes the percentages were 48 and 23 respectively

Infectivity in Marriage.—The transmission of syphilis in marriage is primarily dependent upon the duration of infectivity While this, as we have seen, cannot be exactly defined, a long experience has indicated that the chief danger lies in the first five years.

The general incidence of infectious relapse has been discussed in Chapter XIII. The infectiousness of semen and vaginal secretions, long considered important factors in the transmission of syphilis, has been shown, in the light of recent studies, to be relatively unimportant, except early in the course of the disease (especially at the time of menstruation in women) or in the presence of early infectious or relapsing mucous membrane lesions (Greenbaum Kats and Rule (1935) Kemp (1938) Parser (1941 1942))

Parser (1941) concludes that infectiousness through the vagina is ... at rather than continuous in syphilitic women and depends upon the presence of ... of local lesions The physiologic secretions are not infectious. Kemp studies have shown ... pallida has been demonstrated in the semen of patients with early syphilis in ... same frequency that it has been demonstrated in the other body fluids of patients w ... ia.

There is no adequate reason for persistence of the belief of the infectiousness of the semen of patients with late syphilis.

In the older literature Fournier found that 99 of 142 women (70 per cent) were infected in the first three years of their husband's disease and 26 per cent within the first year. Keyes placed the chance of infection by the untreated husband as 12 to 1 the first year, 3 to 2 the second year, 1 to 4 the third year, and practically nil the fourth and fifth years. In Strandberg's study of 230 marriages in which syphilis was present in one partner or the other it was found that only 67.8 per cent escaped all consequences in their married lives. Recurrence was seen during marriage in 20 per cent without infection of the partner. In 53 cases in which the duration of infection was unknown, 41 per cent transmitted the disease, 59 per cent did not. The disease was transmitted to the partner later than the fifth year in 20 per cent. In 2 cases transmission took place after the eighth year. In the more recent studies of O'Leary and Williams (1940) it was revealed that where the estimate of the duration of the infection was definite, very few partners were infected if the interval between acquiring the disease and marriage was over five years. They felt, however, that the five-year rule was surrounded by too many uncertainties to be considered absolute. Klingbeil and Clark (1941) found that there was no instance of conjugal infection of the marital partners of patients whose disease had been present four years or more before marriage, whether treated or untreated.

So far as we can determine there is no proper evaluation in the literature of the effect of treatment on the transmission of syphilis, although it is generally assumed that arsenical therapy rapidly reduces the possibility of infectiousness. O'Leary and Williams state that in a small group of 18 patients who received adequate treatment (twenty or more injections of arsphenamine and heavy metal) within the first year of infection and who had married before the disease was two years old 6 (33 per cent) of the partners were infected. The incidence of infection of the partner in this series was 40 per cent among those who had been inadequately treated for their early infection.

It should be remarked that most approaches to the problem of conjugal syphilis are clouded by the impossibility of evaluating the importance of extramarital exposure (after marriage). Often the true facts are shrouded in secrecy by the conventional attitude of the patient. Whereas many authors make the statement that they believe the answers to their queries are reliable, even a few misstatements or misinterpretations on the part of the patient could considerably distort the results in the relatively small series of cases that are usually the basis for such reports.

Both O'Leary and Williams and Klingbeil and Clark articles give suggestive evidence of exposure of the marital partner to infectious lesions without transmission of the disease. In the Mayo Clinic series, there were three families in which repeated sexual contacts occurred while one or the other marital partner had active lesions of the mucous membranes which contained *Spirochaeta pallida* and, though prophylactic measures had not been used, not one of the marital partners was infected.

The case histories of Chapter XIII will serve as reminders of prolongation of the infectious period by ineffective treatment or phenomenal resistance. It is evident, therefore, that neither unqualified pessimism nor a careless optimism is justified in estimating the risk of marital transmission in syphilis. Instances of the late transmission of the disease always bulk large on the clinical horizon and exaggerate the unfavorable impressions. But in spite of this fact it is perfectly apparent that unqualified assurance regarding the fitness of a syphilitic patient for marriage cannot be had.

Other Considerations in the Marriage of Persons with Syphilis.—Transmission of the disease to the marital partner while the most important is not the only issue in the weighing of fitness to marry. The acquiring of a syphilitic infection, especially by the male, induces automatically a certain inescapable risk of future breakdown. The families of such patients may become a cost to the community, to say nothing of the social loss entailed by the removal of parental influence. The younger the patient with syphilis who seeks marriage and the less prepared economically to meet the risk of complications, the more cautious should the physician be in sanctioning the establishment of a family.

Economic Consequences of Paternal Syphilis.—While the risk of late involvement of the central nervous system and cardiovascular system do not loom as large with ideal treatment as

they did in times past, yet, under average conditions of modern therapy they are still important considerations. The age period thirty-five to forty-five, as has been most apparent from the studies of the preceding chapters, is the one in which the most disabling consequences of syphilis make their appearance. The damage done to the integrity of the family in its critical years is most apparent. Industrial declines (see Stokes, Beerman and Ingraham, Syphilis and Industry 1938), personal and marital anxieties and discords, the incapacitating and disrupting influences of syphilis and the ultimate costs to the state of family wreckage which must be salvaged or sustained, take huge aggregate toll of the community and social resources each year (Beerman, 1940, Costs of Syphilis)

Dalton (1937) determined that the life of white males with syphilis between thirty and sixty years is shortened 17 per cent and that of Negro males 30 per cent as compared with the general population. Lilleywhite (1940) in analyzing the statistics from group of relief applicants in Fulton, Ga., found that illness resulting in time lost from work, was greater in syphilitics than in nonsyphilitics and that only 51.9 per cent of syphilitics could do hard labor as compared with 92.0 per cent nonsyphilitics. The predisposition of syphilitics engaged in heavy work to develop cardiovascular involvement has been shown by Cochems and Kemp (1937). Of one hundred syphilitic paretic men investigated by Williams, seventy-eight were married and left debit of $218,948 in lost earning power and the one hundred men cost the state $30,518 for their personal support until death. One hundred nine children were left to their own resources without the adequate protection of their parents. Solomon and Solomon found that 63 per cent of the families of 41 paretics required permanent financial aid. I 50 per cent the family was more or less completely disrupted.

Fitness for marriage varies, then, first with the duration of the disease in the infected party· second, with sex, women being almost more uncertainly eligible than men because of the possibility of transmission of the disease to the unborn child third, with the course of the individual infection. "Mucous relapses," neurosyphilitic patients, serological recidivists, and fixed positive cases must be judged solely on their individual merits. The amount of treatment given the infected person is the fourth criterion. It should meet the best proved requirements of the present day as outlined in previous chapters. In the fifth place the economic responsibilities to be assumed have a social right to consideration. The marriage of elderly noninfectious syphilitic patients in easy circumstances is a matter of small concern. That of young and recently infected partners with the prospect of children and an unknown economic future confronting them is an issue of great concern to themselves and to the state.

Theory vs. Practice in the Marriage of Syphilitic Patients.—Difficult though it is to outline theoretically sound requirements for fitness to marry it is vastly more difficult to induce acceptance of such theoretical requirements in practice. It is a very practical fact that the majority of patients will give little consideration to rules in their individual decision to marry While theoretical requirements like those of Fournier grow more rigid as the individual proponent s experience broadens, willingness to adhere to a decade of celibacy decreases with the youth of the patients. We are inclined to believe that the ultimate control of the marriage of syphilitics will come through a practical proposal for protected or precautionized marriage, unless infallible cure can attain the celerity of a one-week affair

Conservative European opinion has been summarized by the Hoffmann rule, which is little more stringent than that of Finger and calls for three years of treatment with arsphenamine and heavy metal, and two years of symptom-free observation before marriage. In terms of the second decade of the twentieth century instead of the first, this freedom from symptoms would include repeated negative blood and spinal fluid from the end of the first six months of treatment.

French opinion, summarized in the report of commission for the study of the question which included in its membership Queyrat, Hudelo, Spillmann, Gastou, and Simon, differ-

entiated between serologically positive and seronegative primary syphilis, permitting the latter to marry at the end of two years with only one year of treatment if he had remained free from secondary symptoms the first year while the seropositive case was expected to take treatment for two years. Even though the blood Wassermann reaction remained positive at the end of the second year marriage was permitted if the spinal fluid was normal. A positive spinal fluid examination at the end of the second year or other evidence of neurosyphilis was accepted as a definite bar to marriage, and positive accounts of both duration of infection and amount of treatment were to be required of all patients.

Our personal theoretical requirement for the marriage fitness of the average early case would approach the Hoffmann rule. Adequate treatment would be defined as presented in Chapter XIV carried through regardless of initial or interim negative blood Wassermann tests but seriously regardful of any tendency to positive serological relapse It is not as yet possible to define fitness to marry in terms of the newer rapid methods of therapy so that duration of the disease plus treatment must be considered a safer criterion than treatment alone. The spinal fluid must have been negative long enough to convince the experienced consultant that neurosyphilis has been completely overcome The cardiovascular examination must be negative at all points in the fifth year Such a rule somewhat less detailed in its provisions, had already been adopted by the All American Conference on Venereal Disease at Washington in 1920 as the accepted American practice.

Prevention of Infection in Marriage.—Measures to prevent the transmission of syphilis in marriage must be based upon the statements previously made regarding the infectiousness in some cases of even slight abrasions of the genital mucosae both male and female and upon the bringing about of pregnancy at times when the husband and wife can be assured so far as present knowledge permits, that neither is in an infectious condition. The precise instructions which the physician in whose hands the matter should always rest, may give to the individual pair to whom he gives permission to marry or whose marriage he must supervise within the infectious period of the disease, will be limited by his state and national laws, which in striking at contraception hamper the control of infectiousness in some instances. Only a mechanical protection in the form of an inspected and approved condom which absolutely precludes contact of infectious lesion or secretion, with uninfected surface is adequate in our present knowledge of the transmissibility of syphilis. There is as yet no effective gel or ointment to be used in intercourse. The value of chemical prophylaxis in the woman is virtually unknown. Special precaution should be observed during periods when the patient is not on spirillicidal treatment, with some relaxation permitted when he is and finally possible systemic prophylactic treatment may be given to the syphilitic mother during gestation even though she may be at the time serologically and clinically negative for syphilis. Under no circumstances should the mere negativity of the blood serologic reaction, especially in an early case be made a ground for withdrawing precautions. Measures for preventing transmission of the disease to marital partner and child must remain in force during a period of years, while the disease becomes spontaneously noninfectious, and could well be in some particulars, extended throughout the reproductive life of the parties. By such a series of measures pregnancy would be given some assurance of a healthy beginning and ending even within a year or two of the date of infection and the weak spots in a time-treatment system could be controlled to as full an extent as the peculiarities of the disease permit.

Extramarital escapades and dissemination of infection, an incidental consideration not to be overlooked, would thus also be reduced to a minimum. The testing out and adoption of such a system of marital control in syphilis must, of course, await public education to the necessity for it, the accessibility of the means for carrying it out, and experimental studies of the most effective aids.

In effect such a "precautionized" or "protected" marriage during the theoretical infectious period of syphilis supplants the always somewhat hazy concept of "safe" marriage which, in our experience is the hardest thing in the whole field of modern syphilology to define for the particular case. While it may well be asked how closely a married pair would follow a regimen of "precautions," our observation indicates a much closer adherence could be secured than to one of abstinence.

The Partner Must Know the Facts.—Any plan for the control of infectiousness in marriage, whether it begin with a five-year rule or none requires as a basic feature full information as to the situation given to the noninfected partner before or in marriage. It is unconscionable social and medical short-sightedness, to say nothing of unpardonable cruelty and dishonesty to sanction any withholding of the facts from the woman or man who is asked to take the risks inseparable from our only too patent ignorance and fallibility

It is interesting to note that of the numerous State premarital laws recently enacted, that of Virginia is unique in permitting medical certification for marriage of syphilitics only after: (1) *informing both parties of the fact*, (2) discussing the possible consequences of the infection, (3) reporting them to the state health department and (4) securing the infected person agreement to pursue treatment until dismissed. Failure to continue regular treatment then constitutes misdemeanor punishable by court action.

Legal Status of Marriage in Relation to Syphilis.—Scandinavian countries in particular have had laws requiring freedom from venereal disease in the contracting parties to marriage. In 1935, the first state law in this country requiring blood test for syphilis was adopted in Connecticut. By 1942, thirty states had laws requiring some type of examination for syphilis before marriage. Twenty-seven of these states required blood serologic tests, as follows

California	Kentucky	New York	Pennsylvania	Vermont
Colorado	Maine	North Carolina	Rhode Island	Virginia
Connecticut	Massachusetts	North Dakota	South Dakota	West Virginia
Illinois	Michigan	Ohio	Tennessee	Wisconsin
Indiana	New Hampshire	Oregon	Utah	Wyoming
Iowa	New Jersey			

As of April, 1943 (Mahoney) the District of Columbia and eighteen states, as follows, still had no legislation directed toward venereal disease control in marriage

Arizona	Florida	Maryland	Montana	Oklahoma
Arkansas	Georgia	Minnesota	Nebraska	South Carolina
Delaware	Idaho	Mississippi	Nevada	Washington
District of Columbia	Kansas	Missouri	New Mexico	

The differences between the various laws which have been enacted have been summarized by Forster and Shaughnessy (1942), Peckham (1941) and Edwards (1940). Many of the laws have been drafted without due regard to our knowledge of the transmission of syphilis but some conform t the ideal statute which has been suggested by Johnson (1938, 1939).

The Model Marriage Law with respect to syphilis embodies the following: (1) that both applicants for marriage license be examined for syphilis by licensed physician, (2) that the examination be both clinical and serologic including blood test of type approved by the state department of health, preferably in an approved laboratory (3) that the tests should not be made more than thirty days before the license is applied for and that the license when issued be

valid for not more than sixty days; (4) that the blood test when necessary be performed without charge on request through the health department; (5) that the filing of a certificate of medical examination may be waived by the judge of a proper court because of an emergency or some other cause. With this single exception, the physician must file a certificate of examination accompanied by the report of the laboratory test, which includes the name and address of the applicant, the date and type of test, but not the result. The result of the test should be filed with the medical record. (6) The decision as to the issuance of the medical certificate is left to the physician. He may certify the applicant even though syphilis is present, provided he feels that the applicant is in a stage of the disease which is not likely to become communicable. Otherwise treatment must be given and the immediate issuance of the certificate refused. The remaining portions of the model law deal with instructions to the licensing authority to persons performing the ceremony and provide a penal clause.

Prenatal Examination Law.—Up to the end of 1940 there were nineteen states in which physicians were required to examine pregnant women for syphilis:

California	Indiana	Maine	New York	Rhode Island
Colorado	Iowa	Massachusetts	North Carolina	South Dakota
Delaware	Kentucky	Michigan	Oklahoma	Washington
Illinois	Louisiana	New Jersey	Pennsylvania	

In general the prenatal examination law requires that a serologic test for syphilis be made at the time of the pregnant woman's first visit to her physician. The test must be a standard one done in an approved laboratory. On request the test may be made without charge by the health department. The birth certificate of the child should state whether the test has been made, and if it has not, the reasons for failure to make the test must be given. The results of the test itself should not be recorded.

The Value of Premarital and Prenatal Legislation.—There has been considerable difference of opinion among physicians as to the worth of and justification for such laws. This has been summarized by Stokes and Ingraham (1939), Moore (1939), Nelson (1939), Kolmer (1939). Most are in agreement that they have great educational value for the general public, as was pointed out by Hall as early as 1925, in connection with the Wisconsin law. Some feel that this type of legislation is a great social advance.

It will be many years before premarital and prenatal legislation can be evaluated. The more important benefits to date include: (1) *the discovery of a large number of hidden cases of syphilis.* Sheppe (1941) in analyzing the results of 677,832 premarital blood tests from 13 states found 9,017 (1.3 per cent) positive. Edwards (1940) states that between 70 per cent and 90 per cent of these individuals did not know they had syphilis, at the time the examination was made. (2) *The prevention of the spread of syphilis by preventing the marriage of infectious individuals.* Hall (1939) analyzed the disposition of 258 seropositive premarital cases in New Jersey and found that marriage certificates had been granted to 45 per cent and refused to 33 per cent (no report on 5 per cent). In the 147 instances in which the certificate was refused 61 per cent were not legally married and 20 per cent were married outside the state (in 19 per cent the outcome was not known). (3) *Decrease in the incidence of congenital syphilis.* Talbot (1940, 1942) venereal disease control officer of Connecticut, the first state to pass such legislation, found a marked decrease in the reported new cases of syphilis under one year of age in a four year period 1936—35 cases; 1937—24 cases, 1938—16 cases, 1939—11 cases. Since then, the rate has become about stationary; 17 cases were reported for 1941. Although reporting of syphilis, in most areas, is grossly incomplete, this may indicate a trend. Howard (1941) states that in Massachusetts the reported cases of congenital syphilis under one year remained stationary between 1930 and 1937, but after that they have shown a sharp drop until only 8 were reported for the entire state in 1940.

Medical Examination for Syphilis before Marriage.—In the face of widespread legislation directed toward the prevention of familial and prenatal syphilis most of which depends upon a blood serologic test it must be reemphasized that there is *no single infallible test of fitness* for either marriage or pregnancy. The negative blood test, too often relied upon by both the physician and the patient, may be wholly untrustworthy. The positive test, if it results from syphilis at all, will have no necessary bearing upon possible infectiousness. In spite of the legislative confidence that has been voted it, it has, when used alone, a limited deciding value in determining either the

presence of the disease or its transmissibility. A complete appraisal of the case is necessary.

Such an examination should include a carefully taken history, serological tests checked on separate samples of blood, sent, if possible, to two laboratories, and a complete physical examination for syphilis. If evidence of a previous or probable syphilitic infection presents, the examination should be carried farther, may include a period of observation, and may require interpretation by an expert. If reasonable doubt as to the validity of the serologic positive (biologic false positive) exists, expert appraisal of the case by a competent syphilologist should be made available by the state health authority. The basis of such a check is outlined in Fig. 87. There is no single landmark or milestone which when passed indicates fitness for marriage.

THE SYPHILITIC FAMILY

The Proportion of Infected Individuals in the Syphilitic Family.—The family in which a syphilitic member has been discovered will include between twenty and forty per cent syphilitic individuals depending upon the stage of the disease, the number of children in the family, and the effectiveness of antecedent therapy for syphilis. Numerous epidemiologic studies which have been performed in various sections of the country during the last ten years have shown that with early syphilis, the marital sex contact will be infected on an average three fourths of the time and that about one third of the immediate members of the syphilitic family will be found to be diseased.

The Solomons in a survey of 555 families largely with late syphilis, some years ago found 22 per cent syphilitic individuals. Casselman and Cadwallader (1939) found 35 per cent of their family syphilis contacts to be infected, all stages of the disease being included. When early syphilis is present this figure may approach 40 per cent.

Other members of the household who have not been exposed sexually to the original patient will have about the same prevalence rate of syphilis as would be expected from that class of individual in the community as a whole. The summary of Clark's (1940) work may be considered typical of the average clinic in which 62 per cent of the patients are Negro.

In discussing the high prevalence of syphilis in siblings over fourteen years of age living in the same household, E. G. Clark (1940) states that this probably indicates family promiscuity rather than transmission directly from one member of the immediate family to another. In our experience it is not infrequent for various members of the same household to acquire syphilis from different sources outside the family. A word of caution is sometimes necessary in interpreting such a situation lest these extra household infections be too readily considered as having occurred from exposure within the immediate family.

Prevalence of Syphilis in Children.—With the decreasing incidence of congenital syphilis which should follow the better medical care of the syphilitic woman at the time of marriage and during pregnancy, the generally accepted estimates of the prevalence of congenital syphilis at about 3 per cent (Vonderlehr 1936) in the population at large, will probably turn out to be too high. This figure even now applies largely to the public clinic class of patient and not to the population of the country as a whole where rates are apparently much lower, but much more difficult to determine because of failure to file public health morbidity reports.

Jeans (1921) noted the striking differences produced by social status. In St. Louis 16 per cent of colored infants, 1.8 per cent of poor whites and less than one per cent of infants in well-to-do families had the disease. The Cooperative Clinical Group studies, with Cole (1940) as spokesman, estimate that each year syphilis is transmitted to at least 85,000 fetuses in the country 25,000 of which die before birth and 60,000 of which are born alive with syphilis. They further express the opinion that about 10 per cent of fresh syphilis is congenital in origin. The high mortality of syphilitic conception in the untreated syphilitic mother and the effectiveness of antepartum therapy when the disease has been discovered, keep the proportion of infected children in the population lower than that in adults.

Syphilis in the Parents.—While the ease of demonstrating syphilis in the mother or father will vary with the age of the congenitally syphilitic child, and hence that of the parent, a careful appraisal of the family situation, including serologic testing, will usually though by no means invariably give valuable diagnostic leads. In the original Mayo Clinic Series 69 per cent of the mothers and 50 per cent of the fathers (90 men and 139 women) examined showed clinical or serological evidence of syphilis. Jeans and Cooke (1930) reported 85.8 per cent of mothers and 56.4 per cent of fathers seropositive. With preponderantly infant material the proportion will tend to be higher. Thus, in Wile and Mundt's (1942) series of 98 infants with congenital syphilis, there was no instance in which the family history was negative for syphilis (in 95 per cent the mothers had a positive blood serologic test and in the remaining cases there was hearsay evidence unsupported by laboratory findings). These same authors found that in 402 patients with late congenital syphilis the family history corroborated by serologic tests was positive in 74 per cent and that in an additional 20 per cent the history was doubtful. In only 6 per cent was history completely negative with negative blood tests in parents and siblings.

On the other hand, wholesale serologic testing of young adults (the selective service system, premarital examination, etc.) is disclosing persons with clinical stigmas of congenital infection and positive serologic tests, whose parents, now in their old age, may one or both be seronegative. The difficulty of conducting an adequate history-taking and examination of such parents is considerable and caution must be used in evaluating their status by blood tests alone, in relation to the now adult child's congenital infection.

Sterility in Syphilitic Families.—If sterility be defined as the inability of childless couples to conceive, there is no reason to think that syphilis, in itself, is an important cause of sterility in syphilitic families. Gonorrhea may be responsible for a portion of sterility in syphilitic families. Untreated syphilis may cause childless marriages through miscarriage or neonatal death of the diseased fetus, but seldom through involvement of the reproductive organs themselves.

Syphilis of the ovary in the acquired form of the disease is virtually unknown (Warthin, 1928) and syphilitic lesions elsewhere in the female genital tract have not been shown to impede fertilization. Hubner (1940) states that in the male a history of syphilis is a rarity in either impotence or sterility cases, though Ritter (1937) lists it among the infrequent causes of sterility. Treatment of the male syphilitic alone has been known to result in the birth of a healthy child (Moore, 1923), and Hagner (1925) reports a case of bilateral gumma of the testicle in which spermatogenesis was restored by treatment.

Syphilis is listed by Tew (1939) and Burns (1940) among the systemic diseases which may be associated with sterility through upsetting the normal constitutional balance. Hamilton (1941) reporting on the etiologic factors in 483 patients in the sterility clinic at Bellevue Hospital, N. Y. C., found syphilis to be a factor in only 2 per cent (in four cases it was felt to be the primary cause and in four a contributory factor). Béclère and François (1938) rated syphilis as never a primary cause of sterility in women, but felt that it was a secondary cause in 3 per cent of their cases.

Examination for syphilis should always be made in patients complaining of sterility and

appropriate treatment instituted if the disease is discovered. In most instances, however the sterility will be found to result from conditions other than syphilis.

Birth Rate of Syphilitic Families.—The live birth rate of untreated syphilitic mothers is only a little more than half as high as that of the general population. This arises largely from the fact that syphilis affects reproductivity largely through its damage to the fetus prior to birth. On the other hand, those syphilitic mothers who conceive may do so at a higher rate than the general population, which is probably explained by the short course of a large proportion of the lost syphilitic pregnancies. According to the Solomons, the syphilitic birth rate is 2.06 as compared with 3.8 in a similar social group. Harman found 150 syphilitic mothers responsible for 1001 pregnancies, while 150 healthy mothers had only 866 pregnancies. Jeans and Cooke found 4.8 pregnancies the average in 250 syphilitic families, 4.9 per cent in 250 nonsyphilitic families. A more recent series (1936–39) reported by Dill, Stander and Isenhour (1940) of 386 syphilitic and 414 nonsyphilitic women gives rates of 3.0 and 2.7 respectively. These figures will tend to become identical as prenatal therapy of the expectant mother may be universally applied.

Mortality and Morbidity of Syphilitic Conceptions and Living Children.—Untreated syphilis may be a major cause of loss of life of the fetus during the latter months of pregnancy and of the infant during the first few months of postnatal life. Although many of the studies which appear in the literature fail to take fully into account the normal fetal and infant mortality of a nonsyphilitic control group, the disastrous effects of untreated syphilis are unmistakable. The older literature on this subject has been completely reviewed in the previous editions of this text and by Ingraham and Kahler (1934). Without dwelling upon individual experiences, these studies collectively show that the incidence of stillbirths is roughly eight times more frequent in the untreated syphilitic mother than in the population at large and that, whereas the infant death rate during the first week of life is about three times that of the average for the country by the end of the first year of life about four in every ten will have perished. Fully one half and in some groups larger percentages, of the living children are moreover syphilitic.

Literature in the last decade gives a similar picture. McKelvey and Turner (1934) found of their untreated syphilitic mothers only 34.1 per cent had live births and of these 64.5 were syphilitic. McCord (1936) reporting on 3000 syphilitic deliveries, stated that the untreated mothers gave birth to dead or diseased children 65 per cent of the time. Halloran (1939) had two stillbirths and 11 diseased children in 16 untreated syphilitic pregnancies and Benesohn (1942) reported 61 per cent dead or diseased children in 146 untreated diseased mothers.

The general application of antepartum therapy to the syphilitic woman has made the majority of studies descriptive of fetal and infant mortality from syphilis a decade or more ago, inapplicable to the present situation. Even greater advances in this field are to be expected in the immediate future. Stillbirths and neonatal deaths from syphilis are already uncommon in centers where treatment is readily available and the standards of medical practice high.

Dill, Stander and Isenhour' (1940) well controlled study of two separate groups of syphilitic mothers may be considered typical. They found in their syphilitic groups 77.1 per cent and 91.6 per cent full term living children as compared to 96.9 per cent and 96.3 per cent respectively in their control group; dead born children were 7.3 per cent and 2.5 per cent in the syphilitic group compared with 3.0 per cent and 0.7 per cent for the control groups; and neonatal deaths 4.8 per cent and 2.7 per cent in the syphilitic group as compared with 0.5 per cent and 0.2 per cent in the control group.

In the obstetrical clinic at Western Reserve University stillbirths resulted four times as frequently among the syphilitic as among the nonsyphilitic women (Cole, 1936). As late as 1941, Peckham stated that 10 per cent of the last 1000 consecutive fetal deaths occurring at Johns Hopkins in the preceding ten years resulted from syphilis.

Jeans (1921) noted the striking differences produced by social status. In St. Louis 13 per cent of colored infants, 1.8 per cent of poor whites and less than one per cent of infants in well-to-do families had the disease. The Cooperative Clinical Group studies, with Cole (1936) as spokesman, estimate that each year syphilis is transmitted to at least 85,000 fetuses in the country 25,000 of which die before birth and 60,000 of which are born alive with syphilis. They further express the opinion that about 10 per cent of fresh syphilis is congenital in origin. The high mortality of syphilitic conception in the untreated syphilitic mother and the effectiveness of antepartum therapy when the disease has been discovered, keep the proportion of infected children in the population lower than that in adults.

Syphilis in the Parents.—While the ease of demonstrating syphilis in the mother or father will vary with the age of the congenitally syphilitic child, and hence that of the parent, a careful appraisal of the family situation, including serologic testing will usually though by no means invariably give valuable diagnostic leads. In the original Mayo Clinic Series 69 per cent of the mothers and 50 per cent of the fathers (99 men and 139 women) examined showed clinical or serological evidence of syphilis. Jeans and Cooke (1930) reported 85.8 per cent of mothers and 56.4 per cent of fathers seropositive. With preponderantly infant material the proportion will tend to be higher. Thus, in Wile and Mundt's (1942) series of 98 infants with congenital syphilis, there was no instance in which the family history was negative for syphilis (in 93 per cent the mothers had a positive blood serologic test and in the remaining cases there was hearsay evidence unsupported by laboratory findings). These same authors found that in 402 patients with late congenital syphilis the family history corroborated by serologic tests was positive in 74 per cent and that in an additional 20 per cent the history was doubtful. In only 6 per cent was history completely negative with negative blood tests in parents and siblings.

On the other hand, wholesale serologic testing of young adults (the selective service system, premarital examination, etc.) is disclosing persons with clinical stigmas of congenital infection and positive serologic tests, whose parents, now in their old age, may one or both be seronegative. The difficulty of conducting an adequate history-taking and examination of such parents is considerable and caution must be used in evaluating their status by blood tests alone in relation to the now adult child's congenital infection.

Sterility in Syphilitic Families.—*If sterility be defined as the inability of childless couples to conceive* there is no reason to think that syphilis, in itself, is an important cause of sterility in syphilitic families. Gonorrhea may be responsible for a portion of sterility in syphilitic families. Untreated syphilis may cause childless marriages through miscarriage or neonatal death of the diseased fetus, but seldom through involvement of the reproductive organs themselves.

Syphilis of the ovary in the acquired form of the disease is virtually unknown (Warthin, 1928) and syphilitic lesions elsewhere in the female genital tract have not been shown to impede fertilization. Hubner (1940) states that in the male a history of syphilis is a rarity in either impotence or sterility cases, though Ritter (1937) lists it among the infrequent causes of sterility. Treatment of the male syphilitic alone has been known to result in the birth of a healthy child (Moore, 1923), and Hagner (1923) report a case of bilateral gumma of the testicle in which spermatogenesis was restored by treatment.

Syphilis is listed by Tew (1939) and Burns (1940) among the systemic diseases which may be associated with sterility through upsetting the normal constitutional balance. Hamilton (1941) reporting on the etiologic factors in 453 patients in the sterility clinic at Bellevue Hospital, N. Y. C., found syphilis to be a factor in only 2 per cent (in four cases it was felt to be the primary cause and in four a contributory factor). Béclère and François (1938) rated syphilis as never primary cause of sterility in women, but felt that it was a secondary cause in 3 per cent of their cases.

Examination for syphilis should always be made in patients complaining of sterility and

pregnancy only (c) Gräfenberg (1909) who has carefully studied the bacteriology of fetal syphilis and whose work has been confirmed by many European investigators and generally accepted (Schneider 1921 Matzenauer 1926 Pick, 1928 Klaften and Priesel 1930 Casazza, 1934 Levaditi *et al.*, 1935) Hoffmann (1938) states that he has discovered no embryo which contained spirochetes prior to the sixteenth week of fetal life. Histologic changes in the embryo suggestive of syphilis have been described prior to the fourth month (*cf* Orsós (1939) who found such changes in a 6 mm. [one month] fetus) but *Spirochaeta pallida* has not been found, which must cast some doubt on the syphilitic nature of these lesions. (d) Syphilitic skeletal changes have not been shown to occur prior to the sixth lunar month (Fraenkel, 1911 Alexander 1912) which would indicate that infection of the fetus had occurred not earlier than the fourth lunar month (*cf* Ingraham, 1936)

The maternal portion of the placenta may be infected as a result of the occasional showers of *Spirochaeta pallida* which gain access to the blood stream of the mother as in any active syphilitic infection. The ease with which the placenta is infected by means of the blood stream has been shown in rabbit syphilis by Uhlenhuth and Mulzer Kolle and Evers. The fact that the fetus occasionally escapes infection, even when the syphilitic mother goes untreated, may be explained, not only by the time which is necessary for the organism to penetrate from the maternal to the fetal tissues after spirochetemia has occurred but also by the circumstances which govern the accessibility of the organism to the maternal blood stream. These include the stage of the disease the amount of previous treatment and (especially with older infections) other poorly understood factors. In general however in the absence of treatment, the more recent the mother s infection with syphilis, the longer more intense and more frequent the bouts of spirochetemia and therefore the greater the chance of infection of the fetus (Cole, Jeans *et al.*, 1940)

The manner of passage of *Spirochaeta pallida* from the maternal to the fetal circulation has been variously explained and is probably not always the same. Most usual, perhaps, is the formation of an infected embolus which gives rise to small infarct in the placental blood vessels, through the walls of which the spirochetes may grow much as they grew through the Berkefeld filters in Noguchi experiments with artificial culture media. That no histologically demonstrable lesion is necessary for this transfer to take place, however has been shown by Trinchese (1910) *who found that in small veins the individual spirochetes were able to pierce the vessel walls without causing visible injury* Larger numbers of spirochetes ruptured the vessel wall in order to enter the blood stream.

A third mode of transfer has been suggested by Reitschel (1927), who feels that, in the majority of cases, it is unlikely that the spirochetes can pierce the intima and adventitia of the blood vessels, but gain access to the fetus by their own locomotion through the perivascular lymph channels of the umbilical vessels.

The reason that the spirochetal invasion of the fetus does not take place earlier finds, theoretically ready physiological explanation, when it is remembered that it is only after three or four months of pregnancy have passed that the cylindrical Langhans cell layer commences to atrophy and that it is not until the sixth month that it can no longer be detected. From this time on, the spirochetal invasion is at its height, very important protective cell layer having been removed (Kristjansen, 1927; Hoffmann, 1930; Trinchese, 1910, who found spirochetes penetrating the Langhans cell layer in only one per cent of the cases). Rooth (1914, 1918, 1920) and Macgillan (1930, 1933) have, moreover performed work which suggests spirochetieidal action of certain of the placental ferments.

Death of the fetus, when it occurs, is said to result from failure of adequate blood supply through closure of the placental vessels (Browne, 1927; McCord, 1929).

It should be borne in mind that for syphilis to be present in the fetus spirochetes must have passed over the placental barrier and the mere detection of syphilitic lesions on the maternal side of the organ does not necessarily mean fetal syphilis. Almost any large series of cases will show a few instances in which the placenta was diagnosed as syphilitic, but the child remained symptom free and serologically negative.

We may, with reasonable assurance, therefore, conclude that infection of the ovum before rupture of the Graafian follicle does not occur. Equally improbable is infection of the ovum at the time of fertilization. In rare instances *Spirochaeta pallida* invading the uterine cavity from infectious material deposited in the vagina after conception may traverse the decidua reflexa. But, it has been shown beyond question that whether preconceptional or postconceptional syphilis is in point, diaplacental invasion, especially in the latter half of pregnancy, is the habitual route.

SPECIAL PROBLEMS IN TRANSMISSION OF PRENATAL SYPHILIS

Diaplacental Passage of Infection to Fetus before Appearance of Primary Lesion in the Mother.—As might be expected, syphilis acquired by the mother in late pregnancy is readily transmitted to the fetus. Bickers (1942) reports an instance in which the fetus was infected prior to the appearance of the initial lesion which became clinically evident in the mother three days after delivery. The almost uniform passage of *Spirochaeta pallida* from mother to child when the disease is acquired in late pregnancy, almost irrespective of antepartum therapy, has been emphasized by Ingraham (1938), Moore (1930), Howard (1941). The supposed repressing effect of pregnancy on the symptomatology of maternal syphilis, which may make diagnosis difficult even though the disease is active, will be discussed in the section on the syphilitic mother to follow.

Syphilis Transmitted to One of Twins.—The general experience is that, with single ovum twins, both will either acquire or escape infection. Wolk's (1941) recently reported case of syphilis in one of identical twins does not bear careful scrutiny, principally because adult life was reached before the observation was made and because of the difficulty of differentiating between congenital and acquired syphilis at that age (see also Penrose, 1937, McKendree, 1937). Although we, personally, have never had the opportunity to observe an instance in which one of twins escaped infection while the other was diseased, with double ovum pregnancies, there are a few well authenticated instances in the literature where such a situation has occurred. Wile and Welton (1933) and Smith and Spence (1941) have completely reviewed the literature in this field, the latter authors' critical analysis revealing five case reports in which the phenomenon is well established to which they add four of their own. These "four instances occurred in the course of 44 twin pregnancies in forty women with syphilis," which makes the authors feel that the probability is by no means remote.

The infection of one of twins has, in the past, been advanced as possible evidence of paternal germinal transmission in which one ovum was infected, the other not. It would seem, however, that the operation of chance alone, with the diaplacental mode of transfer, would form a satisfactory explanation as to why only one of double ovum twins is at times infected. Under any circumstances, the protection afforded by the membrane separating the maternal and fetal circulation is such that occasionally in any series of pregnancies, the fetus escapes infection even in the presence of active, untreated maternal syphilis. The same explanation could apply to the infection of one of twins, the protection afforded by the placental barrier being the determining factor.

Instances in the field of congenital syphilis, in which one of twins develops more severe clinical manifestations of the disease than the other, are well known (Dennie, 1941, Hadsell, 1941, Cassel, 1933, Thoenes, 1942).

Third Generation Syphilis.—This subject is of interest for two principal reasons: (*a*) in determining the duration of infectiousness of syphilis through the placenta, and (*b*) in arriving at an opinion on the question as to whether it is necessary to be unduly concerned with the marriage or treatment during pregnancy of an expectant mother with a *bona fide* congenital syphilis, especially when she may have had adequate treatment for her own protection

during infancy or childhood. The diagnostic problems of this topic are also indirectly related to such considerations as acquired syphilis in infancy and childhood reinfection (superinfection) of congenital syphilitics and with the whole field of *Syphilis Héréditaire Larvée* which are discussed elsewhere.

The recent literature of third generation syphilis has been completely reviewed by Beerman, Wammock and Magnuson (1942) Although the experience of any one group of individuals in this field is so limited as to make authoritative statement difficult, an appraisal of the field would seem to indicate that there are few (probably less than ten) well established instances of third generation syphilis in the recent literature, and that the occurrence of the phenomenon is so uncommon as to cause little concern in questions pertaining to marriage or pregnancy

The older authors, while the cases presented by them do not always bear careful analysis in the light of the advances which have been made in the diagnosis of both congenital and acquired syphilis, still have presented group of criteria which are as valid today as when originally published. The much quoted Fournier Finger criteria include (1) Acquired syphilis must be demonstrated in the grandmother and preferably also the grandfather (2) prenatal as distinguished from acquired syphilis must be demonstrated in the mother of the third generation case. Acquired syphilis must be excluded in her case and the father must be proved to be healthy (3) There must be incontestable evidence of prenatal syphilis in the third generation. (4) Manifestations must appear soon after birth in both the second and third generations.

Indirect Hereditary Influence.—This topic has two aspects: first, the question of paternal influence on the second generation without infection of the mother and, second, the influence of both parents on the third generation and beyond, without the necessity of transmitting *Spirochaeta pallida per se*. In general, it may be concluded that valid instances of the influence of syphilis on the health of the next generation without actual transmission of the causative organism from mother to child, are, to say the least, hard to establish. It is equally difficult completely to deny the plausibility of the reasoning behind some of the examples brought forth in support of these ideas. A number of interesting observations in this field, however are worth mentioning.

Widakowitch has shown that the spermatozoa of the syphilitic patient are definitely abnormal structurally It is therefore conceivable that through chromosome or functional abnormality an abnormal slant may conceivably be imparted to the development of the fetus in an unknown proportion of cases. The frequency of testicular syphilis and the occurrence of seemingly healthy pregnancies in the wife following treatment of the syphilitic husband have both been cited as arguments in favor of male responsibility for the abnormalities of syphilitic fetus. On such foundation, if it could once be determined for both male and female, could be laid the elaborate structure of the French pediatricians and syphilologists discussed under the title of Syphilis Héréditaire Larvée.

Stokes has had one family suggesting these possibilities under observation in which 3 children were normal, though the husband was syphilitic. The mother herself was, so far as clinical demonstration goes, entirely healthy With the appearance of the symptoms of paretic neurosyphilis and the accompanying general physical deterioration in the husband, 2 pregnancies resulting in abnormal children ensued. The first of these (Fig 787) was typical Mongolian, though this abnormality should not be regarded as intrinsically suggestive of the influence of syphilis; the second and youngest child presented stigmata suggestive of heredosyphilis and had strongly positive blood Wassermann reaction. Such investigation is obviously too incomplete for final evaluation, but in view of the complete negativity of the mother and the first 3 children in the family the influence of the deteriorating syphilitic father in producing germinal dystrophy *in the last 2 children is at least strongly suggested.*

The summary by Bietschel (1931) of the differences between the German and the French points of view is courteous and generous, if politely incredulous, presentation of the subject of Syphilis Héréditaire Larvée. The conception of occult syphilis has the ardent support of most French pediatricians, including especially Martelli, Picard, Marfan, Hutinel, Lemaire. According to this group, the incidence of syphilis in France, including generations beyond the second ranges from 19 per cent (Lemaire and David) to 40 per cent (Hutinel) of the population. Included in the conditions grouped under the possible influence of *syphilis héréditaire larvée* are the following: (*a*) failure to gain weight at the breast (*b*) the atrepsies (athrepsia); (*c*) endocrine disturbances *such as myxedema and hypophyseal dystrophies of all types*; (*d*) bone and joint conditions on the rachitic borderline; (*e*) nervous diseases, including Mongolian and other idiocies, meningitis, hydrocephalus, Sydenham chorea and 15 to 50 per cent of mental disturbances; (*f*) gastrointestinal disturbances such as habitual vomiting, melena, obstinate enterocolitis in infancy; (*g*) forms of jaundice, especially in childhood, and the so-called "benign jaundice of infancy";

(h) chronic bronchitis and asthma, (i) congenital heart anomalies; (j) skin diseases of certain kinds, including vitiligo, sclerema, scleroderma and tuberculids, even infantile eczema, (k) hematopoietic disease, including the anemias of childhood, and enlarged spleen with anemia; and (l) lymphatic abnormality including general adenopathy and status lymphaticus. Other occult signs include intracranial hemorrhage (Voron and Pigeaud, 1909), increase in the size of the skull (Kamal, 1929; Marfan, 1927) inequality in the length of the fingers (Mikulowski, 1933) and epicranial phlebosclerosis.

Milian (1937) and Arcangeli (1936) have rediscussed the subject of dystrophic (as opposed to microbic) hereditary syphilis and Hoffmann (1938) has resummarized the German viewpoint in the statement "it may be regarded as certainty that the germ cells are not injured by syphilis toxins and that germinative syphilis does not exist at all.

Syphilis in the Father—Study of this question at once indicates how serious a matter it is to give the prospective father of a family unguarded assurances as to his "cure. A disconcerting proportion of the fathers we investigated married in good faith often following medical permission and

Fig. 787 —The two children of paretic father described above. There are three normal older children.

in the belief that they were cured It is a matter of considerable difficulty however to secure complete investigations owing to the reluctance of an apparently healthy man to submit to a week of tests. Approximately 50 per cent of the fathers of syphilitic children will have positive blood Wassermann reactions and 20 per cent will present suspicious but not diagnostic evidence It is important to realize that especially where neurosyphilis has appeared in the children the father may because he has not been protected by pregnancy show evidence which the mother does not. In the investigation of doubtful heredosyphilis this detail is often of value. Partial information was obtained on the condition of 99 fathers in our series, of whom 50 per cent had positive blood serologic reactions 18 per cent, suspicious signs, and 32 per cent were frankly negative. Jeans and Cooke (1930) report 50 4 per cent of fathers seropositive as compared with 85.8 per cent of mothers.

The Syphilitic Mother—The fact that the syphilitic mother presents few symptoms of her disease was recognized in the early writings on congenital

syphilis and postulated in Colles' law (1837). During the pre-Wassermann era, the absence of clinical findings in the mother was taken to indicate that she frequently escaped infection completely and that the congenitally syphilitic infant was the result of paternal transmission of the disease to which the mother was rendered temporarily immune by the pregnant state. Routine serologic testing of pregnant women *close to the time of the birth of the child* has indicated that when the newborn infant is syphilitic, the mother has a positive blood serologic test or other evidence of the disease in almost every instance. A typical example of the exceptional case in which it is next to impossible to establish a diagnosis of syphilis in the mother of the diseased child is reported by Handley (1940) (see also Waugh 1937). All those concerned with large volumes of pregnancy or congenital syphilis material see such instances occasionally. We are in accord with the opinion of most authorities that, on

Fig. 783.—The only clinical sign presented by the mother of two heredosyphilitic children—slight swelling of the right sternoclavicular junction. She was examined because her older child had symptoms, and her blood serologic test was found to be positive.

the whole the apparently normal mother of a congenitally syphilitic child is herself syphilitic.

The older the child with congenital syphilis before the disease is discovered, the more difficulty may be experienced in establishing the diagnosis of syphilis in the mother. The failure to take this into account in many of the reported series, confirmed with variations in the expertness of the physicians responsible for the original diagnosis of syphilis, account for the marked differences in the reported ability to detect maternal syphilis. In the original Mayo Clinic series dealing largely with late congenital syphilis, the mothers yielded positive blood serologic tests in 60 per cent, but later studies such as those of Jeans and Cooke found in younger material than ours, 85 per cent, and Wile in earlier material from the standpoint of age of infection, 95 per cent positive bloods. Good histories were obtained in mothers 3 per cent *vs* fathers 15 per cent; late syphilids, mothers 7 per cent *vs* fathers 13 per cent; neurosyphilis, mothers 12 per cent *vs* fathers 20 per cent. At best in our own study we were obliged to rate 21 per cent of the mothers of syphilitic children as negative

to an ordinary clinical and serological examination. It might be expected from the foregoing that the value of clinical history and physical examination in the diagnosis of syphilis in the infected mother would be extremely low in most instances. While it is unsafe to rely wholly on this means of investigation without resorting to the blood serologic test in addition evidence suggesting the presence of the disease is to be found in a surprisingly large number of cases. Various authors (Browne, 1922 Moore, 1923 Boas, Gammeltoft and Siecke 1926 Dodds 1927 Halloran, 1930) have found signs, symptoms or

history of syphilis in 23 to 64 per cent of mothers. (Refer also to the previous section on Syphilis in the Parents.)

Ingraham (1935) in a careful study of 239 syphilitic pregnant women at the Philadelphia General Hospital found that when the syphilitic pregnant woman was questioned alone *carefully* and confidentially with the thought of syphilis uppermost in mind evidence of the disease other than positive serology could be obtained in 80 per cent of cases, a number almost equal to those who possessed positive blood serologic tests (see Fig 780) Points in

the history were missed in about one-half of the cases, but only one seventh of the suspicious points in physical examination had been earlier detected. The points in history which Ingraham *found to be of greatest value* were (1) treatment prior to pregnancy (46 per cent) and (2) occurrence of late miscarriage or neonatal death in earlier pregnancies (35 per cent) story of symptoms suggestive of syphilis (25 per cent) and syphilis in other members of the family (21 per cent) Diagnostic physical signs of syphilis were present in the mother in only 10 per cent, but suggestive evidence was present in an additional 13 per cent. This emphasizes the necessity for routine blood serologic testing of every pregnant woman as recognized in the prenatal blood test laws.

The relatively asymptomatic course which syphilis seems to run in many women who have borne children, early gave rise to the idea that pregnancy exerts a beneficial effect on maternal syphilis (Swediaur 1809; Bertin, 1810; Colles, 1837) Ingraham (1934) has reviewed the literature on this subject and the effect of pregnancy on maternal syphilis has been effectively demonstrated from the standpoint of clinical statistics by the Cooperative Clinical Group Studies (1934) with Cole as spokesman. In surveying the records of 958 syphilitic women they found that among those who receive adequate treatment for this disease clinical progression occurred in only 4 per cent who had been pregnant since their infection was acquired and in 7 per cent of those not pregnant since infection. With inadequate treatment these percentages became 11 and 18 respectively showing progression. Pregnancy is most effective in ameliorating the course of syphilis once latency is reached, but also exercises this influence to a lesser degree in early infections. After the disease has progressed to the symptomatic late stage pregnancy is, if any thing, injurious. Among the adequately treated women, those with early syphilis showed 7 per cent relapse if pregnancy occurred after infection as contrasted with 9 per cent if pregnancy did not occur after infection. For latent syphilis these figures are 6.7 per cent and 5.4 per cent respectively while for late syphilis they are reversed: 10 per cent of the women who became pregnant after diagnosis of late syphilis was made showing evidence of progression of the disease as compared with only 3 per cent of those not pregnant since late syphilis developed. The occurrence of pregnancy in association with early syphilis is especially effective in reducing the incidence of central nervous system involvement and mucocutaneous relapse in the mother

Prolonged absence of clinical signs, leading to mistaken permission to marry is well illustrated by Fig. 435 (p. 642) One of us (Stokes) has watched the mother of a syphilitic boy for five years through a period of complete serological and clinical negativity only to have her develop a typical late syphilid of the cheek. In the present state of our knowledge, it is a safe clinical rule to withhold a pronouncement as to the condition of the asymptomatic mother of a syphilitic child and to regard her as in all probability a quiescent case

Blood Serologic Reaction in the Syphilitic Mother—The proportion of positive serologic reactions obtained in the mothers of syphilitic children will vary with the age of the mother and the child who is under investigation. The young mothers of syphilitic infants produce the highest proportion of positives because of the activity and short duration of their infections. Figure 790 summarizes the relatively small number of cases in the literature These results would seem to indicate that when we are concerned with late congenital syphilis, from two thirds to three fourths of the mothers may be expected to show a positive blood serologic reaction, but with early congenital syphilis this probability will usually exceed 90 per cent.

Proportion of Syphilis in Pregnant Women in General.—No accurate information on this subject has been available until recently since the publication of results of routine serologic tests on large unselected groups of the population through the application of prenatal blood test examination laws.

that the probability that the child will have syphilis exceeds 70 per cent. Cole *et al.* (CCG 1934) found that in a group of treated and untreated syphilitic women with a negative blood serologic test during pregnancy 81 per cent were delivered of living, apparently nonsyphilitic children, as contrasted with 57 per cent in mothers with a positive blood test. Moreover almost twice as many children were born alive but subsequently died among mothers with a positive blood serologic test, as among those with a negative test

The significance of a positive test on the pregnant woman from the standpoint of antenatal treatment varies, of course, with the age of the patient and the age of the infection and is subject to interpretations not unlike those which attach to the positive blood serological test in syphilis in general and to the test when employed as a guide to infectiousness. Belding wisely points out that the older mothers late in the course of the infection may bear healthy children even with strongly and repeatedly positive serological tests. The Cooperative Clinical Group Studies (1934 1936) were able to collect 58 women who became pregnant after being considered "cured" on whom the data furnished did not give evidence of a single syphilitic child having been born among pregnancies which occurred up to fifteen years after the infection. Birnbaum (1927) had previously reported 34 normal pregnancies among 21 "cured syphilitic women. The decision in such cases must be individual, however and one always has the feeling, perhaps in the hypersensitivity induced by modern 'paper syphilis that he is subjecting mother and child to unjustifiable risk of transmission of the disease if he decides not to treat. At least it may be said that the younger the mother and the earlier the syphilitic infection, the more serious the positive blood serological test and the more urgently does it demand treatment along the lines subsequently discussed

Routine Blood Serological Tests on Pregnant Women.—The enactment by many states of prenatal blood test laws has brought to national recognition the necessity for performing routine blood serologic tests for syphilis on every pregnant woman at the time of her first prenatal visit. Such a procedure will continue to be imperative as long as syphilis maintains an appreciable prevalence in the general population.

The fact that routine blood test for syphilis are not, even now universally applied during pregnancy makes it necessary to point out some of the studies which have indicated the desirability of such practice even though they have been performed many years ago. In hospital clinics for example Belding (1925) has shown for Boston that in 6000 maternity patients who were examined routinely without especial attention to syphilis, definite clinical signs were obtained in only 0 54 per cent and suspicious signs in 1 7 per cent, a total of 2.2 per cent whereas the blood serologic test for syphilis in the same group was 8.8 per cent. In Philadelphia, in 1931, the prevalence of syphilis was about 5 per cent in 25 prenatal clinics making routine serologic studies and it was only 1 per cent in 11 comparable clinics employing the test merely as they felt it indicated

Moore who has long vigorously attacked the objections of the physician in private practice to this problem was able to collect from his own practice 40 disasters attributable directly to the failure of the physician or obstetrician to make the required blood serologic study

It is well to remark that a single blood serologic test taken at the time of the first prenatal visit while it is probably the most valuable single diagnostic procedure in the control of congenital syphilis, will not completely control its transmission Aside from detection of the disease in the seronegative

syphilitic mothers above cited, it should be remembered that syphilis may be, and moreover not unfrequently is, acquired at the time of conception or even in the later months of pregnancy Such women may or may not present symptoms, depending upon the duration of their infection and the development of the normal clinical course of their disease prior to delivery The fact that a woman has had a negative blood serologic reaction early in pregnancy should not exclude syphilis *from consideration should suspicious signs develop* at a later date To detect all of these cases, moreover every pregnant woman should have, in addition to the initial blood test at the time of the first prenatal visit, a repetition of this test at, or near term. (Ingraham, 1939 Stokes and Ingraham 1939 Cole Jeans *et al.*, 1940)

Most active obstetrical services, particularly those of a large general hospital, or those which care for many unmarried mothers or sexually promiscuous women will have several instances yearly in which women, symptom-free and serologically negative early in the pregnancy develop clinical

Fig. 791.

THE MOTHER WHO ACQUIRES SYPHILIS AND BECOMES SERO-POSITIVE DURING THE PREGNANCY

B. D twenty-seven-year-old white woman, came under medical observation in the sixth month of her first pregnancy Complete physical examination, performed by the obstetrician, revealed no evidence of syphilis and a blood serologic test taken on the first prenatal visit was reported Kahn negative, Kolmer Wassermann negative Six weeks before *delivery this patient became ill at home with sore throat and slight temperature elevation* to 99.5 F; she developed number of discrete dusky-red papular lesions over her face and upper chest and some two to three eeks later several small papular genital lesions.

Prior to the development of this eruption she had contracted an acute upper respiratory infection and had been taking, internally salicylates, barbiturates and phenolphthalein. Reference as made to the previous blood serologic test which was found to be negative A second blood study was considered unnecessary The symptomatology presented was considered t be erythema multiforme from bacterial infection or dermatitis medicamentosa from ingested drugs. The fact that the mother in actuality had secondary syphilis as not disclosed until she gave birth t her infant. The infant manifested symptoms of congenital syphilis within forty-eight hours after birth and its infection as immediately diagnosed and treatment was begun. Both mother and child have had satisfactory clinical response.

syphilis or become seropositive before term. In some instances the disease has been acquired at the time of conception, the ameliorating effect of pregnancy on maternal syphilis frequently causing a prolonged incubation period and often a relatively symptomless infection. In other cases the disease is acquired through sexual relations in the early months of pregnancy to become clinically manifest close to the time of delivery and, rarely in the first week or two postnatally (See Fig 791 from Stokes and Ingraham Med Clin. N A. Nov., 1939)

Spinal Fluid Findings and Examinations in Syphilitic Mothers.—The repressing and protective effect of pregnancy in women with syphilis so far as the nervous system is concerned has been discussed. Wile and Shaw dealing with a youthful material, found 70 7 per cent to have normal spinal fluids, and 9 4 per cent to have abnormal spinal fluids, while 4 7 per cent showed an increase in cells or globulin alone After th sixth month lumbar puncture has a definite abortifacient effect which must be avoided. If the mother have *an early syphilis, the test may be done immediately postpartum for the detection* of meningeal involvement that may lead to neurorecurrence when the

demonstrated *Spirochaeta pallida* in 105 cases less than one third of which cases gave any degree of positive reaction on the mother's blood.

Macerated Fetus.—Maceration of the stillborn child was formerly regarded as almost diagnostic of syphilis. While it is undoubtedly suggestive, it is not pathognomonic and may be the result of other intoxications which result in the death of the fetus before birth The skull is collapsed, the abdomen protuberant, and the skin of the fetus appears as if scalded the epidermis being raised in enormous bullae containing a serous or hemorrhagic fluid and the underlying cutis being of a livid red color On handling, even the seemingly normal skin rubs off

About 45 per cent of dead syphilitic fetuses are macerated prior to delivery (McCord 1922, Holland and Lane-Claypon 1922, Cruickshank 1924) while between 64 per cent (Browne) and 80 per cent (Williams, 1918 Tecoul, Lasseur and Vernetlin, 1923, Morosoff and Raddin, 1928, Palmer 1928) of macerated fetuses are syphilitic. As syphilis becomes a less important cause of fetal death this latter percentage will obviously decrease.

Spirochaeta Pallida in the Fetus.—The finding of *Spirochaeta pallida* in the organs of the syphilitic fetus is being more frequently used as a diagnostic procedure as technic improves.

Browne obtained the organism by both darkfield and Levaditi impregnation in 8 of his 14 macerated syphilitic fetuses but found the organisms very much more difficult to find in the fresh than in the macerated specimens (1 in 21 as against 8 in 14). The difference may be due as Shaffer has found, to the reproduction of the organism in tissues under incubator conditions after death, and may justify the preservation of organs from such fetuses for later examination in the hope of reaching a positive diagnosis.

The Syphilitic Fetus—Pathologic Changes.—Histologic changes due to syphilis can be found in about 84.7 per cent of fetal autopsies (McCord) They are by no means invariably present, singly or together even in cases in which *Spirochaeta pallida* may be demonstrated (Fraser) so that a complete search may only reveal one or two distinctive features *Spirochaeta pallida* can be demonstrated in the tissues in about 35 per cent of the fetuses (McCord). Enlargement of the fetal spleen (30 to 60 per cent) and sometimes of the liver the presence of chondro-epiphysitis and fibrotic inflammatory changes in the lungs, liver spleen, and pancreas with tendency to multiple hemorrhage into the internal structures (Cruickshank) are the most distinctive gross pathologic changes as summarized by Fraser

Chondro-epiphysitis was regarded as very frequent by the older writers. Fabre and Bhenter found it in 74 per cent postmortem. Shipley *et al.* found by examination of 100 fetuses (sixth month to nearly term) with roentgen ray that 25 per cent showed marked syphilitic bone changes (osteochondritis) and 46 per cent had suspicious lesions. On the other hand, Olsen found it roentgenographically only once in 83 very young viable children of syphilitic patients and it was found in only one of Browne's 22 cases. More recently McCord has found an osteochondritis in 81 per cent of 243 syphilitic fetuses at autopsy The characteristic syphilitic alteration consists in the transformation of the epiphyseal line of the long bones into a thickened, irregular opaque yellowish-white band, sometimes resulting in separation of the cartilage and bone in the region Microscopically along the line of ossification of the bone there is seen proliferating connective tissue in which are areas of necrosis

The liver is not necessarily enlarged, nor need it show gross changes. The most constant alteration in the liver is general retardation in development of the organ, so that at birth there still persists the appearance of an active blood-forming organ (Jeans and Cooke). If enlarged it may simply be edematous and spirochetes be discovered in numbers in the stroma. Microscopically the column of liver cells form multinucleated masses the capillaries are distended and in places contain myelocytes, eosinophils, lymphocytes, and normoblasts. The rarer but quite characteristic pericellular cirrhosis produces an enlarged, hard, rounded liver with feel as of cutting rubber on section The color may vary from dark red to bile-stained green (flint liver) and the cut surface is speckled with opaque yellowish-white spots which are miliary gummas. Confusion with miliary tuberculosis is possible. Fraser emphasizes the absence of giant cell and epithelioid cells as in favor of syphilis Large hepatic gummas are rare.

The only constant change in the spleen is an increase in size, due to hyperplasia of the normal cellular elements. Microscopical examination reveals no histologic changes and usually only small numbers of spirochetes are present.

The changes in the kidneys may be fibrotic or consist of perivascular round-cell infiltration. Often combination of the two is noted in addition to an imperfect development of the glomeruli and, at times, areas of atrophy In rare instances rather diffuse acute interstitial nephritis is present (Jeans and Cooke)

Pancreatic fibrosis, which is common, resembles the inter- and intralobular fibrosis of the liver which causes wide separation of the lobules and acini producing slightly enlarged whitish somewhat gritty pancreas. There is also a developmental retardation with poorly differentiated acini and islands of Langerhans (Jeans and Cooke) The most common and most characteristic syphilitic lesion of the intestine (according to D'Aunoy and Pearson, 1930) usually confined to the small intestine, is raised, yellow plaquelike band which encircles the bowel. Generalized peritonitis may follow ulceration and perforation of these areas but may also occur in the absence of frank rupture. The lesions include necrosis of the mucosa and submucosa of the involved areas, miliary syphiloma and abscess-like foci. *Spirochaeta pallida has been seen in all layers of* the bowel and is especially prominent in the perivascular tissues and in the vessel wall.

The characteristic pulmonary lesion is fibrosis which results in an increase in size and weight of the organ. The fibrosis is usually irregular, producing pale, firm elastic patches of "pneumonia alba. The change is chiefly in the interstitial tissue. Microscopically the consolidated *areas reveal great thickening of* the alveolar walls by loose *edematous* connective tissue containing mononuclear cells and leukocytes. Desquamation of the alveolar epithelium may be seen in many places. The air cells are cubical instead of the usual flattened form and the smaller bronchi contain leukocytes and granular débris. Spirochetes are present in large numbers, more numerous in the consolidated lung tissue. In pronounced cases the lung may be heavy and airless although in the mild degrees of pneumonia alba there may be no detectable gross pathologic changes. Numerous authors, from Ricord (1845), to Virchow (1906) to Mraček (1893), to Warthin (1911) and many others since that date, have described involvement of the heart in autopsy examination of stillborn fetuses, or infants within the first few months of life. The characteristic lesions are of two types, interstitial myocarditis and nodular myocarditis, both occurring with about equal frequency *Spirochaeta pallida* has been demonstrated in these lesions by five authors in 1906 and by many investigators since then. The nodular lesion is not gumma, but localized syphilitic cellulitis or myositis (Williams, 1930) myxomatous in character (Warthin). Fatty degeneration of the heart muscle, though frequently seen, is probably better explained as the result of nutritional disturbances associated with the syphilitic infection, rather than as specific lesion. (*cf* Hinrichsen review 1943.) There is no apparent relationship between syphilis and congenital malformations of the heart.

The suprarenal shows definite changes in about 10 per cent of syphilitic fetuses (Fite) In addition to the large number of spirochetes the most frequent and characteristic change is an extraordinary amount of cellular connective tissue in the capsule, often projecting downward into the cortex, separating the groups of cortical cells (*perihypernephritis syphilitica*). Gummata *of the adrenal although* reported are rare.

Involvement of the testes is frequent but not so common as of the bone and liver. The testis may be laden with spirochetes even when no histologic changes can be recognized (Warthin) Macroscopical changes may be few although the testes may be enlarged in the early stages. The microscopical picture early is an inflammatory perivascular round-cell infiltration with subsequent interstitial fibrosis and destruction of the parenchyma, eventually resulting in trophy as summarized by Menninger The ovary although frequently containing large numbers of spirochetes, shows no constant pathologic change.

The thymus may be the site of multiple granulomatous changes and contain large numbers of spirochetes. The thyroid shows no constant pathologic lesion in the fetus, although it may contain numerous spirochetes.

Diagnosis of Syphilis in the Dead Fetus.—This must, as in other aspects of the disease, rest upon a combination of evidence, of which at times no one element may be absolutely pathognomonic. The investigation may be of great assistance in establishing the status of an asymptomatic mother Maternal and paternal study from all angles with elimination of any other assignable cause for the loss of the child and a careful search of the fetal viscera for *Spirochaeta pallida* are the less frequently used but important modes of

approach Rabbit inoculation of lymph node emulsion was positive in Manteufel and Herzberg's case The investigation of the family the maternal and fetal (cord blood) serologic test obtained by the accoucheur examination of the placenta and cord (the latter for *Spirochaeta pallida* both in section and darkfield) by a pathologist and pathologic and bacteriological autopsy study of the fetus should all be sought in the doubtful or suspected case. Roentgenological findings of Shipley and others and the observations of McLean (Chapter XVI) should be utilized. The clinical appearances aside from maceration which may reinforce the impression of syphilis in the stillborn child will be discussed in connection with early heredosyphilis.

THE LIVING SYPHILITIC INFANT

Types of Infection.—The fact that there are several ways in which the syphilitic infant or child may acquire his disease, and that the relative importance of these various modes of inoculation has been determined only in recent years, has led to much confusion in terminology in particular in the older medical literature By common usage the term *congenital syphilis*, though perhaps not the ideal designation, has come to include all forms of syphilis acquired prior to passage through the birth canal. The term *prenatal syphilis* introduced by Kolmer is preferred in this text for this type of the disease *Heredosyphilis* implies germinal transmission and has its origin in the older French literature, where these concepts abound. Hoffmann's (1936) classification from the older literature of infantile infection into *syphilis innata, connatalis postnatalis syphilis acquisita infantum* and *syphilis binerva* (Tarnowsky 1901) where both prenatal and acquired infection occur in the same individual, while scientifically exact has never gained wide acceptance in this country

Of more importance to the student than the question of exact terminology is a complete knowledge of the manner in which the infant may be infected. Most usual as previously described, is the diaplacental passage from mother to child *in utero* The acquired forms of the disease transmitted through (1) contact with infectious lesions or secretions in the mother's birth canal at the time of delivery (2) infection of the infant (or child) from exposure to infection after birth (3) acquired infection superimposed upon an infection occurring before birth while all are possible are extremely uncommon in actual practice

True prenatal infection involves an overwhelming of the child with organisms whose thoroughness often surpasses anything seen in the acquired form of the disease The child who survives such an infection does so by virtue either of special resistance or special protection. The mechanism of this protection is not established It may be that fetal tissues have an exceptional tolerance of the organism the chief evidence of it being the abundance of organisms in nonreacting tissues (heart, liver) The high fetal mortality of the disease speaks against special resistance as does its invasion of the nervous system in ways and degrees comparable to the adult acquired forms. It is very possible that the defence mechanism of the mother reinforced as it is known to be by her pregnancy is extended over the child *in utero*, and protects it as it does her It may be that the child's internal defence is in some way specially stimulated Clinically at least the child which survives an early uterine infection has a high resistance and makes a phenomenal response to intelligent treatment Extraordinary variability in the course of the infection

after birth may be attributed in part to the influence of the date of uterine infection, and in part, as in the mother to the suppressing and retarding effect of the special defence mechanism. Thus the child infected early in uterine life, or poorly protected presents at birth the changes of late syphilis, already far advanced. The child infected late in uterine life or who carries a suppressed infection through to birth at term, appears well during the first two or more weeks of fetal life and then develops lesions of secondary type, arguing a wide dissemination of the organisms. Most often a combination of the two processes occurs, and the child after birth develops, coincidentally with late lesions due to the long-suppressed infection early lesions of an infectious relapsing type Lastly the child infected early in uterine life with a relatively mild type of the disease may remain asymptomatic except for developmental stigmas for months or even years before showing active signs of the disease. This constitutes the tardive form of heredosyphilis.

Acquired Forms of Syphilis in Infancy and Childhood.—Syphilis acquired at the time of birth seems to be a comparative rarity possibly because the birth chancre is not recognized by the practitioner The development of lesions of a distinctly secondary type in an interval of six weeks to two months after birth, particularly if the mother be known to have had infectious lesions, should always lead to a search for the chancre on the infant. The chancre may occur upon the stump of the umbilical cord and some suspicion should attach to cases in which there is a prolonged delay in cord healing, with the formation of a distinct ulcer

Bumm reports as typical case the development of chancre on the cheek of child whose mother had four-week old chancre on the posterior part of the left labium minus t the time the child was born. This is congenital syphilis in the strictest sense, and is undoubtedly comparative rarity It seems probable, however that very lat hematogenous infection of the fetus, in the last tw months of fetal life, may give rise to the early eruptive picture and the general symptomatic sequence of an acquired syphilis.

Syphilis acquired late in pregnancy or at the time of birth is more difficult to recognize, lacking the "stigmas" of the uterine type and in many instances is not distinguishable from infections of extragenital origin, but obscure history contracted during childhood.

The unrecognized extragenital infection in infancy or childhood just mentioned should, in particular not be lost sight of especially in the inter pretation of juvenile neurosyphilis without the stigmas of the inherited type. While the actual extent of such infections cannot be estimated, enough case histories have been reported by individual observers as early as Fournier to justify a persistent campaign of public education against kissing and handling of infants by strangers and even relatives. The nurse-maid of uncertain credentials and the low-grade servant are the source of too many such tragic situations.

Several papers on the subject of syphilis acquired during infancy and childhood have appeared in the recent literature which tend to show that, while uncommon, it is by no means rare occurrence. Johns Hopkins Hospital, for example, had 45 cases under eleven years in the 17-year-period from 1921 to 1937 while 90 cases between eleven and fifteen years and 4,487 cases in adults occurred during the same interval. Waugh (1936) reports 21 cases eleven years of age or under; Smith (1930) 125 cases ten years of age and under (3 of these were less than one year 23 less than two years and 34 less than four years); Dyar and Goodwin (1941) 19 cases under fourteen years (8 cases under ten years). Shech and Long (1930) and Waugh (op. cit.) report four children and five children, respectively in single family with acquired infections,

which points out the pitfall of too hasty appraisal of such family situation, here the source of the children's infection could be attributed to a seronegative asymptomatic mother after the initial symptoms had cleared in the children. Smith's analysis showed the commonest method of infection in children to be attempted intercourse not infrequently with an adult (43 cases); after this came kissing, 16 cases, household contact, 14 cases, transfusion, 9 cases, unknown, 41 cases.

Superinfection and lesions due to birth trauma but containing organisms and even suggesting chancres, may be elements in the confusion borderline of "congenital and acquired syphilis," according to Hochsinger. Reinfection of patients with congenital syphilis is also known to occur, for discussion of which see the recent case reports and review of the literature by Hahn (1941) and Allison (1942).

Importance of Complete Evaluation of Maternal Syphilis Status.—The first and most important step in the medical care of the living syphilitic infant is to establish the presence of the infection in the mother. Just as the pregnant syphilitic woman is usually relatively symptom-free (see section on syphilitic mother), so the syphilitic infant is often asymptomatic at the time of birth and for the ensuing few weeks. Such clinical observations on the "healthy" syphilitic infant were formulated as early as 1865 into *Profeta's law*. While freedom from symptoms in the offspring of syphilitic parentage was a sufficiently frequent occurrence to be noted even in the prearsphenamine and pre-Wassermann era, with the partially treated syphilitic mother as in the usual situation today, it has become the rule. In clinic and hospital practice as high as 90 per cent of syphilitic infants may show no detectible symptoms of their infection during the immediate neonatal period.

Considering the detailed and expensive study over a period of many months, necessary for a proper medical appraisal of an infant to determine its syphilis status, it becomes physically impossible and financially impractical to carry out these procedures routinely under ordinary circumstances, unless examination of the mother raises a suspicion that she has syphilis. The syphilis appraisal at birth or during the first few weeks of life commences, not with a cord or neonatal blood test and a physical examination of the infant, but with a careful maternal history and a report of the mother's blood serologic test for syphilis during pregnancy. If it is found that the mother had no blood test for syphilis during pregnancy, then, in determining the likelihood of the infant's infection immediately after birth, it is just as important, and usually more enlightening, to obtain a specimen of blood from the mother as it is to test the child.

The Blood Serologic Test of the Newborn Infant.—At the time of birth and in early infancy, the blood serologic test for syphilis must be subjected to special study and interpretation. Even then it has a very limited diagnostic value in the first few weeks of life. It may be positive even though the infant is not diseased. It may be negative even though syphilis is present, at times, though rarely with active clinical manifestations. A seronegative syphilitic mother may give birth to a seronegative or rarely to a seropositive syphilitic child. Figure 792 gives the possible combinations of maternal and fetal serology and the syphilis status of the infant, along with some idea of the relative frequency of each type in clinic practice at the Philadelphia General Hospital. These percentages will vary somewhat from clinic to clinic, depending upon the activity of the maternal syphilis and the effectiveness of antepartum specific therapy in the cases used for analysis, but it becomes at once apparent that certain combinations are common occurrences while others are rarely encountered. Thus, it is very unusual to find a seropositive infant at birth if the mother is seronegative. The percentage of infants of seronegative syphilitic

mothers who will eventually develop syphilis and become seropositive at varying periods postnatally likewise is small.

Seropositive nonsyphilitic infants formed 8 per cent of the total group, but 13 per cent of the nonsyphilitic group and comprised *40 per cent* of the total positives obtained (see Fig. 794) This last mentioned percentage will increase with the adequacy of prenatal care and the corresponding decrease in the number of syphilitic infants born. Between 1938 and 1940 of 27 infants with positive blood serologic reactions at birth, 20 (74 per cent) did not have syphilis. There can be no question, therefore that **a significant number of infants, seropositive at birth, do not have syphilis,** and that the medical care of this type of case requires careful consideration.

Syphilitic infants, seronegative at birth formed about one fifth of the total series, but 28 per cent of the seronegative infants born of syphilitic mothers ultimately proved to have syphilis. Moreover only 30 per cent of the syphilitic

infants were seropositive at the time of delivery This indicates that active medical follow-up of every child born of syphilitic parents is indicated, irrespective of its serologic status at the time of birth While it is true that a syphilitic child is considerably (perhaps three times) more likely to have a positive blood test at birth than a nonsyphilitic child and, while it is likewise tru that the majority (perhaps three fourths) of the infants seronegative at birth will not have syphilis, yet the probable occurrence of seropositive non syphilitic infants and of seronegative syphilitic infants is so great as to make the serologic test at birth unreliable as a basis for diagnosis or an indication for treatment of the newborn child

The Cord Blood Serologic Test.—Considerable discussion has arisen in the past over the desirability of depending upon the examination of blood from the umbilical cord. For detailed discussion of this see previous editions of this text and Ingraham and Kahler (1931) The chief objection to the use of umbilical cord blood is on the score of inadequacy rather than inaccuracy

The cord serum reagin content will usually compare closely with that of the venous blood of the newborn infant, but a single blood serologic test, cord or otherwise, can never be accepted as final elimination or confirmation of infantile syphilis.

It should also be pointed out that a cord blood serologic test cannot be considered a substitute for a test performed on the mother's blood during pregnancy or at the time of delivery for it will frequently be negative in the presence of syphilis in both mother and child. In the Philadelphia General Hospital experience the maternal blood serologic test in syphilitic women was positive at the time of birth in 71 per cent of cases (87 per cent in those who bore syphilitic infants) whereas the cord blood was positive in only 21 per cent. Less than one fourth of the syphilitic women could have been detected by relying on the cord blood alone.

The Quantitative Titered Blood Serologic Test.—The reason for the peculiar behavior of the blood serologic test in the offspring of syphilitic mothers is not clearly understood, but it is usually explained that there may be, in some instances, transfer of syphilis reagin from the

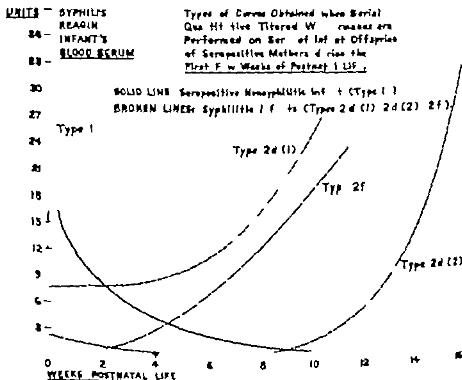

Fig 793.

maternal to the fetal circulation, irrespective of the transmission of *Spirochaeta pallida*. Antepartum treatment apparently is not a determining factor as was shown by Ingraham (1935).

The use of quantitative titered blood serologic tests (Faber and Black, 1936, Christie 1938, Davies, 1937 1938) has made it possible to show that, if the infant is not syphilitic the concentration of syphilis reagin in its blood stream is never more and usually considerably less, than that of the maternal blood stream. *The syphilis reagin will gradually disappear from the normal infant blood stream after some days or weeks* If the maternal blood serum reagin content, and hence the infant's, has been high, the infant titer will decrease rapidly at first, but after it falls to one or two units may persist at this level for many days (*cf* Fig. 793, Type 1).

If the infant, on the other hand, has syphilis, in rare instances, presumably when infection has occurred early in pregnancy and the infection is well advanced at the time of birth, the infant's blood serologic test may have a significantly greater titer of reagin than that shown by the maternal blood. This is considered to be of diagnostic significance. More commonly however, presumably when the fetus is infected closer to term, the infant titer will be in the same magnitude as the maternal serum reagin content for some days or weeks postnatally and may again

rarely decrease even to the vanishing point, only to increase again, rapidly and steadily as the disease becomes clinically manifest (Fig. 723 Type 2d (2)).

Ingraham, Shaffer Spence and Gordon (1941) experience has shown that more than one half of the seropositive nonsyphilitic infants had negative serologic reactions by the age of one month, but about 8 per cent persisted int the second month of postnatal life. Occasional cases have been observed in which complete seronegativity is not reached until from seventy to ninety days. In the sole instance in which the reagin titer of the infant serum was significantly greater than that of the mother' t birth, the mother' serum contained 8 units and the infant 64 units.

The quantitative titered blood serologic test has considerably greater value in eliminating the nonsyphilitic patient with positive serologic reactions, by detecting rapidly falling titer than it has in establishing an absolute diagnosis in the study of the truly syphilitic patient. Our experience has been somewhat in accord with Christie (1933), in that syphilitic infants with positive serologic reactions at birth seldom seem to show rapid or significant increase in the titer short of an observation period of one month to six weeks (Fig. 723, Type 2d (1)).

Our observation, further does not completely corroborate Black' (1930) statement to the effect that delay in diagnosis of from six weeks to two months is not harmful to the infant in some cases. Two babies in the 1936 to 1940 group, each with reagin titer fluctuating between 8 and 16 units on weekly determinations died at the age of sixteen and twenty-five days respectively while awaiting adequate serologic diagnosis. Both of these infants, though presenting no diagnostic lesions of the skin or mucous membranes, had both roentgenologic and autopsy evidence of syphilis.

While one is waiting four to eight weeks postnatally to determine the significance of positive test by serial titrations, repeated roentgenographic interpretation of the long bones will often suffice to corroborate diagnosis of congenital syphilis.

The Seemingly Healthy Child of a Syphilitic Mother —The observations of the majority of writers have indicated that the seronegative syphilitic infant will usually become seropositive by the age of two months, though we have seen very occasional cases, as have Roberts (1933) Dennie (1933) and McKelvey and Turner (1934) in which syphilis reagin was not detectible until the third or fourth month of postnatal life. Adequately studied cases of congenital syphilis in which the blood serologic test has not become positive by the sixth month are apparently so rare as to be of no clinical significance. While conservative opinion indicates a minimal two year and an ideal lifelong period of observation for the offspring of syphilitic parents, there is every indication that such prolonged follow-up is of value principally for purposes of scientific clinical research.

The fact that such a large percentage of infants, seropositive at birth, prove on prolonged observation not to have syphilis, makes most authorities at present feel that the apparently healthy child of syphilitic parentage should not be diagnosed as having the disease and should not be treated for this infection unless clinical or roentgenographic studies indicate its presence or unless the serum reagin titer continues to increase after birth or to persist at significant levels into the third mouth. The one possible exception to this rule would be in those rare instances where adequate serologic and roentgenographic follow-up of the infant is not available and at the same time the mother is known to have early syphilis, inadequately treated prenatally Under such circumstances the infection of the infant is so likely (perhaps better than 95 per cent) that a period of observation before making a clinical diagnosis and instituting treatment hardly seems justifiable. Treatment should never of course, be withheld in the presence of clinically demonstrable congenital syphilis, because of the vagaries of the blood serum reagin titer

Ideally the offspring of syphilitic parentage should have a blood serologic test at birth, or within the first few days of life. If this is positive, and the facilities for determining serum reagin content quantitatively are available,

the test should be repeated at weekly intervals until its trend is determined, remembering that a reversal to negative does not exclude syphilis in every instance A six month follow-up is essential.

If the blood serologic test is negative at birth, when the mother is known to be syphilitic, the test should be repeated at the age of one month, two months and six months. Infants seronegative at six months may normally be considered to have escaped congenital infection. Infants first discovered without previous study to be seropositive after the age of two months, provided the test is properly checked and interpreted, may be considered to have syphilis.

The collection of the blood of a young infant for the blood serologic test when left to the inexpert may prove a bar to the adequate use of the test. In the large majority of cases the superior auricular external jugular or antecubital arm vein (using a 24 gauge ¾ inch needle in the last instance) can be used as in arsphenamine injection (syringe technic) or enough blood can be milked from a deep stab in the heel with the obturator of a small trocar or a lancet (Chapter VIII) for the performance of the test. Blood from the longitudinal sinus or internal jugular may be obtained by the experienced, but these methods are rarely if ever called for and are not recommended.

Clinical Picture of Early Infantile Prenatal Syphilis.—Few children have outspoken signs of syphilis before the third week after birth, although eruptive lesions are common in the stillborn syphilitic infant. The sooner the symptoms appear the more serious the prognosis. Sylvester showed that the most critical and usually fatal cases appear before the fifth week or after the second month, so that prenatal treatment of the mother offers the best hope of reducing the early mortality Snuffles and cutaneous lesions are the commonest mode of onset, though an increasing irritability and restlessness with causeless crying and screaming when the child is laid down or handled may first be noticed. As the nose becomes obstructed nursing becomes difficult and loss of weight ensues, though the good state of nutrition of many syphilitic infants is cause for remark. The appearance of "hacking" or fissuring of the lips (Fig. 809) and an eczematous impetiginous syphilid at the angles of the mouth, whose scars form the rhagades, with mucous patches, condylomas at the anus, enlarged spleen and bone lesions, complete the most characteristic features of the picture The liver is seldom markedly enlarged The aphonic cry is quite characteristic The classical description of the marasmic syphilitic infant, with pot belly withered skin of a *café au lait* color old man facies ("keystone or old horse" face) and syphilitic pseudoparalysis of Parrot, is most often seen in the premature infant and the early severe types. Many children with perfectly typical eruptions, visceral and blood findings, seem only slightly underweight and well formed. Jeans and Cooke in studying the chief complaints which led parents to bring syphilitic children under two years of age for examination found in 610 cases, 230 nonsyphilitic complaints. The syphilitic complaints ranked as follows skin rash rhinitis bone lesions, request for a Wassermann test neurosyphilis eye lesions. Compare our experience with later cases.

Marfan describes as almost pathognomonic, pemphigus of the palms and soles, persistent snuffles with seropurulent discharge crusting and bleeding, chronic splenomegaly cutaneous syphilids, and Parrot pseudoparalysis. Ingraham (1935) found that from purely clinical study of the infant born of partially treated syphilitic mother the diagnosis of syphilis, has the disease is present, cannot be made with any degree of certainty in the *first two months of life*.

in as many as 5 per cent of cases. Definite obstruction to nasal breathing, almost always a symptom of congenital syphilis when it occurs in the first few days of life was actually present in four cases, at the time of birth. Syphilitic skin lesions and clinical osteochondritis were never present at the time of birth and approximately 3 per cent showed such manifestations early in life.

Wile and Mundt (1948) dealing with material up to two years of age, found that 45 per cent were brought to the hospital because of symptoms referable to syphilis; 33 per cent were referred because of positive blood tests, 20 per cent came because of entirely unrelated conditions and 2 per cent were detected in routine physical examinations which included blood tests. Stigmas in addition to the positive blood test were present in 82 per cent, but 56 per cent of the infants appeared healthy and apparently felt well on admission. Active cutaneous lesions were present in 27 per cent; in 19 per cent they were sufficiently characteristic to be diagnostic. About one fifth of the infants were distinctly underdeveloped, emaciated or actually marasmic.

Howles (1930) in a series of 100 infants less than three years of age (73.6 per cent Negro) lists the frequency in per cent, of some of the more important signs of early congenital syphilis as follows Skin and mucous membrane lesions 45 enlarged liver 25.2; rhinitis 24.2 enlarged spleen 20.3; clinically diagnosable chondro-epiphysitis 8.7; pseudoparalysis of Parrot and dactylitis each 1.9

The Cutaneous Lesions.—The outstanding dermatological features of the infantile cutaneous syphilids are in keeping with their general resemblance to the acquired secondary eruption. The most distinctive feature is a striking

Fig. 794 —Note the lesions about the face and mouth, the palms and legs, and the comparative freedom of the trunk in this heredosyphilitic infant. (Collection of Dr William Allen Pusey)

tendency to involve the chin and circumoral region the palms, the soles, and the anogenital region (Fig 794) An eruption which affects all these sites at once is extremely likely to be a syphilid. The macular syphilid is less common than the indurated papule, though the eruption may be macular on the body becoming, as in secondary syphilis, papular on the face and about the thighs and buttocks. The pemphigoid syphilid, with blisters or vesicles on the palms and soles, is relatively uncommon (Fig. 797) though highly diagnostic, and is interpreted as an unfavorable sign. Welde noted pemphigus in 12 per cent of his patients. The palmar and plantar surfaces are usually red and distinctly infiltrated, and may exhibit fissures (Fig 795) Irregular desquamation is the rule, but the merely desquamating palm or sole is hardly sufficient for a diagnosis alone. Pustular syphilids are rarely seen.

Differential Diagnosis.—*Eczematous* ulceration and *secondary infection* may at times produce a highly confusing picture about the buttocks, but the ensemble of regions involved usually makes the diagnosis. It is seldom safe to diagnose syphilis by erythematous lesions about the buttock alone unless indubitable condylomata with positive darkfield findings are present, for the so-called "napkin erythema" may occasionally (Fig 798) produce a corymbose

or grouped arrangement of definitely indurated papules on an erythematous base that is quite deceptive Nor is every erythema of the plantar surface to

Fig. 795 —The desquamating soles and grouping of lesions about the buttocks and genitalia in the heredosyphilitic infant. (Collection of Dr William Allen Pusey.)

be regarded as a syphilid for a very persistent plantar erythrodermia is occasionally seen as a nevus in infancy Changes in the hair are not character-

Fig 796 —The copper-colored spot conception in the diagnosis of cutaneous pigmented syphilids occasionally leads to interesting errors in diagnosis. This baby four months of age was covered with an eruption described by the medical examiner:

"Macular copper-colored syphilid over entire body Indurated plaques on skin of chest and on chin. Vesicular eruption on palms and soles. Spleen down 1.5 cm. Diagnosis: lues hereditaria."

This is an entirely satisfactory description of the eruption as such, the error being in the interpretation of copper-colored spots as diagnostic of a syphilid. The secret of the diagnosis here consists in the effect of irritation on the individual lesion. On stroking, pinching, or slapping the skin there was an immediate response from the pigmented patches in the form of urticarial wheals, limited to the pigmented areas. This is distinctive of the condition known as urticaria pigmentosa, which may come on very early in the life of the child (in this case at the age of one month). Other considerations speaking against syphilid are the child's general well-being, and the tremendous extent and uniformity of the eruption, which had not changed in three months. The serologic reaction on both mother and child was negative Urticaria pigmentosa has no known relation to syphilis.

istic, and the onychia sometimes seen may be well simulated by impetiginous infections. Even the highly characteristic "hacking" or rhagades (Fig. 800)

are occasionally simulated by eczematous fissures and secondary infection about the mouth (Fig 808) The exfoliative dermatitis of infancy (Ritter's disease) due to a staphylococcus septicemia, is sometimes mistaken for a

Fig. 797 —Syphilitic pemphigus of the soles. (Collection of Dr P C. Jeans.)

syphilid in the first few days of its course. This eruption usually begins on the trunk, extending as a bright erythematosquamous rash, and usually becoming confluent, with occasionally pustular and furuncular elements. It is

Fig. 798.—Papular lesions associated with "napkin erythema" and suggesting papular syphilid. The lesion disappeared in three or four days with an alkaline wash and dusting-powder.

superficial and without induration, advances more rapidly than a syphilid, and shows no special tendency to localize on the face, buttocks or palms, and soles at the outset, though they may be involved later The mucous membranes are seldom involved but may present a grayish membrane or a dry lividity

Impetiginous bullae may appear and the spleen be slightly enlarged. The infant may be febrile, and the disease progress rapidly to a fatal outcome. The vivid red of the acute dermatitis is in marked contrast to the indolent

Fig 799 —Papular lesions of miliary cutaneous tuberculosis in child. The distribution and ... ppearance suggest papular syphilid. The condition is rare.

brownish red of a syphilitic eruption Psoriasis does not occur in infancy The severer types of ecthyma produce ulcerative lesions which are rare in infantile syphilis and practically always associated with evidence of secondary

Fig 800 —The "hacking or 6 suring of the lip regarded as very characteristic early sign of heredosyphilis. Produced by cracking of the infiltrated skin and vermilion border

pyogenic infection, such as pustules and furuncles. Annular lesions are sometimes striking

Nose and Throat.—Snuffles is more diagnostic if hemorrhagic or purulent, although Findlay says mild forms are seen. Mucous patches as typical as any

seen in adults may be found at the commissures of the lips, and fissures and ulcers of the tongue and pharynx occur though rarely

Skeletal Involvement—Osteochondritis and Chondro-epiphysitis.—The first symptomatic warning is a flaccid paralysis if the lesion be in the upper extremity (humerus most often) or a spastic paralysis if in the lower extremity (Findlay) Parrot's pseudoparalysis, as this is called, may simulate Erb's

Fig 801—Rhagades and hacking (scars) produced by infiltrative and erosive syphilids about the mouth and chin in infancy

palsy The child cries when handled, and although no gross lesion may be seen it may often be palpated as a swelling at the end of a long bone All the characteristic bone lesions of acquired syphilis, plus dactylitis, more frequent in infancy may appear. Wile and Mundt (1042) found active bone lesions in 5 per cent of their infantile group The roentgenogram should be employed if there is any doubt as to diagnosis. The characteristic epiphyseal lesion is a

Fig. 802.—An ecthymatous fissuring of the lip, not due to syphilis, but to staphylococci.

thickening and irregularity of the epiphyseal line In advanced cases the line is replaced by a zone of fatty degeneration and necrosis between epiphysis and diaphysis which shows yellow in the cut specimen (Fig 803) Periosteal lesions and osteomyelitis and osteitis may be associated. The presence of cranial lesions is unusual. Craniotabes, the thinning of the central margins of the occipital and parietal bones with indentation on pressure is suggestive but not diagnostic of syphilis. Jeans and Cooke believe most of the skull changes

are rachitic. The deformity produced by a prolonged gummatous destruction of the septum differs not at all from that seen in late syphilis, but should be differentiated from the milder type with uninvolved septum seen as a developmental stigma in the heredosyphilitic facies, and shared with such conditions as oxycephaly and congenital ectodermal defect (Fig 839) Nonsyphilitic nasal suppurations may produce pictures suggesting the saddle nose of gummatous osteochondritis of the septum.

Roentgenographic Diagnosis of Infantile Congenital Syphilis.—The fact that widespread roentgenographically demonstrable epiphyseal and periosteal lesions of the bones, even in clinically normal children may occur in the first few weeks of life when congenital syphilis is present, has led to universal use of the roentgenogram in recent years for diagnostic purposes, in the apparently

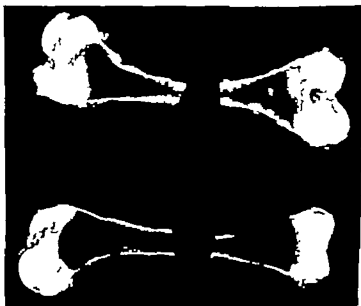

Fig 805.—Comparison of the ends of a normal and syphilitic femur in infants dying shortly after birth. The upper bone shows the irregular wavy epiphyseal line and the light (yellow) zone of fatty degeneration bet een epiphysis and diaphysis, seen in syphilitic chondro-epiphysitis.

healthy offspring of syphilitic mothers. The nature of these lesions is described in detail in the chapter on syphilis of the skeletal system

In applying this knowledge to clinical diagnosis, it is necessary constantly to bear in mind that the majority of these changes, particularly in their early stages are not diagnostic of syphilis, but may be produced by a variety of conditions (Chiari, 1938 Evans, 1940) Even prenatal therapy with bismuth, through producing areas of increased density in the shaft of the long bones close to the epiphysis, may cause confusion for the inexperienced (Caffey 1937 Christie, 1939 Whitridge 1940)

Fortunately the various conditions which Caffey (1939) has so admirably described as confusing the diagnosis of syphilitic osteochondritis (erythroblastosis, familial hemolytic anemia, and various forms of bacteremia, such as pneumococcic septic hemolytic and tuberculous) are sufficiently uncommon and are not often seen among the offspring of syphilitic mothers during the first few weeks of life. For accurate interpretation of the roentgenogram

A — Normal | B — Congenital Syphilis | C — Rickets | D — Bismuth Line

Fig. 804.—*Radius and ulna in early infancy to illustrate diagnostic value of roentgenographic demonstration of syphilitic osteochondritis. A,* Normal infant six days old. At this age the epiphysis (1) is radiotranslucent. The metaphysis (2) the first visible portion of the bone appears as a very narrow uniform band of increased density (temporary zone of calcification). The submetaphyseal area (3) and the diaphysis (4) are of uniform density with the normal trabeculation of the bone faintly visible. The periosteum is smooth. *B* In *congenital syphilis* the temporary zone of calcification in the distal metaphysis (2) of the radius and ulna illustrated is thickened and characteristically jagged (saw toothed) in appearance. The submetaphyseal zone (3) is rarefied from decreased calcium deposition as the bone grows in length and tongues of calcification extend into the rarefied zone from the diaphyseal side (4) The width of the rarefied zone indicates roughly the duration of the intrauterine infection. The illustration is from a three-week-old infant. *C*, In *rickets* the metaphysis is cupped (2) and the temporary zone of calcification is not definitely demarcated. Normal trabeculation is not clearly visible but there is no zone of submetaphyseal rarefaction. Periostitis (5) is visible along the shafts of the bones. Rickets generally makes its appearance at a more advanced age than does syphilitic osteochondritis. The illustration is from a 8½-month-old infant. *D Bismuth* therapy given to the mother close to term causes an area of increased density in the metaphysis and in the submetaphyseal area, sometimes extending deep into the shaft of the bone if bismuth is given throughout the latter months of pregnancy After birth, as the bone grows in length, the osseous tissue which is laid down in the submetaphyseal area (3) appears rarefied in contrast to the denser area or "bismuth line" (6) just proximal to it which has been caused by the antepartum bismuth therapy This change may usually be differentiated from syphilitic osteochondritis by the fact that the areas of increased density and of apparent decreased density are perfectly uniform, whereas in an infectious process like syphilis the decalcified areas are irregular The illustration is from a ten-day-old infant whose mother received a course of eight weeks of bismuth therapy the last injection being given thirteen days before delivery (three weeks prior to the taking of the roentgenogram)

it is, in our experience, critically essential that the roentgenologist consider in addition to the general physical status of the infant and the amount and duration of heavy metal therapy given to the mother prepartally the exact age of the infant being studied We emphasize this last point in particular because in the majority of instances, by the time an infant with congenital syphilis, who of course has usually been infected some days or weeks prior to delivery reaches the age of six weeks, there can usually be little doubt as to the nature of the osteochondritic changes. Most of the other conditions to be

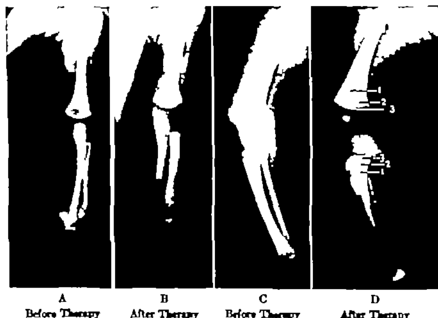

Fig 803 —Radius and ulna (A) and femur (B) from five-month-old infant with congenital syphilis. The roentgenogram shows a marked periostitis of all the long bones, in several layers on the outer aspect of the femur which is particularly characteristic in appearance in this location The osteochondritic changes seen earlier tend t heal as the periost tis ppears. Periostitis is seldom present at the time of birth and is rarely demonstrable until the infant is several weeks old. It likewise tends t heal spontaneously provided the infa t survives and is a less characteristic finding in the second than in the first six months of lif

confused with syphilitic osteochondritis, on the other hand, being acquired postnatally rather than prenatally develop at a somewhat later period in the infant's life (two to three months) and at this more advanced age show a type of early osteochondritic change that is usually demonstrable in congenital syphilis during the first month postnatally

Our experience has been in conformity with that of Black (1939) to the effect that the existence of unequivocal osseous syphilis roentgenographically demonstrable in the presence of negative serologic reactions when the better serologic technics are employed, is extremely uncommon. It may occasionally

occur however as observations like those of McCord (1038) have shown, in which not only the abnormal roentgenogram but *Spirochaeta pallida* as well was demonstrable in seven *infants with negative results to serologic tests.* (*Cf* also Ingraham 1935)

The roentgenogram has its **greatest** diagnostic value in early infancy up to the *age of six or eight weeks, during the period when serologic testing may* still leave uncertainties. It should be routinely employed as an adjunct to serologic diagnosis in those infants who appear healthy at the time of birth

A Before Therapy B After Therapy C Before Therapy D After Therapy

Fig. 606.—Effect of antisyphilitic therapy in healing early congenital osseous syphilis. *A*, Pathologic fracture of the radius in three-week-old child, as result of mild trauma to grossly diseased bone. Note in the distal metaphysis the jagged band of increased density with spur on the distal radial metaphysis. *B* The bone has healed normally after splinting and two months of sulpharsphenamine intramuscularly *C*, Marked syphilitic osteochondritis in six-day-old infant. Note jagged metaphyseal line and irregular band of subepiphyseal rarefaction in the distal metaphysis of the femur and in both the proximal and distal metaphyses of the tibia. *D* After two months of treatment the rarefied area (*1*) has receded onto the shaft and is gradually becoming denser as the bone grows in length. Just distal to this rarefied area is ide band of increased density (2) in contrast to which the tip of the bone next to the metaphysis (3) appears rarefied. This band of increased density results from bismuth therapy given the infant. The bone at the end of the shaft is of normal density This infant received five eeks of bismuth therapy and was then placed on sulpharsphenamine

though their blood tests are positive. Only unequivocal multiple osteochondritis (or periostitis) should be accepted as diagnostic. Doubtful or suggestive signs should be completely gnored as absolute diagnostic criteria, or as a basis for commencing treatment. Instead the infant should be restudied roentgenographically in two to three weeks for evidence of progression of the lesion or for the development of a more characteristic picture. A progressing osteochondritis which may occasionally be accompanied by a periostitis, occurring in a seropositive infant during the first six weeks of life may be considered as establishing a diagnosis of syphilis

Ingraham, Shaffer Spence and Gordon (1941) have shown that early diagnostic errors (before the age of two months) usually arise from too close reading of the roentgenograms, which tend to place too much significance on minor changes without adequate knowledge of so-called "normal variations," or from misinterpretation of the densities produced by antenatal therapy. Later diagnostic errors (*i. e.*, after the age of two months) from the roentgenographic standpoint result almost invariably from confusion caused by the periosteal changes often associated with developing rickets. Periostitis in the seronegative offspring of a syphilitic mother is more apt to develop into frank rickets than into advanced *infantile syphilis of the bone* though we have seen occasional cases in which the initial periostitis disappeared without either of the courses just mentioned being pursued.

The roentgenogram should not be used as a routine diagnostic procedure on all infants born of syphilitic mothers, but only in selected cases. Our Philadelphia General Hospital experience has shown the roentgenogram to be of some positive diagnostic value in 27 per cent of cases in which the mother had had no prepartal treatment, in 10 per cent of cases in which she had had less than two months and in no instances in which as much as sixteen weeks of prepartal treatment had been given.

Hemorrhagic Disease.—Syphilis is one of a variety of causes of melena neonatorum and was observed by Thomsen in 9 of 100 autopsies on children born alive of syphilitic mothers. The

Fig. 507

A SUMMARY OF THE CHIEF SYMPTOMS OF INFANTILE HEREDOSYPHILIS

The Eruption Rare before the third week, distribution distinctively to the face and mouth region, the anogenital region and the palms and soles macular maculopapular, secondarily eczematous, and often infected. Condylomas and mucous lesions. Pemphigoid bullae 10 per cent Infiltrations of lips, face, palms and soles.

Snuffles As common as the eruption and as early May be mild and not distinctive. Almost diagnostic if hemorrhagic.

Hacking of the Lips Fissures, especially of the upper lip and the middle of the lower.

Rhagades Infiltrative fissures, eczematous involvement of cheeks and chin near the commissures.

Enlarged Spleen Almost diagnostic before the fourth month (60 to 70 per cent present).

The Cry Cracked and aphonic Very suggestive.

Pseudoparalysis Flaccid of the upper extremity spastic of the lower presumably due to painful movement, but may be neuritic due to osteochondritis and epiphysitis.

Osteochondritis, Chondro-epiphysitis, and Osteomyelitis: Palpable enlargement and tenderness of the ends of the long bones, single or multiple, oftenest the upper extremity May be fusiform involvement of shaft.

Epitrochlear Adenopathy in the Newborn Stressed by some writers.

Saddle Deformity of Nose The sequel of the osteitis and gummatous changes in snuffles.

Pulmonary Hepatic, Marasmic Symptoms less common.

syphilitic infection according to Neumann is accepted at the present time as the cause of an abnormal susceptibility to septic infection rather than the actual directly responsible factor in the hemorrhagic diathesis. Lambkin describes the various local lesions such as ulcers, condylomas, etc., which may cause bleeding from the rectum in children.

Miscellaneous Symptoms.—Eye lesions are infrequent in infancy (Jeans and Cooke). Wile and Mundt (1912) found chorioretinitis in 3 per cent, optic atrophy and extraocular paralyses in 1 per cent each in children under two years. Fever is common, rarely above 101° F and disappears quickly with treatment. *Nephritis* occurred in 10 per cent of the heredosyphilitic children of Welde series The acute parenchymatous nephritis of heredosyphilis is a rarity in our experience as in that of Jeans and Cooke and like that of acquired syphilis, requires corroborative evidence of syphilis and a positive therapeutic test for diagnosis. In the only case under J.H.S.'s observation on Wile service the hemorrhagic pyonephritis, for such it microscopically cleared up rapidly when the child was placed on mercury by mouth and neoarsphenamine. Renal disturbance did not occur in Wile and Mundt (1912) series. Fink *Icterus*, Carpenter (quoted by Findlay), and Findlay have seen cases Varying grades of anemia in infants are attributed to syphilis, but are evidently not common Chiaravalloti found the hemoglobin in 130 cases to range from 11 to 73 per cent. Nitschke found no evidence of any uniform change in 30 children except a slight tendency to lymphocytosis. *Splenic anemia*, while at times ascribed to syphilis, does not seem to bear a distinctive relation to the disease *Icterus neonatorum*, according to Findlay is very rarely syphilitic in origin. Peritonitis and ascites are rare complications, examples of which are described

by Acuna and Casaubon and Spence and Tittle Orchitis develops in the first few weeks of life, according to Findlay in 2 to 3 per cent of cases. Meningitis, of syphilitic origin, is considered under neurosyphilis in childhood. Pulmonary symptoms may rarely arise from syphilitic changes in the lungs, and P Jares believes he has seen 3 genuine cases in the first week of life. Marasmus proved to be associated with positive blood Wassermann reaction in only 8 per cent of Findlay cases, but Barbier describes type of general trophy of the tissues associated with Parrot pseudoparalysis which he thinks is syphilitic in origin.

Increased blood sedimentation rate, in active congenital syphilis, observed by György (1931) has been restudied by Ingraham (1935) Rarely will the blood serologic test be negative when this test is positive and Weiss (1925) has shown that the rate is not much increased until the disease becomes clinically manifest.

Fig. 808.

THE LANDMARKS OF TARDIVE HEREDOSYPHILIS

Major	Secondary	Minor	Debatable.
Positive blood serologic reaction.	Frontal bosses.	Venous ectasia.	Carabelli tubercle.
Interstitial keratitis.	Aplasia of incisor teeth.	Hypertrichosis.	Retromastoid adenitis.
Hutchinsonian incisors.	Scaphoid scapula.	Ulnar deviation of middle fingers.	Persistent infantile hydrocele.
Mulberry molars.	Marked enlargement inner third of clavicle (old osteitis) (Higoumenakis sign.)	Constitutional subnormality	Hypertrophic thymus and thymic abscess.
Eighth nerve deafness.	Disturbance of age development ratio.	Backwardness.	Alopecia areata in children.
Saber tibiae: Osteitis. Periostitis. Simple hypertrophy	Precocity and high nervous irritability	Hypertrophic frontal suture.	Knock-knee elbow
Osteitis of the nasal septum Snuffles. Saddle bridge.	Early epitrochlear adenopathy	Craniotabes.	Absence of the xiphoid process.
Splenomegaly	High narrow palatine arch.	Bilateral dacryocystitis in childhood.	DuBois little finger sign.
Rhagades and scars.			
Early dactylitis.			
Facies.			

Strongly presumptive or diagnostic.
Insufficient for diagnosis alone.

Landmarks of Tardive Heredosyphilis Differentiation of Syphilids and Developmental Dystrophies.—A rough classification of the earmarks of heredosyphilis into syphilids, caused by the presence of *Spirochaeta pallida* in the lesion or tissue affected and developmental or structural anomalies resulting from the syphilitic intoxication, has great value as a guide to clear thinking (Fig. 808) Developmental anomalies may be the product not only of the action of the syphilitic intoxication if such a term may be used, upon the dystrophic structure as such but also upon the growth centers or organs of systemic importance to the growth centers, such as the endocrine glands. Both syphilids and dystrophies are likely to appear in any case in which the infection has been present during uterine and early infantile existence.

From time to time new developmental abnormalities are proposed for consideration as signs of "heredosyphilis, in some instances in the more or less distant ancestry of the patient. Many

of these are parts of the French conception of syphilitic dystrophies (syphilis héréditaire tardive). These debatable signs have been listed as "suggested but unestablished," and no attempt has been made to insure the completeness of the list. Individual impression and experience will always influence decisions on these less significant points. The minor sign is at best merely suggestive and carries no weight alone.

Such a classification cannot, of course, meet with complete acceptance in its details or be all-inclusive, but it serves the purpose of a general impression of relative importance. In Fig. 809 the symptoms and signs of congenital and heredosyphilis are classified on the basis of true syphilids and developmental changes.

Fig. 809

SYPHILIDS AND DEVELOPMENTAL STIGMAS

Syphilids.	Developmental Stigmas.
Positive blood Wassermann reaction.	Facies.
Eruptive lesions:	Dental dystrophies.
Skin.	Age-development ratio disturbed:
Mucous membranes.	Delayed dentition.
Keratitis.	Delayed menstruation.
Early splenomegaly.	Oversize and undersize.
Osteitis:	Gigantism.
Septum.	Dwarfism.
Tibia.	Bosses.
Clavicle.	Scapulae.
Dactylitis.	Some tibiae.
Chondro-epiphysitis.	High arched palate.
Periostitis.	Ulnar deviation.
Bilateral hydrarthrosis.	Venous ectasia.
Dacryocystitis.	Hypertrichosis.
Rhagades.	See also "syphilis héréditaire tardive."
Gumma.	
Visceral syphilis.	
Neurosyphilis.	

THE GENERAL SYMPTOMATOLOGY OF TARDIVE HEREDOSYPHILIS

The age of incidence of symptoms of tardive heredosyphilis was given by Fournier (212 cases) as three to twenty-eight years, with a mean of twelve years. Our own experience includes more than tardive cases. The older patients were usually recognized by stigmas and sometimes presented symptoms which responded to treatment. It is rare to find active manifestations after thirty.

Figure 810 summarizes in order of frequency the lesions and stigmas presented by the most important case series extant. The overwhelming preponderance of eye lesions, which exceed even the positive blood serologic reaction in frequency, in marked contrast to infantile prenatal syphilis, points both to the field of diagnostic and suspicion-arousing clues, and to the social and economic importance of tardive heredosyphilis. The hutchinsonian triad, formerly much emphasized in diagnosis (interstitial keratitis, hutchinsonian teeth and eighth nerve deafness), is now recognized as a rarity in its complete form.

Why the Tardive Syphilitic Child Seeks Medical Advice.—The chief complaint is frequently the deciding factor in a diagnosis, and its analysis

Fig 810.

RELATIVE PERCENTAGE FREQUENCY OF SIGNS OF LATE CONGENITAL SYPHILIS ACCORDING TO VARIOUS AUTHORS

Signs	Stokes (1946)	Jeans and Cooke (1930)	Cole (CCG) (1937)	Howles (1939)	Wile and Mundt (1942)

points to the medical groups which have the best opportunity to identify the heredosyphilitic child.

General ailments lead (32 per cent) with eyesight 24 per cent, ear, nose, and throat 22 per cent, syphilological follow-up 14 per cent, and neurosyphilis 8 per cent.

The general ailments which include 32 per cent of the chief complaints, exclusive of symptoms suggestive of nervous derangement, are as follows:

In the history of childhood ailments, 29 per cent could be interpreted as definitely syphilitic in origin and 27 per cent as questionable. The remaining 44 per cent were obviously nonspecific. In Wile and Mundt's (1942) series half of the group sought hospital care because of symptoms referable to syphilis. Interstitial keratitis was the principal diagnosis on admission in the largest number of patients, central nervous systems syphilis next most frequent, followed by bone and joint disease. The diagnosis of 86 per cent of the patients could be made on the presence of one or more characteristic stigmas, with or without a positive serologic reaction. The so-called "congenital syphilitic facies" was observed in more than one-fourth of the patients and 9 per cent had obvious symptomatic central nervous system syphilis.

The Blood Serologic Reaction in Tardive Prenatal Syphilis.—Speaking from the diagnostic standpoint, the blood serologic reaction ranks lower in the recognition of tardive heredosyphilis than it does in many other forms of syphilis, and contrasts markedly with the 100 per cent estimate of its value

Fig. 811

MISCELLANEOUS COMPLAINTS IN SYPHILITIC CHILDREN

after the first two or three months of infancy. The blood serologic reaction, positive in the aggregate in only 60 per cent, follows an even more pronounced age gradient toward the negative, than does that in the acquired form of the disease. In the first decade its efficiency approximates 88 per cent, in the second 63 per cent, in the third, 46 per cent; in the fourth (over thirty years), 15 per cent. After twenty years of age, more than half the cases are identified by clinical signs.

The Eye Lesions of Tardive Prenatal Syphilis. Interstitial or Parenchymatous Keratitis.—Fifty two per cent of all persons who are brought to medical attention because of heredosyphilis have or have had interstitial keratitis, and only 22 per cent have entirely normal eyes, according to our experience. Figure 812 seems to accord with the importance assigned them in the literature. Lennarson and Jeans (1937) found 45 per cent interstitial keratitis, 15 per cent chorioretinitis, and 6 per cent optic atrophy and Wile and Mundt (1942) 44 per cent interstitial keratitis, 10 per cent chorioretinitis, and 3 per cent optic atrophy in a similar type of material. For the syphilitic child interstitial keratitis thus becomes one of the most serious and distressing

of symptoms. It involves, even in the mild case, a period of absence from school, and of photophobia and discomfort that leaves a permanent impress on the patient's mental organization. Untreated or poorly treated it leaves a residue of actual damage to vision estimated by Igersheimer at 40 per cent of all patients affected, by Cole *et al.* (1937) at 27 per cent and by Klauder and Vandoren (1941) at 19 to 22 per cent. Interstitial keratitis constitutes from 0.4 to 0.6 per cent of all eye disturbances as estimated by Derby and Walker (77 000 eye cases) and Hoor (375 000 eye cases).

The onset of interstitial keratitis is commonly between the ages of five and sixteen though it may appear for the first time as late as thirty. In an analysis of 542 cases Klauder and Vandoren (1941) found that 15 cases developed interstitial keratitis before the age of three years and 8 cases after the age of thirty years. The statistical curves of Cole *et al.* (1937) show that a patient with late prenatal syphilis is in constant danger of developing interstitial keratitis up to the age of twenty to twenty five years. It is more common in girls than boys. The predisposing factors include lowering of general resistance, such as is produced by a sudden severe chilling, an attack of grippe

Fig. 818.

or in one or two of the late cases we have seen, a pregnancy which one would rather expect to have the opposite effect. Dietary deficiencies in particular *ariboflavinosis may play a secondary role* (Takeda, *1934*, Kruse *et al.*, *1940*, Sydenstricker Kelly and Weaver 1941 Woods, 1943). Our experience with the treatment with riboflavin of a limited number of cases of interstitial keratitis, who did not respond well to antisyphilitic therapy at the Philadelphia General Hospital, has been disappointing, no alteration in the normal course of the disease being noted. The condition preserves an unaccountable independence, and may come on during a course of quite intensive mercurial treatment, or from an absolutely clear sky in patients almost devoid of stigmas, and certainly without the slightest evidence of impairment of general health. It may also appear for the first time following the institution of treatment in an asymptomatic patient. Interstitial keratitis occurs rarely in the secondary period of acquired syphilis and in association with chancre of the eyelid (Pariser 1939). It is, however so overwhelmingly an accompaniment of late prenatal syphilis that its diagnostic value is paramount and should be impressed on the student from the outset.

Symptoms.—The earliest symptom is slight ciliary congestion followed by the appearance of small grayish infiltrative deposits either toward the periphery or in the center of the cornea. The inflammation involves the entire thickness of the cornea, the grayish deposit being lymphocytic. Ulceration rarely occurs (deSchweinitz) Circumcorneal injection of the sclera, suggesting an episcleritis, may be the first sign that attracts the patient's attention, or there may be a slight smarting, lacrimation and discomfort in the light, the forerunner of the intractable photophobia from which these patients suffer (Fig 813) When the patient is first seen by the physician, varying degrees of clouding of the central portion of the cornea with impairment of vision, have usually developed and capillary loops have begun to extend in from the

Fig 813.—The photophobic element in typical heredosyphilitic facies. Note the nebula over the right cornea. The process had been reduced to practical inactivity by treatment, but the photophobic habitus persisted.

limbus vascularizing the affected area. Marked degrees of vascularization and opacity produce the so-called "salmon patches" of the more severe cases, with their yellowish-red dull sheen The limbus becomes red and swollen in severe cases from the new formation of vessels.

The physician who will accustom himself to examining the cornea with a lens for cloudy spots and faint grayish stippling whenever a child complains of sore or running eyes, or has a "conjunctivitis" or "pink eye," will contribute inestimably to the diagnosis and perhaps the ultimately successful treatment of interstitial keratitis Even the protracted "cold" which cannot stand strong light is a proper object for a quick survey of stigmas and the taking of a blood serologic test

The infiltration and vascularization of the cornea are almost invariably accompanied by involvement of the iris and the anterior uvea, which accounts for increased pain and lacrimation, although these signs may be masked by the semiopaque cornea. In 700 cases of interstitial keratitis analyzed by Spicer (1924) only 6 per cent failed to show evidences of anterior uveitis Iritis was present in 28 per cent, cyclitis in 48 per cent and anterior choroiditis in 29 per cent (*cf* Wood, 1943) Synechial adhesions result, if the pupil is not dilated, and the iritis may leave pigment deposits on the posterior surface of the cornea. Secondary glaucoma may be a complication. Intractable episcleritis also occurs (John Lane)

Interstitial keratitis, in the older literature is always described as bilateral and as inevitably involving the other eye once it makes its appearance.

Preventing Involvement of the Other Eye.—There can be little question that the course of the condition in the second eye can be greatly reduced in severity and shortened in time by the use of the arsphenamines combined with heavy metal or if need be with fever and involvement of the other eye frequently prevented. Cole *et al.* (CCG 1937) found that among 64 patients with interstitial keratitis affecting one eye, the involvement remained unilateral in 41 (64 per cent) Klauder and Vandoren (1941) found that the chance of escaping bilateral involvement increases in direct ratio to the lapse of time from the onset of interstitial keratitis in the first eye. In 42 per cent of patients both eyes were involved either simultaneously or within one month of each other The percentage with second eye involvement increases slowly to the tenth year At this time the second eye has become involved in 79 per cent.

Guy brought out clearly the contrast between the older ineffective mercurial therapy and the results of modern treatment in this particular but the period of observation in his cases was short. Carvill and Derby reported on the joint efforts of the Massachusetts Eye and Ear Infirmary and the Syphilis Clinic of the Massachusetts General Hospital to make thoroughgoing treatment applicable to this situation Ith series of 388 cases treated with reasonable thoroughness. Among these it was found that the duration of the attack in the second eye is longer than in the first in only 25 per cent of cases, that intensive treatment may have some influence in preventing involvement of the second eye and in reducing the severity of the attack in this eye. In 18 per cent of 100 cases there was no involvement of the second eye. The proportion of recurrences in treated cases was only 3.6 per cent as compared with 27 per cent, 14 per cent, and Spicer 9 per cent. I 100 untreated cases Carvill and Derby observed 27 per cent recurrences, an overwhelming tribute to the value of systemic treatment. Semi-effective treatment, even with the arsphenamines, was not effective in preventing interstitial keratitis in the later years in 10 cases. In an important follow-up report by Carvill on this same series of cases she found that of the 18 per cent in whom intensive treatment had prevented involvement of the second eye, no involvement of that eye had subsequently occurred in 16 out of 17 cases reexamined to determine this question. The period of observation, more than five years in all cases, nine years or more in 12, would seem definitely to establish the fact that the effective use of modern treatment is capable of completely preventing, at least in some cases, the involvement of the second eye Osborne and Putnam also report success in preventing involvement of the second eye in 30 cases after treatment was started. It is, however known that many years may sometimes elapse between the first and the second attack. Klauder and Vandoren large series failed to provide convincing evidence that involvement of the second eye could be prevented by treatment as such, the time factors being more important.

Interstitial keratitis runs, as a rule, a self-limited course punctuated by relapse in untreated cases, the frequency being reduced by treatment as just noted. Hoor estimates the frequency under the old regimen at 18 to 22 per cent, Cole *et al.* (CCG 1937) at 29 per cent with poor treatment during the

acute stage Under proper treatment relapse may be reduced to 15 per cent (Cole *et al*) or even to 8 per cent or less (Klauder and Vandoren). We have seen the first attack and the relapse separated by as much as seven years of apparently complete good health. Each recurrence of course, adds to the damage done the cornea by vascularization and inflammatory deposits. Complete involution is not the rule at least some traces of vascularization persisting indefinitely in most cases, partly we believe because of delay in instituting treatment. Occasionally however the vessels may completely disappear Klauder and Cowan (1939) have however pointed out that with the use of slit lamp microscopy it is possible to make an almost certain diagnosis of a previous interstitial keratitis in nearly every case and after any length of time. It is, moreover usually possible to distinguish syphilitic from other forms of keratitis The value of utilizing this study to establish a congenital infection, even after many years, is emphasized. A negative examination is evidence that the patient has not had interstitial keratitis, but does not, of course, prove the absence of congenital syphilis. The nebula or opacity in, rather than on or behind, the cornea is quite characteristic when present. The impairment to vision is chiefly dependent upon the central location of the infiltrate and since this part of the corneal inflammation is the last to undergo resolution, it is impossible to tell, until the very end of the attack, what impairment, if any will result. Carvill and Derby found that 27 per cent of 200 children lost from a month to three years of school, 24 per cent were definitely handicapped in their work for a livelihood

The differential diagnosis of syphilis from tuberculous interstitial keratitis must be made by general signs. The presence of fine straight vessels extending in from the limbus is good evidence of old interstitial keratitis. The vessels in trachomatous pannus anastomose and are more superficial those of former ulcer are confined to the scar (deSchweinitz)

In taking the history of eye disturbances in childhood tuberculous keratitis should not be forgotten as a possibility in the eagerness to make a case for syphilis.

The remaining eye lesions, detailed in Fig. 812, are in no way distinctive of heredosyphilis, apart from their occurrence in childhood Extra-ocular paralyses and strabismus, chicken-track and sand-grain punctate pigmentary residua of peripheral or anterior chorioiditis, vitreous opacities and remains of uveitis in children should always be regarded with suspicion. Primary optic atrophy is said to be an unusually frequent accompaniment of juvenile tabes, but it is a much less frequent cause of failing vision in the prenatally syphilitic child than are chorioiditis and chorioretinitis. Chorioiditis is apt to follow interstitial keratitis, or be revealed as the involution of the corneal process permits inspection of the fundus.

The Ear Nose and Throat Symptoms of Heredosyphilis.—Kerald and Kemp confirm our observation of a 10 per cent incidence of eighth nerve deafness. Hutchinson found 15 per cent deaf among his cases. Their analysis showed the condition to be more common in males than females, which is at variance with other observers The age of onset approximates puberty but may be earlier It may be sudden or gradual and is usually accompanied by tinnitus and vertigo Interstitial keratitis was the most common associated lesion preceding or accompanying the deafness. The blood serologic test was positive in more than 90 per cent and the spinal fluid invariably negative Breitenstein describes, in addition a type which is annoyed by subjective

noses but has only slight impairment of hearing, and a severe antenatal involvement which gives rise to deafness from birth and consequent deaf mutism. In cases which progress to complete deafness before the tenth year mutism is likely to ensue. Beck and Schacherl describe serologically negative cases.

We have been impressed with the difficulty of basing a diagnosis of prenatal syphilis purely upon eighth nerve deafness in the child, without definite confirming evidence. In one family group, in which the youngest child was totally deaf, two sisters and the mother were found to present the same condition. The youngest child had classical frontal bosses, and the eldest a suggestive facies, but all were seronegative and presented no other stigmas. The fullest investigation of the parents failed to reveal anything. Such borderline cases certainly cannot be swept into the syphilitic category merely by the fact of eighth nerve deafness developing without infectious or toxic accidents in childhood.

Saddle Bridge and Nasopalatine and Nasopharyngeal Gumma.—The flattened bridge of the heredosyphilitic face is only in part due to actual

Fig. 814.—Saddle bridge due to gummatous osteitis of the nasal septum, with destruction of the septum and perforation of the palate in a patient with heredosyphilis. This is to be distinguished from the developmental dystrophy

destructive change in the bones. When such occurs it adds greatly to the worth of the nasal depression as a sign. In fact, high perforation of the nasal septum with collapse of the bridge and flaring of the nostrils, especially if accompanied by perforation of the hard palate, is as nearly pathognomonic of syphilis as any item in the category. The history of trauma is too readily accepted by plastic surgeons as explaining such deformities of the nose, for the trauma merely initiates the gummatous change in many cases. That not every flattened bridge is syphilitic is sufficiently emphasized by Figs. 839 and 840. Perforation of the soft palate (Fig. 815) is highly suggestive but not absolutely diagnostic.

Dangers of Operative Interference in the Nose and Throat.—The otolaryngologist has many opportunities to diagnose heredosyphilis by following to their source the dental dystrophies, depressed nasal bridges, septal perforations, and high palates, which pass before him. Nicolas, Massia, and Dupasquier believe that the incisor bud, from which the central part of the

upper alveolar process is formed is especially susceptible of attack by *Spirochaeta pallida*. Such a special *susceptibility* would seem to extend to the septum and palate in heredosyphilis, and makes the recognition of the underlying condition of the utmost importance before operative interference, either for obstructed breathing deflected septum or plastic restoration of a saddle bridge The type of saddle bridge which represents a developmental dystrophy (Fig 806) may conceivably sustain operative trauma better than one which depends on the destruction produced by an osteitis gummosa (Fig 814). Gummatous involvements of the jaw may be taken for alveolar abscess or

Fig 815 —Cicatricial deformity of the nasopharynx, the result of tonsillectomy performed upon patient with untreated heredosyphilis. The patient had characteristic facies, suspicious upper central incisor teeth, large liver and positive blood serologic test, none of which was recognized before the operation which resulted in permanent deformity

sarcoma in the lower and maxillary cyst or sarcoma of the antrum in the upper jaw and should invariably be checked by the blood serologic test and a search for stigmas. The larynx in severe cases of infantile heredosyphilis may show edema and ulceration (Still found 14 per cent) but in later years, apart from an occasional slight sclerosis of the cords, there are no distinctive laryngeal lesions.

Gummatous breakdown failure to heal and cicatricial distortion in the pharynx (Figs. 815 816) are more frequent consequences of tonsillectomy in heredosyphilis than is generally realized The incidence in our series amounts

to almost 20 per cent in the previously untreated cases while not one of those properly prepared by treatment experienced gummatous complications. Use of the blood serologic test and familiarity with the signs would prevent much of this irremediable damage

The Dental Abnormalities of Heredosyphilis.—The teeth provide the diagnostician with some of the most important clues to the recognition of heredosyphilis The tendency of the average observer if he considers the teeth at all in his study of the patient is to be too inclusive and too indefinite in his conceptions, and to rate as syphilitic a variety of dystrophies which have no

special connection with the disease. The abnormalities which suggest syphilis can be quite exactly defined, and have a rational basis in the embryogenesis of the dental structures.

The first point for the student to grasp is the fact that only the second dentition teeth show changes definitely characteristic of congenital syphilis.

Two groups of teeth whose embryonal anlagen are undergoing development and ossification in the jaw during late uterine and early infant life, bear the brunt of the stigmatization produced by syphilis. These are the upper central incisors of the second dentition, and the first or "six year" molars. The upper central incisors, when typically modified by the influence of the infection, become the so-called "hutchinsonian teeth," described by Jonathan Hutchinson in 1858. The six year molars which are developing in

130 cases

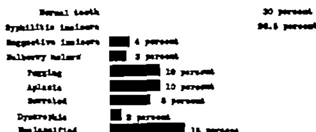

Fig 617

the jaw during the first year of the child's life present, on eruption, defective cusps which produce the appearance described as "mulberry molar "Moon molar" after the English surgeon (1884) or Fournier tooth."

The studies of Karnosh (1926) and the more recent work of Anderson (1939) Johnston, Anderson and McAleney (1941) and Stathers (1942) have indicated that the dental defects of congenital syphilis show wider range of variation than is generally known. This variation may range from complete failure of development of tooth to slight diminution in size and alteration in form. The difference is largely one of degree.

Dental stigmas are more readily recognized when the oral structures are viewed as whole. The incisors of the second (and occasionally of the first) dentition, the cuspids (canines) and the first molars are involved as group The most consistent physical characteristic of the dental malformations is the dwarfing of the entire tooth and lack of development of the premaxillary bone. The *lower central incisor* is involved much less frequently than the upper central incisor and the canines are seldom affected because these teeth usually develop somewhat later The permanent *upper lateral incisors* are rarely affected because they do not begin to develop until much later time (about 10 months)

In those cases in hich the onset of the disease has been early and severe enough to affect jaw development peculiar deformity appears known as the open bite. In differentiation from the open bite produced by thumb sucking and malnutritional disturbances, the open bite of congenital syphilis shows no contraction of the anterior region such as may produce overcrowding of the teeth, there is not the bent or distorted appearance of the alveolar process seen in the open bite resulting from habits, nor is there evidence of failure of proper dental eruption. In the open bite associated with congenital syphilis, the teeth as well as their supporting bony structure, appear to be wanting in sufficient substance to bring them into proper occlusal relations. Stathers found open bite to be present in 56 per cent of his 60 cases. The bite was normal in only 10 per cent; the teeth were edge to edge in 22 per cent, were slightly overlapped in 14 per cent and had *deep overbite in 10 per cent.*

Stathers also found that the *high narrow palatine arch*, which has often been described as characteristic of congenital syphilis is rare, and when found is usually associated with narrow

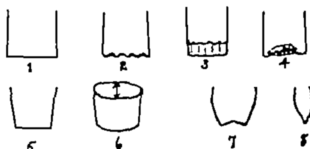
saddle arch. Stoll has emphasized this as a diagnostic sign. In our experience it is only occasionally seen and not in itself diagnostic.

The Deciduous Teeth.—Although it is generally conceded that there is no change in the deciduous teeth which might be considered characteristic of congenital syphilis, and certainly nothing which could be called pathognomonic yet, Brauer and Blackstone (1941) and Sarnat and Shaw (1942) have observed dystrophic changes which almost certainly seem to be related to this disease. The fact that the deciduous teeth are not more frequently affected is explained on the basis that this morphodifferentiation and dento-enamel junction are determined only in utero, usually before syphilis invades the fetal tissues.

Brauer and Blackstone found in 16 congenitally syphilitic children with deciduous central incisors still present, that 37 per cent had cupping or notching of the central lobe of these teeth in the incisal region. Two of the children had marked enamel hypoplasia of the posterior deciduous teeth.

Schour and Massler (1940) report that the deciduous central incisor has its initiation and histodifferentiation stage at approximately seven weeks in utero, that the apposition of the enamel and dentine begins at approximately four to four and one-half months in utero and that the crown of the tooth is five-sixths formed at birth. Since the last phase of incisal apposition takes place at the seventh or eighth month of fetal development, it is conceivably possible that apparent hypoplasia of the central lobe could be a manifestation of syphilis.

Sarnat and Shaw found that in each of four instances when roentgenograms revealed characteristic hutchinsonian incisors in unerupted teeth (see subsequent section), the deciduous teeth had chronologic enamel hypoplasia. The time of disturbed enamel formation corresponded approximately with the neonatal period and the period of earliest infancy.



Brauer and Blackstone found that syphilis had no effect on the eruption or exfoliation of the teeth.

Morphology of the Syphilitic Upper Central Incisor.—Hutchinson's original (1861) description of the malformed permanent central incisor states that it is shorter and narrower than normal with mesial and distal sides converging from the gingival margin to the incisal edge. Failure of development of the central mamillon causes formation of a half moon shaped notch on the cutting edge. Deficient enamel covering on the incisal edge permits staining of the underlying dentin and consequently this portion of the tooth may become darkened. In 1887 Hutchinson stated that he did not believe the notching to be essential and introduced the descriptive term "screw driver" form (see Fig. 818). The upper central incisor undergoes ossification from three centers largely in the first year of infancy. During or just preceding this period, any nutritional disease or febrile illness may leave traces upon the developing tooth causing defective dentinization and enamel formation, pitting and serration. As a rule in nonspecific disturbances, the three centers develop equally however and the tooth on eruption presents the parallel or slightly flaring sides of the normal tooth. The distance between the teeth may be influenced by their general underdevelopment as well as the narrowing of the jaw so that they may appear abnormally far apart or abnormally close.

In syphilis the effect on the ossification centers of the upper central incisors seems to differ in character or time exerted from that in other diseases. The middle denticle which forms the central portion of the tooth, is suppressed and the lateral denticles, by their continued and uncompensated growth produce the bulging sides and anteroposterior thickening or "barrel shape" of the characteristic syphilitic incisor. The cutting edge of the tooth, lacking the portion produced by the middle denticle bears a crescentic notch or defect, most marked on its anterior surface. The shape of the entire tooth, rather than the notch alone is characteristic.

Figure 818 gives in condensed form the morphology of the hutchinsonian incisor and its differentiation from other types of nonspecific serration and notching.

The classical upper central incisors of heredosyphilis are shown in Figure 819 Such teeth may we think, be regarded as pathognomonic. On the other hand, the "pegging" and the widening of the spaces between the lower in-

cisors cannot be regarded as distinctive of *syphilis, although it often occurs* among the dental dystrophies of heredosyphilitic patients. The legends describe the differential points.

Fig. 819 —Typical hutchinsonian teeth

Sarnat and Shaw (1942) give the following important differential characteristics in the diagnosis of the hutchinsonian incisor: It is important to recall that, in congenital syphilis, the dentino-enamel junction is dwarfed. Consequently the crown is smaller This should not be confused with enamel hypoplasia (chronologic enamel aplasia) which is not in the outline of the dento-enamel junction but in the enamel formation. Hypoplasia occurs at later time and may be caused by rickets, hypoparathyroidism or fluorosis.

In partial anodontia, arachnodactylia, facial hemiatrophy mongolian idiocy achondroplasia and few other conditions, the upper permanent incisors may have narrowed dentino-enamel

junction and a peg shape. Whereas the incisal third is affected in hutchinsonian incisor the entire crown is affected in these other conditions, and the remainder of the teeth show similar

Fig. 840.—Syphilitic upper central incisors without the notching. This patient had had interstitial keratitis, undiagnosed for years, had become almost totally deaf, and had suffered collapse of the nasal septum, before syphilis was sufficiently suspected to lead to blood serologic test and treatment. Note the rounding of the anterior face of the incisor due to anteroposterior thickening, and the "screw-driver" shape.

Fig. 841.—Borderline incisors in boy with interstitial keratitis, facies, and positive blood serologic reaction. A diagnosis could not be based on such teeth, but their anteroposterior thickening and rounding of the face might stimulate further study.

Fig. 842.—Upper central incisors in heredosyphilitic patients, showing the fusiform or nut shaped tooth with bulging sides and anteroposterior thickening. Note also the pegging of the lower incisors. These teeth arouse suspicion, but are not diagnostic.

disturbances which cannot be correlated on chronologic basis with events during the neonatal period and earliest infancy. This will usually make absolute differentiation possible.

Roentgenographic Demonstration of Hutchinsonian Teeth.—The demonstration of unerupted hutchinsonian teeth radiologically was first accomplished by Stokes and Gardner in the case of a five-year-old child who had lost her

Fig 883—Traumatic notching of the upper central incisors. This patient was suspected of having heredosyphilis and the photograph has repeatedly been so diagnosed. The notching was produced when the patient face was stepped on in football scrimmage. He had tuberculous glands.

Fig. 884—A suspicious right upper central incisor markedly thickened anteroposteriorly in patient with heredosyphilis and positive blood serologic reaction.

Fig. 885.—Nonsyphilitic dental dystrophy Hutchinson, in his original description, warned against regarding this picture as due to syphilis. Painstaking investigation of this patient and her family was entirely negative. The "pegging" of the lower incisors cannot be trusted in diagnosis.

first dentition incisors and whose delayed second dentition incisors had not yet erupted. Meyer Buley from the Bonn (E. Hoffmann) Clinic has confirmed our observation, finding it usable in diagnosis as early as the second year Quinlan from Schamberg's Clinic found hutchinsonian incisors in 2 of 14

cases, Sarnat and Shaw (1942) in four of sixteen cases. The appearance should be distinctive for diagnosis

The typical notch and bulging sides are apparent in Fig 837 By having the child bite firmly down upon the film it is held in position sufficiently well for this purpose and little cooperation is required. A particular interest attaches to this case because the child's infection was recognized when she was four months old. Six injections of arsphenamine reversed the blood serologic reaction, controlled the gummatous manifestations, and reduced the infection to quiescence. When seen more than four years later the child was in excellent health and without gross

Fig. 836.—Aplasia of the upper central incisors with conical malformation of the laterals, picture occasionally seen in heredosyphilis and in congenital ectodermal defect.

evidence of syphilis, and was still seronegative. Yet the treatment which had accomplished the seemingly good result, given her at the age of four months, had failed to protect or influence the anlagen of the second dentition incisors.

The low vitality and inability to resist decay so frequently observed in the first dentition teeth of syphilitic children, may affect the second dentition teeth though much less frequently. Occasionally one finds the upper central incisors partially or completely destroyed in spite of considerable protective effort, while the remaining teeth, apart from dystrophic shape, seem

Fig 837 —Unerupted Hutchinson upper central incisors demonstrated by roentgen ray in child aged five years.

Fig 838.—The mulberry or six-year molar in heredosyphilis. Note the dwarf cusps of the anterior tooth and the hypertrophied enamel ridge which surrounds them.

quite sound. This circumstance is hardly diagnostic, however Stathers (1942) found that with the exception of the first molars, the permanent teeth seemed no more susceptible to caries than could be expected from the general dental care of the group examined.

The Mulberry Molar—The first molars of the second dentition erupt at about the sixth year and, if seen before decay sets in, present a deficient development of the cusps which is due to suppression not unlike that which

affects the middle denticle of the hutchinsonian incisor A shoulder of enamel bulges out around the crown of the molar and from well within the margin spring the four defective, dwarfed cusps (Fig. 828) deficient in enamel and usually early victims of decay Once caries sets in, the cusp is soon replaced by a pit. The cross-ribbing of the grinding surface with enamel and pitting from decay have earned it the name "honeycomb molar"

Wall and Stoll consider the mulberry molar more frequent and suggestive than the hutchinsonian incisor *If the latter term be strictly interpreted, this is probably so, but we feel more* hesitation in stressing the molar in an interpretation than we do the incisor It is, none the less, very valuable clue when typical and may be the only dental abnormality in the mouth of an undoubted, serologically positive, otherwise negative patient, with complete substantiating family history

Recent writers, particularly with the use of the roentgenogram, have stressed the importance of the mulberry molar as diagnostic sign of congenital syphilis. Stathers (1942) found that this type of tooth was or had been present in 66 per cent of his cases studied as compared with 60 per cent typical hutchinsonian teeth in the same group of patients In the forty patients in whom the first molars were still present, all four teeth were affected in 13 cases, there were 3 mulberry molars in 7 cases, 2 in twelve cases and 1 in 8 cases

The roentgenogram was first used to demonstrate the unerupted mulberry molar by Pincherle (1937). Excellent radiographic reproductions of the mulberry molar are given by Sarnat, Schour and Heupel (J A. M. A., June 21, 1941). Johnston, Anderson and McAlenney (1941) showed conclusively by direct comparison, that the mandibular first molar was smaller than the mandibular second molar in 80 per cent of their cases of congenital syphilis in which the teeth could be measured. They further emphasize the importance of the roentgenogram when they state that only one half of their 36 patients showed dental stigmata to clinical examination, whereas two thirds showed diagnostic changes in the roentgenogram.

The very obvious dystrophic tendencies of syphilitic teeth have led to multiplication of dental signs of heredosyphilis, which we think is not justified. The so-called "Carabelli tubercle, an accessory cusp on the inner aspect of the upper first molar has been supported as diagnostic point by Sabouraud. Sprawson and Dennis have examined both children and adults to the number of more than 500 without finding anything to support the claim. Our own experience has been similar

The small proportion of entirely normal teeth (30 per cent) in heredosyphilis, as shown by our series, is evident in Figure 817 The large proportion of nonspecific dystrophies is evident.

Should a diagnosis be based on teeth alone? The classical hutchinsonian tooth can be regarded as practically pathognomonic, and we have never known the finding to remain unconfirmed by history or course. The suggestive types cannot, of course be accepted without some confirmatory evidence. To that evidence we would especially admit the facies (Fig. 835) which, in combination with *suspicious teeth, we have many times seen confirmed by* the familial study or the course of the case

Bone Stigmas of Tardive Heredosyphilis.—Bone changes bulk large among the recognition marks of late heredosyphilis. In general they are the result of osteitis or overlying periostitis in the earlier months of life, which produce, respectively diffuse thickening and exostosis or roughening, especially of the shafts of the long bones. Their roentgenological interpretation appears in Chapter XVI As in acquired syphilis, the tibia and the clavicle being near the surface and frequently affected are the most used diagnostic landmarks. The frontal bosses, when exaggerated sufficiently to form Parrot's nodes (natiform or "hot cross bun" skull), have a high diagnostic value but are relatively rare. The milder grades of frontal and parietal prominence have less weight. Jeans believes many of them to be rachitic. In addition to these osseous residua, active periosteal and osteomyelitic lesions may occur in tardive cases, quite often in association with outbreaks of interstitial keratitis.

Chief among these are periostitis of the tibia and fibula, and of the radius and ulna and symmetric hydrarthrosis especially of the knee.

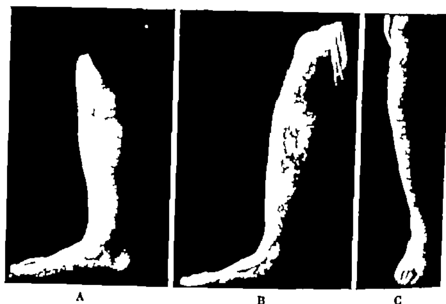

Fig. 829.—Types of saber tibia in tardive heredosyphilis.

Fig. 830.—Technic of palpating the saber tibia to detect the fusiform thickening, which is quite as important as the anterior bowing.

The older literature contains references to a nonarticular diaphyseal process adjacent to but not involving the joints and simulating tuberculosis; and arthritis leading to ankylosis the status of which with reference to syphilis is still unsettled. Bone gummas are occasionally seen Charcot joints

and spondylitis are among the rare manifestations. The frequency of these various types of lesions is indicated for our experience in Fig 810 In addition

Fig. 831.—Roentgenograms of the right tibia shown in Fig 830. The fibula also shows slight involvement.

Fig. 832.—Anterior bowing of the tibiae due to rickets. Note the absence of osteoperiosteal thickening. (Collection of Drs. Keidel and Moore.)

to the actual bone syphilids, certain developmental bone stigmas, such as the high palatine arch previously mentioned under dental abnormalities, and scaphoid scapula to be described, have a much lower diagnostic value.

The Saber Tibia.—Anterior bowing of the tibia is not sufficient of itself for a diagnosis of saber tibia. A case of rachitic origin is shown in Figure 831. The combination of bowing with thickening is essential to the full value of the sign. This thickening is usually fusiform, involving the middle third of the shaft, and palpable not only as a widening between the two fingers, as shown in Figure 830, but also as a rounding of the sharp edge and flat anteromesial face of the bone (Fig. 829). *If there has been no periostitis, there may be no roughening or pitting whatever.*

Marked grades of saber tibia are apt to be accompanied, according to Codman, by localized cortical thickening of the fibula, but this is detectable only by roentgenogram. If active periostitis is present, it differs in no respect from that described for acquired syphilis. The thickening of the tibia produced by chronic syphilitic osteitis, as seen roentgenologically, is described by Aikens as a diffuse, uniform, distended and spongy bone shadow.

Fig. 833.—A marked grade of epiphyseal enlargement in a child of seven years.

Clavicular Enlargement.—While this is not common it is often overlooked. The demonstration of gross thickening of the inner third of the clavicle with roughening and irregularity should be checked by roentgenray examination. Figure 50 is an excellent clinical illustration. Higoumenakis has stated that this enlargement tends to be unilateral, occurring on the right in right-handed and on the left in left handed individuals.

Dorne and Zakon (1933) found this sign present in all of their 14 reported cases. Yang (1940) reports the sign in all of his 6 patients with late congenital syphilis. Higoumenakis (1930) stated that it could be found in 86 per cent of cases. According to this last mentioned author the enlargement of the sternal extremity of the clavicle, as proved roentgenographically, results neither from a defect in the statics of the patient nor to a loosening and distention of the articular capsule, but merely to an augmentation in the volume of the bone caused by a hyperostosis resulting from a syphilitic osteitis. Since anatomically the inner third of the clavicle, the area involved, arises from a secondary nucleus which appears between the eighteenth and twentieth year, it would seem that occurrence of the sign might indicate activity of the congenital infection in adult life.

and further that the sign would not be present in patients adequately treated in infancy or childhood. Aldach (1941) encountered the clavicular sign in 4 of 92 patients with definite diagnosis of late congenital syphilis.

Epiphyseal Enlargement.—This is relatively frequent among bone changes in older syphilitic children appearing as a disproportionate enlargement of the joint when compared to the skeleton as a whole. The "heavy knees" and large wrists and elbows are not altogether trustworthy however and the roentgenogram may be helpful, although as a rule, no active chondro-epiphysitis remains. The shortening of the long bones, due to epiphyseal changes, may occasionally by contrast, accentuate the impression of enlarged joints. Figure 835 is an unusually pronounced case.

Osseous Overdevelopment.—We have no intention of proposing a new stigma of heredosyphilis, but it is none the less interesting to note the usual contrast between the malnourished or rachitic frame and the skeleton of the heredosyphilitic child. The tendency to bony overgrowth in the latter manifests itself in a heaviness of limb, a columnar massiveness and lack of modeling of the lower extremities which may or may not be dependent on unrecognized osteitis of the long bones in infancy

Dactylitis.—This is most diagnostic in the first year or two of infant life, but may be seen occasionally in older children, in whom a differentiation from tuberculous spina ventosa must be made. Our incidence of 2 per cent corresponds exactly to that given by Still.

The fusiform swelling of the proximal phalanx rarely softens or breaks down in syphilis as it does in tuberculosis. The finding of periosteal involvement as well as the osteochondritis of the epiphyseal end of the diaphysis, with less destruction and more thickening due to actual excess bone formation, is in favor of syphilis. The tuberculous process is usually solitary; the syphilitic and rachitic, multiple (Brickner Ware). The possibility of confusion with syphilis through false therapeutic test is illustrated by Figure 612.

Symmetric Hydrarthrosis (Clutton's Joints) —This painless hydrops, unassociated with bone changes and usually bilateral, involving the knees was fully described by Clutton in 1886 though noted earlier by Richet (1853) Förster (1877) and Virchow (1884) A synovitis is the primary and most important pathologic process. The disease is confined to syphilitic children and is the most common form of syphilitic change of the joints in the congenital variety of the disease A number of illustrative cases have come to our attention over a period of years (see Fig 596) The joint is usually not tender and shows no crepitus or other findings of note except the effusion, with consequent separation of the joint surfaces. Febrile reaction is usually absent unless from intercurrent disease or unless the joint has been aspirated for diagnostic purposes, not an infrequent procedure if the condition remains unrecognized. The roentgenogram is negative except for enlargement of the joint cavity Blood serologic test for syphilis is almost uniformly positive (Klauder and Robertson, 1934 report two seronegative cases in their series of 63 patients)

Although the knees are the usually involved joints, the condition has been reported as occurring also in the elbows, wrists, fingers and ankles. The maximum age incidence is from eight to fifteen years and cases are rarely seen prior to five years or after twenty years. There are two types (1) congestive bursitis, (2) hydrops. Gummas of the bursa may produce similar clinical picture.

The diagnosis, according to Pendergrass, Gilman and Castleton is dependent on: (1) presence of constitutional syphilis, (2) spontaneous development independent of trauma, (3) slow evolu-

tion and chronicity (4) absence of pain, tenderness or functional disability (5) symmetrical involvement usually of the knees without evidence of bone involvement, (6) response to specific treatment.

Klauder and Robertson (1934) state that, untreated, the condition may exist for months or even years but tends to terminate with spontaneous recovery. Treatment for syphilis probably shortens the course of the disease but improvement (in the congenital form in contradistinction to the acquired form) is seldom rapid. When the effusion disappears, the joint becomes normal,

Fig. 634 —Osteoperiostitis of the ulna in heredosyphilis. The child had every stigma of the disease except venous ectasia.

relapse seldom occurs, ankylosis is not a feature and surgical intervention is normally unnecessary and contraindicated.

The so-called "von Gies joint," in contradistinction to Clutton's joint is a syphilitic chondro-osteo-arthritis which may lead to ankylosis. Fournier describes a polyarthritis with changes resembling arthritis deformans which is probably closely related, if not identical with, von Gies polyarthritis. It occurs in older children and is decidedly rare.

Since interstitial keratitis is the commonest active clinical manifestation of late congenital syphilis it is not surprising that it is frequently associated with Clutton's joint. Instances are not

uncommon in which treatment of one of these conditions seems to have precipitated the other. Klauder and Robertson (1931) found that Clutton joints were slightly more common in patients with interstitial keratitis than with other manifestations of congenital syphilis but review of the literature and of our own experience fails to indicate that, from the statistical standpoint, there is any apparent relationship. Of some practical importance is the fact that at times Clutton joints precede the development of interstitial keratitis chronologically in the course of development of the disease and, if recognized, may form valuable premonitory sign to the more serious eye involvement.

Developmental Stigmas and Constitutional Inferiorities.—The developmental stigmas not already considered include disturbance of the age-development ratio, constitutional inferiority giantism and infantilism, venous ectasia, general hypertrichosis, the bony abnormalities of cranial bosses,

Fig. 633.—The classical "map of heredosyphilis, with all accessories, including bosses, corneal nebula, and hutchinson incisors. Examination failed to reveal any evidence that this patient had ever had osteitis of the nasal septum to account for the flattened bridge.

scapulae, palate and middle fingers, and that most interesting and significant of composites, the facies. There is little of specific value in the majority of these items. Venous ectasia is most apparent in the enlargement and tortuosity of the superficial scalp veins. A retiform blue tracery may be rather conspicuous over the upper thorax, and the external jugulars may seem unusually large and corded. The anomaly is, however frequently absent or becomes inconspicuous as the child grows older The chief disturbances of age-development relations concern late walking, which is not especially characteristic of the syphilitic child over or underdevelopment amounting at times to dwarfism or giantism, and delayed puberty especially in girls. The eccentric development of the syphilitic child seems not to be especially distinctive in any particular unless it be the mental side discussed on page 1145 For a period of several years the Section of Dermatology and Syphilology at the Mayo

Clinic made numerous examinations of constitutionally inferior children in the effort to trace syphilitic dystrophies, with very disappointing results. While the child with a severe syphilis may for a period exhibit a good deal of depression the large majority of tardive types are not as ill or underdeveloped as the seriousness of the disease would lead one to expect. DeAngelis reached the conclusion that most of the undernutrition of the child was due to environment, not the disease. They are in a sense a picked group, who have survived the grueling test of uterine and infantile infection and not infrequently include very fine specimens of athletic young manhood and attractive girlhood. Even the sharply stigmatized patients have little of a general nature to complain of. The impressions conveyed by the monstrous exhibits of the visitation of the sins of fathers on children do the heredosyphilitic child the grossest injustice. Of grossly crippling deformity and disfigurement there is very little indeed.

Endocrinopathies as a Source of Stigmas.—Opinion on the influence of syphilis upon the endocrine mechanism controlling growth in the heredosyphilitic child continues in the speculative stage. The demonstration of syphilitic lesions or spirochetes in such organs as the suprarenal glands and testes does not necessarily imply structural or functional change. That there are endocrine changes in syphilis, however, is evident from the studies of Brown on the rabbit. The French and Italian writers in particular are inclined to attribute a variety of dystrophic changes to the influence of syphilis upon the endocrine mechanism. In the case of pituitary dystrophies the connection is more apparent than following many of the thyroid and gonad disturbances for which a causal relation is claimed. Progeria, that astonishing picture of senility in childhood described by Gilford and more recently by Curtin and Kotzen, whose case we saw, compares for example with Simmonds' disease in which acquired syphilis of the hypophysis is implicated. Progeria, however, is not prenatal syphilis so far as is now known. Syphilis seems, at times, also to impart a species of developmental stimulus to the organism, expressing itself in hypertrophies of structure and vivacity, of which the precocity and physique of well-developed syphilitic children are examples. Very little that is tangible and diagnostically useful, however, can be derived from this material at the present time. For more recent discussion of this subject in relation to the pituitary and thyroid see Bleus (1938, 1939).

The Facies of Heredosyphilis.—The facial make-up of the heredosyphilitic child in a typical case is a composite of syphilids and developmental dystrophies. The rhagades, the dimming of the eyes from corneal nebula, the flattening of the nasal bridge through collapse of the nose following gummatous osteitis of the septum, the hutchinson incisors, create an impression sufficiently obvious for detection by the tyro. There is, however, a special and more occult "impression" produced by the facial make-up of heredosyphilis, which is independent of these grosser stigmas, and which rests apparently upon anomalies in embryonic development similar perhaps to those which produce the grosser teratologic monstrosities of oxycephaly, acrocephaly, turricephaly, and acrocephalosyndactylism, and the dermatological rarity of congenital ectodermal defect.

The difference between the normal and the heredosyphilitic face does not depend on any one feature, but resides mainly in the upper part above the upper lip and at times even above the tip of the nose. A certain touch of fulness and excess breadth and height to the forehead is an element, yet the rachitic and constitutional inferiority complexes may have it without giving the true impression. False impressions may be had by relying too much on the beetling or Olympic front. The essence of the matter lies in a certain maleficness, a sleepy, tired, fagged, clouded, dreamy or obscured appearance of the upper face, an appearance of veiledness as if a smudge had lightly swept across

Fig. 836.—A, The facies of heredosyphilis. The suggestion of apathy, listlessness, fatigue, and "blurring" or "smudging" is not produced by focusing defects, for with a hand lens the lanugo hair between the brows and the delicate cleavage lines of the skin can be recognized in the original photograph. The boy had never had interstitial keratitis. The blood serologic test was positive. He had double dacryocystitis, which was practically quiescent when the photograph was taken. The "facies" is not lost by distortion of the lower face, nor is the forehead essential. In B the forehead is covered, there are no upper central incisors, and the "grin" showing the lower teeth does not conceal the impression.

Fig. 837.—A less pronounced, but nevertheless definite facies, estimated at 60 per cent. Note the look of fatigue and apathy, though the patient was well. She had a right upper central incisor quite definitely of the syphilitic type, a negative blood serologic test, saber shins, and interstitial keratitis. Her mother had a neurosyphilis of long standing.

the brows and eyes and the nasal bridge of a crayon portrait. It is possible to obscure the jaw and mouth with a card and still get the impression. Changes in expression (Figs. 836, 837) and angle of inspection do not destroy it. Wile

has laid stress upon the upward and outward flare of the nostrils which results from the depression of the nasal bridge and this is undoubtedly important. To us, however the effect is produced more by the increased distance between the eyes. Neither corneal nebula nor teeth are essential. With the brows more accentuated and the eyes deepened, with the blue iris and black pupil in sharp contrast, the facies becomes Celtic. We have seen the "map of Ireland in a deaf girl produce a quandary among experts.

The impression or facies of heredosyphilis may be sufficiently clear cut to permit the expert to make diagnosis with an accuracy exceeding 90 per cent, and it may prove just the reverse The conversion of the "impression into words is difficult, and reinterpretation should be undertaken only with photographs and the patient before one. Mere verbal description is not a safe basis for diagnosis, and only experience gives actual assurance. The chief value of the facies is in the arousing of suspicion, which should then seek confirmatory clues, for the facies should practically never be allowed to make the diagnosis alone.

Fig 838.—Brother and sister each with certain of the elements of the heredosyphilitic facies. The dome in the boy case is less suggestive than the face of the girl. There is corneal nebula of the right eye which heightens the effect.

Familial resemblance and subjective interpretation must be watched in passing an opinion upon the facies. *Two or three observers* should, if possible, form independent opinions before comparing notes. The actual diagnostic value of an expert ppraisal of this clue is difficult to state, but it certainly greatly exceeds in value such items as scaphoid scapula, high palatine arch and the numerous minor and debatable signs. In fact, we would place it among the major diagnostic aids, never acceptable alone, but of great confirmatory value.

The differentiation of the heredosyphilitic facies from other types is not difficult. A box shaped head and square beetling forehead is rachitic rather than syphilitic and if nothing else can be found cannot be trusted as a sign. The open mouth and vacant look of the adenoid type emphasize the lower face. Constitutional inferiority and idiocy are caricatures, which the facies is not. The long keystone or horse face is emphasized by some writers. Mongols have the slit eye, the overlapping inner canthus, the high cheek bones, and macroglossia to distinguish them In progeria the caricature of senility—huge dome (suggesting hydrocephalus) wasted ears beaked nose, and underdeveloped

jaw and clavicles, with the skeletal underdevelopment, sexual retardation and atrophic skin are distinctive.

Frontal Bosses.—The minor degrees of frontal prominence and even quite pronounced bosses cannot be regarded in spite of their frequency as

Fig. 839.—A family group illustrating mild grade of oxycephaly The length of the face and the ears "on the neck" are better seen in profile but the absence of supra-orbital ridges and wide separation of the eyes, with the familial resemblances, are apparent.

more than contributory evidence (Fig 841) Extreme degrees, involving both frontal and parietal bones, with the anterior fontanel lying in the cruciate depression between them, are however considered as almost pathognomonic.

Fig. 840.—The facies of congenital ectodermal defect. The patient had neither hair (wig) nor sweat glands and few teeth. Note the flattened nasal bridge. There was no osteitis or destruction of the septum.

Scaphoid Scapula.—Concavity of the vertebral border of the scapula was described by Graves (Fig. 842) as developmental anomaly which occurs in constitutional inferiority complexes, syphilis among them, without being pathognomonic of any particular condition. Wile and Mundt (1942) in their series of 402 cases found scaphoid scapula to be present as diagnostic criterion in 27 per cent.

Ulnar Deviation of the Middle Fingers.—This is an inconclusive clue found in small percentage of cases (Fig. 843).

Post-rhagadic Scars.—These lesions are in reality produced by atrophy of the elastic tissue, resulting from diffuse syphilitic infiltration of the skin such as is seen only in the congenital type of infection (see Figs. 800, 801). The lips, chin, cheek, corners of the eye or nose or perianal region

Fig 841.—Profile of the dome. This abnormality alone does not constitute a "facies.

Fig. 842.—The typical scaphoid scapula—concavity of the vertebral border of the scapula (Graves' scapula). The patient must relax to permit the slipping of the fingers under the edge as shown.

may be involved. Post-rhagadic scars of congenital syphilis on the face are distinguished by diminution in the color of the lip, by partial loss of the mucocutaneous border and by the presence of linear furrows of the lip which extend but radial scarlike lesions of the surrounding skin

(Hochsinger, 1896) Strakosch and Nelson (1941) illustrate one case with rhagades in retiform arrangement on the cheeks. Krantz (1941) feels that when the scars project as white pegs into the vermilion border or when they extend far into the surrounding skin they are pathognomonic even when other stigmas are lacking

DuBois Little Finger Sign.—In 1866, DuBois described a sign which he felt occurred in as high as 80 per cent of cases of congenital syphilis. According to DuBois the skin fold between the *terminal and middle phalanx of the little finger, is not at the level of the skin fold between the* basal and middle phalanx of the fourth finger as normally but somewhat more proximal. This sign is supposed to result from a dystrophy of the middle phalanx of the small finger. Our ex

Fig. 843.—Ulnar deviation of the middle fingers, a relatively unimportant sign.

perience has been that this is a relatively uncommon finding. Aldach (1941) has pointed out that it occurs in about 7 per cent of apparently normal persons.

Late Visceral Changes.—In spite of the supersaturation of the patient with organisms before birth, the early involvement of the spleen and liver in a large proportion of cases, the fibrosis that affects to a greater or lesser extent the pancreas and the ductless glands, and the enormous numbers of spirochetes which are demonstrable in such tissues as the myocardium, the *tardive heredosyphilitic patient presents very little in the way of cardinal* symptoms from the visceral and vascular structures. He has, in fact, conquered or subdued his infection, and survived the fibrosis which it has induced. The liver and spleen are enlarged in only a slightly larger proportion of cases than in late acquired syphilis. One of us (Stokes) has seen only three really huge spleens, one in association with hepatic cirrhosis and multiple bone lesions. The stomach and intestine have more than the relative immunity of acquired syphilis.

D'Aunoy and Pearson (1939) report an incidence of 1.5 per cent intestinal lesions in 500 children with congenital syphilis who came to autopsy. More than 75 per cent of all cases of syphilis of the intestine are observed in macerated stillborn infants and in infants who live less than twenty-four hours (see previous section on pathologic changes in the syphilitic fetus)

Cardiovascular Involvement in Congenital Syphilis.—Curiously enough, the cardiovascular system of prenatally syphilitic individuals, while demonstrably especially so far as the heart muscle is concerned, the lurking ground of innumerable *Spirochaeta pallida* in early life, presents an almost complete immunity to serious syphilitic cardiovascular disease. In his entire experience

Stokes can recall only once having seen the clinical homologue of syphilitic aortitis in child. Yampolsky and Powel (1942) have reported such a case in nine-year-old Negro girl at autopsy and have reviewed the literature in the field. They emphasize the reports of previous authors as to the likelihood of sudden death from the involvement of the mouths of the coronary arteries. Hinrichsen (1943) review points out: (1) it is often difficult in adult life, and often even in childhood, to differentiate between the congenital and the acquired form of the disease; (2) other conditions, such as acut infection, especially rheumatic fever and congenital malformations of the heart may produce aortitis and aneurysm, so that syphilis, even if present is not necessarily the causal factor (3) rheumatic fever moreover especially in its acute phases may occasionally be responsible for biologically false positive serologic tests (Koons and Kimana, 1940, Fordyce, 1930) The clinical importance and interest of the question of cardiovascular syphilis in childhood led to the presentation of three important papers before the American Heart Association in 1930, dealing with thorough studies by Previtali, Nicolson, and Moon-Adams (30 cases) clinical,

Fig. 844.—Hypertrichosis as sign in heredosyphilis. This was a girl of eleven years, with numerous other and more significant stigmas.

electrocardiographic, and roentgenological findings Givan (417 cases, thirteen months to forty-two years) and McCulloch (830 cases under fifteen years). In Givan series only 1 case with findings that might be classified as cardiac disease due to congenital syphilis appeared. All three groups of cases led their investigators to the same conclusion—that hile syphilitic heart disease occasionally ppears as reportable rarity in the literature which they review it is all but negligible in clinical practice despite the recognized occurrence of the organism in the heart muscle. The criteria for the recognition of the occasional case differ in no particular from those applicable to cardiovascular disease in acquired syphilis.

Peripheral vascular lesions, including symmetric gangrene are occasionally reported, the literature to 1914 being summarized by Lisser and Hand and Reilly having recently reported 3 children aged two and half, five and eight and half years in one family whose parents had syphilis. Of this condition Stokes has seen one case through the courtesy of Dr J C Gittings, lesion of which is illustrated in Fig. 710 Chapter XIX.

Hinrichsen (1943) has completely reviewed the literature of this subject and comes to the

conclusion that congenital syphilis produces definite myocardial lesions of two types, namely interstitial and nodular myocarditis, in which *Spirochaeta pallida* can be demonstrated. No conclusive evidence that congenital syphilis produces valvular heart lesions appears in the literature. The rôle of this disease in producing aortitis and aneurysm and in the production of congenital malformations of the heart has not been determined definitely. Arteritis, particularly of the cerebral vessels, may be produced by congenital syphilis. It is possible that congenital syphilis may be a factor in some cases in producing arteriosclerosis and Raynaud's disease. Congenital syphilis is one of the causes of hemorrhagic disease of the newborn.

The above statements should not leave the impression that the heart of the congenital syphilitic to ordinary physical examination is a normal-sounding, normally functioning heart. A number of minor abnormalities—split second sounds, tachycardias, over-action etc.—suggest the contrary, though no specific pathologic abnormality may be recognizable.

Neurosyphilis and Nervous Disorders in Tardive Prenatal Syphilis.—The importance of this group of manifestations is evident from the place of neurosyphilis (26 per cent) mental retardation (25 per cent) nervousness (22 per cent) and precocity (12 per cent) in our table of signs (Fig 810)

Neurosyphilis presents the same forms in the tardive heredosyphilitic that it does in the adult, but with some recognizable differences in symptomatology especially in tabes. Paresis, tabes, and taboparesis, cerebral arteritis, meningitis and meningo-encephalitis, spastic diplegia, epilepsy and imbecility are all recognized as occurring in heredosyphilis. There is also an asymptomatic type which could undoubtedly be recognized earlier and effectively treated if more attention were paid to the spinal fluid examination in the young child.

The 92 cases of tardive congenital neurosyphilis recently reported by Wile and Mundt (1942) were analyzed into 46 per cent asymptomatic, 21 per cent paresis, 11 per cent tabes dorsalis, 3 per cent taboparesis, 3 per cent meningovascular 2 per cent meningitis, 1 per cent cranial nerve palsies. A miscellaneous 10 per cent was composed of patients with epilepsy convulsive disorders, hydrocephalus and mental retardation.

Unrecognized Juvenile Preparesis.—The medical profession has not appreciated its responsibility in identifying neurosyphilis in children and young adults by spinal fluid examination at the earliest possible moment after syphilis is recognized. The Army Selective Service and inductee examinations are disclosing the frequency of such shortcomings. After months and years of routine ineffectual treatment for an irreversible serologic test in a child or adolescent, a spinal fluid examination after a "nervous breakdown" or a selectee or employment serologic test discloses the existence of a paretic formula. The then grave clinical situation and impending tragedy could have been averted by fever therapy at least had the practitioner in the case recognized the necessity A spinal fluid examination early in the course of congenital (prenatal) syphilis is as essential as in any phase of acquired syphilis.

The analysis of our cross section of 150 patients completely examined with reference to the nervous system showed that 20 per cent had abnormal spinal fluids (Figs. 845) and 20 per cent had some form of neurosyphilis. The proportion is greater the younger the patients in the group, ranging from 31 per cent between the ages of birth to nine years and 17 per cent between ten and nineteen to 10 per cent in the third decade and none at all over thirty

These figures correspond closely with those of Jeans and Cooke (1930) and Wile and Mundt (1942). Jeans found that 40 per cent of his syphilitic infants, 31 per cent of older children with active lesions, and 20 per cent of older latent cases showed involvement of the nervous system. Wile and Mundt found positive spinal fluids in 47 per cent of their cases under two years and in

27 per cent of their cases over two years. In each type of clinical congenital neurosyphilis males were affected more frequently than females in the ratio of three t two. The tendency of neurosyphilis toward a fatal ending in infancy or early childhood probably accounts for some of the decline in the older age groups. It may moreover serve t explain the differences noted in various reports. Figure 845 summarizes several of the recent estimates in the literature

Meningitis.—Meningitic symptoms appear most frequently in the younger children—40 per cent of Jeans and Cooke s children under one year of age. The symptoms are not distinctive Kernig sign neck rigidity and an onset with convulsions. In half their cases there was a bulging of the fontanel. The serological tests are positive the cell counts high often 500 or over Treatment response is good.

Hydrocephalus. Congenital syphilis is frequently the cause of hydrocephalus internus of moderate degree but involvement is seldom so marked as t cause hydrocephaly of the dimensions

Fig. 845.

INCIDENCE OF NEUROSYPHILIS IN HEREDOSYPHILIS

Author	*Date*	*Cases.*	*Spinal fluid abnormal per cent.*	*Clinical neuro-syphilis, per cent.*	*Remarks.*
Jeans	1919	214	32 7		None over fourteen years.
Taeuser	1921	45	41 8		
Kingery	1921	58	28 8

		140	22 9	4 3	Negro under two years.
		249	29 7	10 5	White over two years.
		190	12 5	1 7	Negro over two years.
Menninger	1936	653		less than 10	43 cases of author 610 cases collected from literature
Wile and Mundt	1942	19	47	36	Under two years.
		843	27	11	Over two years.

sometimes reached result of congenital malformations (Benda and Tedgell, 1941). Woodall (1929) found prevalence of syphilis of 11 1 per cent in hydrocephaly and 7 1 per cent in microcephaly. Hydrocephalus appeared in 30 per cent of Jeans and Cooke group of children with neurosyphilis. The cell count on the fluid is increased but not as high as in the acute meningitis. With early and adequate treatment these authors found the response to be good.

Juvenile General Paralysis.—The onset of juvenile general paralysis may be veiled by the youth of the patient, and lacks the striking features of the adult type in part because of the psychically undeveloped nature of its victims. Menninger found that juvenile paresis represents less than 2 per cent of all cases of general paresis, and between 5 and 15 per cent of congenital neurosyphilis. Less than 1 per cent of all cases of congenital syphilis develop paresis. The average age of onset is thirteen years, 68 per cent of cases being between nine and eighteen years, with 0 4 per cent becoming manifest before

W. C. Menninger s excellent monograph entitled Juvenile Paresis, Baltimore Williams and Wilkins Co., 1936, should be read by all interested in detailed study of this subject.

the age of six years and 3 6 per cent after the age of twenty Epileptiform seizures, mild grades of conduct disorder and imbecility are the presenting symptomatic aspects in most cases. Not infrequently before the onset the child may present a normal or even a precocious mentality Failure to pass a grade in school may be the first warning, and months and even years of slowly progressive retardation may only finally be unravelled as the dementia becomes complete, by an examination of the spinal fluid.

Gardner (1930) reports accurate measurement of physical and mental growth in patient with juvenile paresis, over period of years, both before and after the appearance of clinical symptoms. Both mental and physical development were normal up to the age of ten years when he suddenly failed to progress in school. With the development of symptomatic paresis physical growth ceased over period of five years and learning capacity fell to the imbecile level. Antisyphilitic treatment was more effective in reinstituting normal physical growth, than it was in restoring normal mentality

Menninger (1936) concludes that the mental symptomatology of juvenile paresis is characterized by confusion, mental regression to simple dementia, inadequate emotional response and restlessness. Clinical pictures approximating psychoses of the adult are infrequent, because of, as is pointed out above, the undeveloped nature of its victims.

It is often not easy adequately to differentiate the mental symptoms produced by congenital neurosyphilis from those produced by heredity and environment. Menninger reports that mental disease (exclusive of dementia paralytica) sufficiently severe to require hospitalization occurred in one or more nonsyphilitic members of the family in 14 per cent of 399 cases. Jenkins and Crodela (1941) in study of the relation of juvenile paresis to behavior problems in children state that the paresis contributes largely to such traits as restlessness, exclusion from school, poor work in school, distractibility emotional instability excitability immaturity and childish manner and destructiveness; and that traits referable to such factors as lying, stealing, truancy and sex delinquency though frequently associated with paresis, are the result of environmental and parental influence rather than of disease.

Klauder and Solomon, who have reviewed this subject with presentation of 23 cases, found the age onset of symptoms to lie between six and fifteen years, lapse of time from birth corresponding quite clearly with that observed in adults. They comment on the recurrent convulsive or epileptiform seizures which may occur daily for long periods of time with strikingly little effect on the patient. Toni Schmidt Kraepelin, with series of 64 cases, found one fourth of their patients showing arrested development, one third with mental deficiency The studies of Howard (1936), Jenkins, Brown and Cisler (1940) and of Lurie, Greenebaum and Brandes (1941) all show that syphilitic children with involvement of the nervous system tend to be intellectually inferior to their nonsyphilitic siblings and to groups of children in the same economic strata. The latter authors found that by the Stanford revision of the Binet test only 29 per cent were of verage or superior intelligence, whereas 60 per cent ere distinctly below normal. The epileptiform symptoms with focal signs suggest brain syphilis in some cases, and in others, to judge from Dahlstrom cases, may suggest brain tumor and lead to needless surgery especially in those not infrequent cases in which head injury precipitates.

The most important single group is, of course the preparetic, recognized by all the writers cited, in which a typically paretic spinal fluid unaccompanied by symptoms occurs. The improved outlook for paresis under modern treat ment makes it doubly important to seek early identification of these cases by spinal fluid examination.

The clinical stigmas of prenatal syphilis may or may not be present in patients with juvenile paresis. As a rule, in our experience, those who present marked stigmas seem to suffer from a more severe infection, and to have undergone an earlier and more pronounced degeneration. The discovery of a juvenile paretic in a family should be a signal for examination of parents and other children.

In Frühbeck series 16 per cent of the parents had paresis, and an additional 13 per cent had other forms of neurosyphilis (quoted by Klauder and Solomon) Kemp and Poole found neuro-

syphilis eight times as frequent in mothers and three times as frequent in fathers of twenty families with neurosyphilitic children as in twenty normal controls. Jeans and Cooke wisely emphasize that not all mental deterioration in prenatal syphilis is paresis, and much that passes as paresis may be meningovascular syphilis, which is common in syphilitic children.

Juvenile Tabes.—The juvenile tabetic runs a milder course than the acquired type. It is rare indeed to see the pronounced ataxias and the severe subjective symptoms of the adult. The taboparetic type is not uncommon, the proportion of this type to the whole being swelled perhaps, by the undoubted cases of early arrest with minor and unrecognized neurological signs which escape detection of which we have seen several excellent examples. The insignificance of symptoms in the tabetic child makes these signs the more easily overlooked.

Parker who reviewed number of the cases seen at the Mayo Clinic, directed attention to the large immobile irregular pupil in contrast with the myosis of the adult type and the frequency of optic atrophy and urinary incontinence. The latter is marked enough to justify a thought in children who have late enuresis. Both Rosenbeck and Parker found the average age onset to be fifteen years. The *former found* blindness from optic atrophy in 40 per cent of his cases. Parker noted 3 cases with neurological signs, but negative fluids in his series. White and Veeder (1921) found a 12.6 per cent incidence of optic atrophy in 79 congenital neurosyphilitics and Lemaresse and Jeans (1937) an incidence of 22 per cent in 19 cases. The early treatment of congenital syphilis decreases directly the incidence of neurosyphilis and consequently of optic atrophy. Tabetic gastric crises with negative spinal fluid can occur in the child, and offer possibilities of confusion with the cyclic vomiting associated with septic foci. They are as resistant to treatment in the cases e have seen as are the crises of adults. Rosenbeck states that trophic disturbances do not occur but Stokes has seen Charcot spine in a juvenile tabetic.

Cerebral Arteritis.—Hemiplegia of syphilitic origin may develop in syphilitic children An early symptom may be obstinate and intractable headache terminating suddenly in a vascular accident or epileptiform convulsion. Such cases are in our experience more often unearthed in the familial examination and are apt to be seronegative on both blood and spinal fluid when seen in later life, though presenting definite physical stigmas.

Figure 883 (mulberry molars) was an example of such a case. In another instance, the father while under treatment for rapidly progressive syphilitic meningomyelitis, received word that his six-months-old daughter had just had "stroke. The child was serologically negative on both blood and spinal fluid, and the mother likewise negative on the blood, but the vascular accident lacking other apparent cause as considered justification for treatment and observation. Park and Veeder had 9 cases of hemiplegia, 4 with positiv spinal fluids, making this the second in frequency of the neurological conditions they enumerat (excepting mental retardation). In two of their cases gangrene of the leg or foot on the affected side had occurred. Additional cases have been reported by Marquézy Jammet and Chevalier (1930), Saal (1931), Mikulowski (193 Lüdtke (1933)

Epilepsy —In our experience, epilepsy at all approaching the essential type, is negligible in the clinical picture of heredosyphilis. Not a single case appeared among our 200 patients, and only 1 case in Park and Veeder's series of 443 children

Menninger and Menninger (1931) collected 51 cases of epilepsy of the so-called idiopathic type due to congenital syphilis. They concluded that congenital syphilis can produce convulsions directly and indirectly without the presence of gross brain lesions or juvenile paresis and that it *may rarely parade as idiopathic epilepsy* Whitehman (1940) concludes that it is by no means certain that syphilis can produce typical epilepsy since convulsions may occur in individuals with and without syphilis and syphilis can be present with and without convulsions. The treatment of typical epilepsy by antisyphilitic therapy even when syphilis is present has been disappointing

Baboneix (1929) reports that in study of 323 cases of essential epilepsy 54 (17 per cent) had syphilis, but in only one case did treatment result in cure of the epilepsy with some improvement in 3 additional cases. While the older literature (Solomon, Jeans) reports as high as 20 per cent congenital syphilis in epileptics, more recent studies indicate much lower prevalence. Pigott, Weingrow and Fitch (1939) report prevalence of 0.7 per cent congenital syphilis among 1,000 juvenile cases confined to the New Jersey State Village for epileptics. Baballan (1939) reports case treated for several years as idiopathic epilepsy before he subsequently developed interstitial keratitis when the family history of syphilis was first noted. Epileptic seizures, usually idiopathic and *petit mal* in type, may follow serologic involution and favorable clinical progress of juvenile paresis after treatment has been suspended.

Spastic Diplegia and Quadriplegia.—This condition seems to be quite generally accepted as a manifestation of neurosyphilis of the spinal cord in syphilitic children, but it is comparatively rare.

T cases appeared in our series and 4 in that of White and Veeder an incidence of 1 per cent. The onset is apt to be noted at the time the child begins to walk. Jeans and Cooke saw 14 cases. Mingazzini reports group reproducing the picture of familial spastic paralysis. Woodall (1929) found prevalence of 3 per cent syphilis in institutionalized cases of spastic paralyses.

Mental Deficiency—The recent studies of Benda and Tadgell (1942) have tended to confirm the older work of the Solomons which indicated that syphilis is present in about 6 to 7 per cent of the feebleminded population. They further state that from 40 to 50 per cent of the feebleminded individuals with congenital syphilis have their mental deterioration because of this disease.

Menninger (1930) approached this problem from two angles in his review of the literature (1) with respect to the incidence of feeblemindedness among congenitally syphilitic persons and (2) with respect to the incidence of syphilis among mentally defective persons. With respect to the former he found that in nine studies in the literature from 7 per cent of 148 cases to 37.2 per cent of 42 cases (mean 22.3 per cent) of congenital neurosyphilitics are feebleminded. The percentages of syphilis among mental defectives in eight studies ranged from 1.5 per cent to 8.5 per cent with a median of 4.8 and mean of 4.6.

There is definite evidence that much of the low grade mentality among congenital syphilitics is not the direct result of the disease but rather of other hereditary factors. Dayton (1923, 1930) as result of extensive statistical analysis involving some 40,000 syphilitic and nonsyphilitic, mentally defective and normal persons concluded that syphilis is negligible factor as cause of mental deficiency

Myerson (1930) points out that tremendous amount of low grade mentality and feeblemindedness occurs among the parents of the syphilitic feebleminded. While it cannot be denied that syphilis causes alterations of the brain, there is very little in the general appearance and the *reactions of the congenital syphilitic feebleminded to distinguish them from the mass of feebleminded.* Benda (1940) on the other hand, has presented histologic evidence that the pathologic process underlying feeblemindedness in some congenital syphilitics may be the end stages of meningo-encephalitis syphilitica or Nissl-Alzheimer endarteritis, and that occasionally these pathologic processes may be present in typical form at autopsy even with negative blood serologic test and negative spinal fluid study

In the large percentage of morons no signs of neurosyphilis are present, and family studies reveal the presence of hereditary factors in most instances. Congenitally syphilitic imbeciles and idiots, on the other hand, give evidence of neurosyphilis in the majority and there is every indication that, in these cases, the mental deficiency is the result of the destructive process of neurosyphilis. The material of Benda and Tadgell (1942) has shown that in study of the parents of syphilitic idiots, there was little evidence of mental deficiency in the family With morons and low grade imbeciles, however there was definite factor of heredity

It should be noted that according to some reports Mongolian idiots will frequently show biologically false positive spinal fluid-blood serologic test for syphilis and mild zone colloidal gold curve This was reported by Paddle (1933), who mentions also the work of Stephens and of Riddel and Stewart. Mongolism, is, none the less, not to be considered manifestation of congenital syphilis.

Backwardness and Mental Retardation.—A depression of the level of mental activity and energy seems to be quite frequent in heredosyphilitic children, and fortunately responds well to treatment. The importance of mental retardation as an initial symptom of serious neurosyphilis is so considerable that a spinal fluid examination is indicated in all cases in which it is at all pronounced or progressive even though the test may not be routinely performed.

White and Veeder, in 443 cases, found 18.7 per cent of mental retardation including all grades from idiocy upward, the milder grades being much the more common. In our series 11 per cent were below par mentally as expressed by slow progress in school and difficulties in adaptation, some of which is undoubtedly due to the influence of physical defect such as impaired vision, poor hearing, and susceptibility to illness causing absence from school. The studies of Luria, Greenebaum and Brandes (1931) and of Jenkins, Brown and Cisler (1940) previously mentioned show that the general tendency is for the congenital neurosyphilitic to be intellectually inferior.

Conduct Disorder.—As distinguished from mere dulness, on the one hand and active mental disturbance or juvenile paresis, on the other there is in the heredosyphilitic group a distinct type of unruly or "wild" child, difficult to manage and at times distinctly inclined toward outright delinquency. The first outright expression may be at school.

The studies of Jenkins and Cradein (1941) show that the behavior pattern of stealing, lying, truancy, sex delinquency, unconventionalism, etc. found in some juvenile paretics is the result of social and environmental factors rather than of the disease syphilis.

Precocity.—Twelve per cent of our heredosyphilitic children showed a mental development well beyond their years. In many cases in spite of the handicaps of eye trouble and susceptibility to other illness, it was quite sufficient to place them well beyond the average in school. The resemblance to the precocity of rickets and the momentarily suggestive appearance of the rachitic child are sufficiently confusing so that little reliance can be placed upon the symptom in diagnosis. It will be remembered that with any normal group of children a large percentage will be distinctly above average and an equally large number below the mean intelligence of the group. Where the mind has not been affected by the disease, therefore, precocity may normally be present in a small percentage of cases and this should not necessarily preclude the diagnosis of congenital neurosyphilis.

Nervousness.—A heightened nervous irritability is present in too large a proportion of syphilitic children to be merely a coincidence (22 per cent in our series). It may manifest itself in emotional instability, fits of temper, night terrors, the easy development of tics and habit spasms, and definite hysteric manifestations, or simply assume the form of spoiled precocity and wilfulness. The improvement which occurs under treatment is the best confirmation of the connection. The nervous make-up may appear in the children of neurosyphilitic parents without clinical evidence of the disease or with only a suggestive sign or two leaving the physician indefinitely in doubt as to the exact state of affairs and the advisability of treatment. In general we have been more inclined to demand positively confirmatory clinical or laboratory signs than to make the nervous state alone a reason for specific treatment.

Psychoses.—Nonne in particular has voiced the impression that dementia praecox is more frequent in the children of syphilitic parents than in those of

ordinary parentage. Solomon, speaking from the psychiatric standpoint, is unwilling to concede a necessary connection.

Miscellaneous Considerations. Trauma and Influence of Other Diseases. —In these matters prenatal syphilis follows the general rules applicable to the disease as a whole.

A blow on the head may precipitate the early symptoms of paresis as in two of Klauder and Solomon cases, or syphilitic epilepsy as in that of Menasse. The strain of war may bring on breakdown as in the 8 cases reported by Spackman. Bone gummas, especially of the tibia, may come on following trauma. A good example of traumatic excitation of osteo-arthritis is given in Chapter XVI. Wetting, chilling, slips, and strains are often the starting points of hydrarthroses. Deafness likewise comes on after falls. Infections may alter the course of favorably progressing paresis and bring on convulsive seizures even in older children, with permanent impairment. The precipitation of interstitial keratitis by influenza, tonsillitis, and childbirth has been mentioned. Hunt states that scarlet fever measles, and influenza are especially likely to be followed by lighting up of latent heredosyphilis.

Cyclic Vomiting.—The entire question of syphilis as a factor in cyclic vomiting of childhood needs thorough revision in the light of focal infection, acetonemia, etc.

In two cases under Stokes' observation treatment was apparently effective in one, but while the boy had positive blood serologic reaction repeatedly little could be found to support it in the family. A year later he had another attack associated with a typical toxic erythema and diarrhea. The beneficial effect of treatment was possibly that of intestinal antisepsis, and perhaps nonspecific action on streptococcal focus. In the second case the girl, fifteen years of age, had vomited for several days at intervals ranging from month to six weeks. The only evidence of syphilis in the entire family was her repeatedly positive blood serologic reaction. This and the vomiting were alike uninfluenced by treatment, and finally in perplexity the patient was sent to two other serologists for examination, both of whom returned unqualified negatives with several antigens. The mechanism of our repeated and probably biologically false positive result remains obscure. Ingraham (1935) mentions one case in his series which was operated upon for partial pyloric obstruction. Continental writers such as Vaglio report 75 per cent of syphilitic origin in 20 cases. Acuna promptly cured 5 syphilitic infants with mercurial treatment, and then with equal success cured 3 other infants who also had incessant vomiting, but without syphilis, by the same measures. Lozano (1930) in his study of habitual vomiting among nurslings concluded that syphilis is slightly more frequent among infants with hyperemesis than among normal infants, but it cannot be said that syphilis is either the sole cause or the most frequent cause of this condition.

Paroxysmal Hemoglobinuria.—This condition, in which a systemic reaction with hemoglobinuria follows chilling occurs in syphilitic children and adults, though we have only seen it in adults. Moss showed that a hemolysin is liberated in the blood which attacks red blood cells on chilling the body surface, causing *protein shock symptoms of chill, fever and prostration, with* hemoglobinuria.

Matsuo (1912) states that seven of his eleven patients had congenital syphilis, the others acquired syphilis. Hinrichsen (1943) points out the association between congenital syphilis, Raynaud' disease and paroxysmal hemoglobinuria in the older literature. There is some indication that paroxysmal hemoglobinuria is becoming much less common. Thus, in surveys of syphilitic cases Donath and Landsteiner (1905) found the condition in 9 per cent of 65 patients with dementia paralytica, Kumagai and Inoue (1912) in 20 per cent of 35 patients with tertiary syphilis, Ghezzi (1920) in 5 per cent of 85 syphilitic patients and Jones and Jones (1922) in 7 per cent of 43 syphilitic patients. Yet, Dill, Douvres and Isenhour (1930) found one case in survey of 900 syphilitics (no cases in 100 nonsyphilitic controls) and Howard, Mills and Townsend (1936) remark that the disease is seldom encountered. The more recently reported cases have been uniformly improved or arrested by antisyphilitic therapy (cf also Wenfter ad Parks 1936, Dickson

1936) Dill *et al.* remark that the rarity of the disease in modern times as compared with the older literature may result from the more satisfactory treatment of syphilis. For a description of the technic of laboratory diagnosis see any of the more recent articles just mentioned. This condition is not to be confused with paroxysmal nocturnal hemoglobinuria described by Marchiafava, Nazari, Michel and numerous other authors. (See also Stats and Wasserman, 1943.)

Syphilis and Tuberculosis in Childhood.—Vignolo-Lutati in 1914 called attention to the tuberculogummatous syndrome in heredosyphilitic children, especially as it affected the cervical lymph nodes. A fairly typical example of this type is given in Figure 456. Nasso found that heredosyphilis directly predisposes children to tuberculosis, 24 per cent of the syphilitic children presenting evidence of the disease as compared with 14 per cent of 26,500 normal children. Hertinel and Merklen believe tuberculous meningitis to be more frequent in syphilitic children.

In all interpretations of the syphilitic factor in tuberculous children the unreliability of weak positive Wassermann reactions and the nonspecificity of the arsphenamines must be borne in mind. Menninger (1933) mentions the fact that juvenile paretics who become emaciated, untidy and careless present fertile soil for tuberculosis and calls attention to Schmidt Kraepelin's (1900) report of six such cases.

Sclerema and Edema Neonatorum.—This condition occurs occasionally in heredosyphilitic infants, as a hardening and edema of the body fat, with subnormal temperature, coming on this the first few days after birth. The skin is thickened, lardaceous, pale and stiff, the lower extremities being most affected. The cases are usually fatal, and not generally recognized as of syphilitic origin. In two cases seen with the late F. G. Harris, and in one of our own, the recovery under mercurial inunctions was rapid and complete. All three children had heredosyphilis, and the one which appeared on J. H. S.'s service was the child of a woman who because of thorough treatment and prolonged freedom from signs had been permitted to become pregnant.

THE TREATMENT OF FAMILIAL AND PRENATAL SYPHILIS

General Principles.—The value of treating the syphilitic pregnant woman to prevent congenital syphilis, recognized since the middle of the seventeenth century, has never been more conclusively demonstrated than in the last twenty five years. Studies conducted in this country by Williams (1920, 1922), McCord (1930, 1935), Jeans and Cooke (1930), McKelvey and Turner (1934), Cole *et al.* (1934, 1936), Halloran (1939), Dill, Stander and Isenhour (1940), Benensohn (1942), by Boas and Gammeltoft in Denmark, by Nabarro and Findlay in England, by Hoffmann in Germany and by many other authors too numerous to mention, have shown that, from the therapeutic standpoint, syphilis transmitted from parent to offspring is practically a preventable disease (see Fig. 846). Its prevention rests upon the diagnosis and treatment of syphilis complicating pregnancy. Treatment to be effective must be with a strong spirillicide such as neoarsphenamine or an arsenoxide (mapharsen). For an outline of general principles see Figure 847 and for a suggested treatment course to use in the uncomplicated case see Figure 848.

Treating the syphilitic mother to preserve her child is reputed to have been first advised and carried out in France in about the middle of the seventeenth century. At this time Garnier, because pregnant syphilitic women were refused admission to the lying-in hospitals in Paris, proposed to house them in a separate hospital, feeling that, contrary to the then current opinion, treatment with mercury rubs would cure them and their children. The value of the treatment was recognized by Mauriceau (1695), became generally used in the eighteenth and nineteenth centuries as recorded by Astruc (1754), Mahon and Lamauvem (1804), Bertin (1810), and is enthusiastically reported upon by the elder Fournier (1880, 1891, 1906). Mercury and even bismuth, while producing some beneficial effect on the syphilitic fetus, have now been almost completely replaced by the trivalent arsenical drugs, which when properly administered prevent the transmission of the infection from parent to offspring in virtually every case.

Results of Treatment.—An examination of Figure 846 shows that the untreated syphilitic woman will give birth to a normal nonsyphilitic child in

Fig 846.

RESULTS OBTAINED BY SELECTED AUTHORS SHOWING PROTECTION OF THE CHILD BY TREATMENT OF THE PREGNANT SYPHILITIC MOTHER

Author	Year	Cases.	Treatment given mother	Percentage normal children.
Benesohn.	1942	789	Neoarsphenamine and bismuth.	93 5
		140	None.	60 0
Mowley Callaw y and Sharpe.	1940	21	Neoarsphenamine before and during pregnancy	100 0
		66	Neoarsphenamine during pregnancy only	90 9
		17	Neoarsphenamine before pregnancy only	88 2
		46	None.	35 6
Halloran.	1939	84	More than 10 weekly neoarsphenamine.	92 9
		140	6 to 10 wks. neoarsphenamine.	79 9
		264	less than 6 wks. neoarsphenamine.	72 4
		16	None.	18 8
Cole *et al.* (CCG)	1934	131	Trivalent arsenical and heavy metal begun before fifth month.	78 4
		30	Same as preceding but more than 10 weeks trivalent arsenical.	90 7
		132	Same as preceding but begun after fifth month.	60 6
McKelvey and Turner	1934	18	Arsphenamine during pregnancy 4 to 6 Gm.	100 0
		33	Same 3 to 4 Gm.	87 5
		65	Same 2 to 3 Gm.	83 8
		127	Same 1 to 2 Gm.	79 7
		113	Same less than 1 Gm.	73 0
		288	None.	35 4
McCord.	1930	95	More than 6 weekly injections neoarsphenamine plus mercury inunctions.	91
		94	Less than 6 weekly injections as above.	57
		137	None.	20
Gammeltoft.	1923	7	Arsphenamine before and during pregnancy	85 8
		36	Arsphenamine during pregnancy	80 7
		26	Arsphenamine before mercury during pregnancy	73 1
		111	Mercury during pregnancy	28 0
		15	Arsphenamine before, no treatment during pregnancy	20 0
		301	None.	3.5
Williams.	1920	163	4 to 6 injections arsphenamine and mercury	92 6
		103	2 to 3 injections arsphenamine.	63 0
		137	None.	47 0

PREVENT OR CURE CONGENITAL SYPHILIS BEFORE BIRTH

from 3.5 per cent of cases (Gammeltoft) to 60 per cent of cases (Benensohn) depending upon the type of material surveyed the criteria used in the diagnosis of congenital syphilis in the offspring and the duration of observation of the child after birth The improvement of statistics in recent years is probably accounted for by the increasing numbers of syphilitic women receiving treatment prior to conception All of the studies cited with the exception of those of Gammeltoft show better than 90 per cent normal children when the trivalent arsenicals are used in sufficient amounts, and some authors have obtained 100 per cent success in small series. The best results have been obtained when treatment is given both before and during the pregnancy but, since the fetus often is not infected until close to the time of delivery it is never too late to begin treatment. A satisfactory outcome can usually be expected if it is possible to start arsenical therapy by the twentieth week, and active treatment is continued until the time of delivery

Fig 847

PRINCIPLES OF TREATMENT SYPHILITIC PREGNANT WOMAN

1 Begin treatment of the syphilitic pregnant woman as soon as the diagnosis is established. A delay of even few days may mean a syphilitic child.

2. T be effective the drug must be spirillicidal. Intravenous neoarsphenamine and mapharsen are the drugs of choice. The heavy metals (mercury or bismuth) have relatively much less protective effect for the fetus.

3. Protection of the child is the primary aim of treatment during pregnancy Maternal syphilis must be cured after delivery

4. Treat largely with arsenical during the late months, largely with heavy metal during the early months. The fetus is seldom infected prior t the 20th week.

5. Reduce the initial dose of arsenical if treatment is begun after the fifth month The first injection may be 0.2 Gm. of neoarsphenamine (or its equivalent) the average dosage for the first three eeks should not exceed 0.3 Gm. neoarsphenamine per eek. Total weekly dosage need never exceed 0.45 Gm. for the 150-pound adult.

6. Continuous alternating is preferred to concurrent treatment.

7 After the fifth lunar month the length of the bismuth course should not exceed 4 to 6 weeks, lest infection of the fetus result from lack of spirillicide

8. T eatment should be continuous. No rest interval.

9. Arsenical should be given for 4 to 6 weeks immediately before delivery

10. If reactions occur stop treatment and reevaluate. Do not injure the mother from the overzealous applications of treatment for the unborn child. The average pregnant oman tolerates normal antisyphilitic therapy ell, but should reactions occur they may be serious nd should not be considered lightly

A number of investigators have remarked upon the small amount of arsenical therapy necessary t protect the child in the verage case Cole *et al.* (CCG) (1931) have pointed out that ... eeks of arsenical therapy begun before the m lpoint of the pregnancy is sufficient to produce 91 per ce t satisfactory results. Figure 819 illustrates one of the 9 per cent who are not protected by thi amount of therapy Findlay (1942) remarks that, in his experience healthy child has always been born hen treatment as begun before the beginning of the eighth month of pregnancy While this latter viewpoint is certainly an underestimat of the amount of treatment necessary t protect the child, yet there is every evidence that it is unnecessary to overburden the pregnant woman by using large dosage of the drug or to give injections ith more than the usual frequency in order t obtain a healthy child.

It should be noted that proper evaluation of therapy both in the prevention of congenital syphilis by treating the pregna t oman and in the treatment of the syphilitic child, has been confused by failure on the part of most authors t use normal control series in interpreting the results of pregnancy and by variations in the criteria employed for the diagnosis of the infection in the child and occasionally even in the mother Dill, Stander and Isenhour (1940) are virtually

the only recent authors who have used control series of normal pregnant women in the evaluation of their results.

Technic of Treatment of the Pregnant Woman.—For adequate protection of the fetus, the dosage of arsenical need not exceed 0.45 Gm. of neoarsphenamine or its equivalent (see Fig. 848). Minnich (1941) has shown that mapharsen in dosage up to 0.05 Gm. once weekly is as effective as neoarsphenamine

Fig. 848.

TREATMENT OF PREGNANCY WITH LATENT SYPHILIS OF UNKNOWN DURATION (UNCOMPLICATED)

(Modified from Stokes and Ingraham, Medical Clinics of North America, November 1930.)

Week of pregnancy	Lunar month. 1 to 4	5	6	7	8	9
1 to 16	varying amount NS & Bi					
17	Bi, 0.2 Gm.	NS, 0.2 Gm.				
18	Bi	NS, 0.3				
19	Bi	NS, 0.4				
20	Bi	NS, 0.45				
21	NS, 0.45 Gm.	NS, 0.45	NS, 0.2 Gm.			
22	NS	NS, 0.45	NS, 0.3			
23	NS	NS, 0.45	NS, 0.45			
24	NS	NS, 0.45	NS			
25	NS	Bi, 0.2 Gm.	NS	NS, 0.2 Gm.		
26	NS	Bi	NS	NS, 0.3		
27	NS	Bi	NS	NS, 0.4		
28	NS	Bi	NS	NS, 0.45		
29	Bi, 0.2 Gm.	Bi	Bi, 0.2 Gm.	NS	NS, 0.2 Gm.	
30	Bi	Bi	Bi	NS	NS, 0.3	
31	Bi	NS, 0.45 Gm.	Bi	NS	NS, 0.45	
32	Bi	NS	Bi	NS	NS	
33	NS, 0.45 Gm.	NS	NS, 0.45	Bi, 0.2 Gm.	NS	NS, 0.2 Gm.
34	NS	NS	NS	Bi	NS	NS, 0.3
35	NS	NS	NS	Bi	NS	NS, 0.45
36	NS	NS	NS	Bi	NS	NS
37	NS	NS	NS	NS, 0.45 Gm.	NS	NS
38	NS	NS	NS	NS	NS	NS
39	NS	NS	NS	NS	NS	NS
40	NS	NS	NS	NS	NS	NS

NS = neoarsphenamine
Bi = bismuth subsalicylate
Dosage is calculated for 150-pound individual.

There is some evidence to indicate that mapharsen or other arsenoxide given in one tenth the above dosage every five instead of every seven days is also effective.

and possibly better tolerated. Castallo, Coppolino and Rakoff (1950) had, however, obtained less satisfactory results with this drug. It is probable that mapharsen should be given every five days to the pregnant woman to obtain maximum beneficial effect for the fetus. *Intramuscular arsenical preparations* (*e.g.* bismarsen) *are not effective* (Benensohn, 1942) and should not be used in the treatment of the pregnant woman. Some authors have reported the successful use of intensive arsenical therapy five-day drip in the pregnant woman

with early syphilis (Rattner 1943 Sadusk and Shaffer 1942) but considering the excellent results normally obtained with more conservative treatment, as well as the increased risk to the mother when the more intensive methods are employed we do not consider that they are indicated.

Some discussion and difference of opinion have centered about the question of the use of an arsenical and bismuth preparation concurrently particularly if treatment is not commenced until the latter months of the pregnancy Although this type of treatment has been used successfully by some authors and has been recommended by McKelvey and Turner (1934) Hoffmann (1938) and Benensohn (1942) the fact that the heavy metals have relatively little protective effect for the child makes this seem unnecessary especially when the use of heavy metal concurrently increases the risk of complication for the mother

Cole et al. (CCG 1934) found that mild reactions from arsenicals were more frequent when combined therapy was employed. The increased frequency these authors state, was especially noted in transient kidney irritability it being seven times as common with combined as the alternating therapy McKelvey and Turner (1934) found that when the mother received some heavy metal during her pregnancy the child was normal in 93 4 per cent of cases as compared with 78.0 when only arsenical was used, but did not control the duration of treatment in their series, which could be factor of considerable importance They state that those patients who received heavy metal were in general those who had reported early in pregnancy

Control of Treatment Reactions.—Antisyphilitic treatment during pregnancy should be accompanied by more than ordinarily careful obstetrical prepartal care. Ingraham Ingraham Beerman, Spence, Arnold and Hasler (1941) have pointed out the desirability of conducting separate clinics for the pregnant syphilitic woman where this is practical in the larger urban hospitals. These patients should have frequent, preferably weekly urine analyses and should have physical inspection by a physician and questioning concerning symptomatology which might indicate circulatory or kidney strain, incipient toxemia, or intercurrent infection producing fever before each treatment. Blood pressure should likewise be taken at each visit. Blood and platelet counts should be available in reactive patients.

While it is difficult to set arbitrary rules, and individual case problems should be decided upon only after competent obstetrical and syphilologic consultation in general treatment should be withheld until competent appraisal of the situation is possible (1) if the woman s blood pressure, which has been normal, increases to exceed 150/100 (2) if vaginal bleeding, hematuria, purpura or other hemorrhagic phenomena (hematopoietic injury) occur (3) if there is jaundice or other evidence of liver damage (4) if severe headache visual disturbances or other evidence of central nervous system involvement become manifest (hemorrhagic encephalopathy) or (5) if the woman reports with a temperature of more than 100° F

With normal precautions, standard treatment as outlined in Figure 315 may be given without hesitancy to the pregnant woman. When complications of syphilis occur (as e g cardiovascular involvement) treatment of this stage of syphilis, as described in the preceding chapters, takes precedence over the protective treatment for the child When special types of treatment are indicated (as fever therapy for central nervous system involvement) these had best be postponed until after the termination of the pregnancy continuing normal protective treatment for the child until delivery occurs. In general,

spinal fluid studies also should be postponed until after delivery Tryparsamide should be withheld since its effect on the optic tract of the fetus is unknown.

A considerable literature has accumulated in the last few years on the subject of treatment reactions in syphilitic pregnant women, and a number of deaths, usually from acute hemorrhagic encephalitis have been reported (*cf* Ingraham, 1939, Moore, 1939, Kennedy and Healington, 1943) As a rule, these complications are treated as in the nonpregnant adult as described in previous chapters.

A word of caution should be interjected concerning the diagnosis of acute hemorrhagic encephalopathy in the parturient woman because, not infrequently in the past, these cases have been considered and treated as toxemias of pregnancy until the terminal and hopeless stage of coma and convulsions was reached or until death had occurred and the correct diagnosis was revealed by autopsy Toxemias of pregnancy are no more frequent in the treated syphilitic than in the nonsyphilitic woman (Peckham, 1941). Eighty-one per cent of the cases of acute hemorrhagic encephalopathy collected by Ingraham (1939) were precipitated by three or less arsenical injections. Everyone who treats syphilitic pregnant women should be familiar with the premonitory signs of acute hemorrhagic encephalopathy in order that recognition and treatment may be immediate should it occur Pregnant women are also said to present an increased susceptibility to severe liver damage as a result of antisyphilitic therapy but we have never personally seen such a case.

Collateral Aspects of the Treatment of Syphilis and Pregnancy—It has been advised by some writers that pregnant women be treated on the mere suspicion of syphilis that the expectant mother be treated if her husband has syphilis that active syphilis complicating pregnancy may be an indication for inducing abortion that a woman once syphilitic should be treated through each subsequent pregnancy that the syphilitic mother should not nurse her infant after delivery We would like to say a few words about each of these points.

With present day diagnostic standards, there is no reason to treat a pregnant woman for syphilis unless she is definitely known to have or to have had the disease. Inadequately treated seronegative syphilitic women, who may still give birth to diseased infants unless proper therapy is instituted, may form something of a diagnostic problem and point out the need for careful history taking and careful physical examination supplemented by complete family investigation when indicated.

The Follow-up of the Syphilitic Family—The detection of a family focus calls at once for the medical examination of every member Pressure to secure this should be first brought by the physician. While the problem may present difficulties in private practice, it should, nonetheless, be systematically attempted.

Ingraham (1938) has pointed out that even assuming an almost perfect medicotherapeutic approach to the problem of congenital syphilis control, three problems of social and public health administration still block full accomplishment in this field (1) the pregnant woman with syphilis often does not report for prenatal supervision until late in her pregnancy when infection of the fetus may already have taken place (2) a delay of some weeks between the initial antepartum visit and the commencement of antisyphilitic treatment is a common occurrence. This interval should never be more than a few days; (3) congenitally syphilitic offspring are frequently not treated in early infancy Treatment could always be started in the first few months of life if proper diagnostic procedures are carried out.

The premarital laws and routine blood test procedures previously discussed have many pitfalls for the unwary Bedard (1940), in citing three instances in which seronegative syphilitic mothers in whom the disease remained undetected and untreated prior to delivery gave birth in each case to a syphilitic child, asks with some justification: "Why not Wassermannize the expectant father?"

Since the mother frequently escapes infection even though the father may be syphilitic, and since infection of the fetus is via the placenta and not from

the seminal fluid there seems to be no reason to treat the pregnant woman merely because her husband is diseased. Occasional cases are seen in which the husband has acquired or the wife has been exposed to infectious syphilis during her pregnancy We have found it satisfactory to withhold treatment in such cases until infection if present, is proven in the expectant mother performing the same type of routine medical and serologic follow-up as with any other patient who is known to have been exposed to infectious syphilis.

Syphilis in itself is no reason for interference with the pregnancy of a syphilitic woman. From the standpoint of the mother carrying the pregnancy to term may be conceived as a reinforcement of her defense mechanism, of which she should take full advantage. Moreover the treatment of the mother during pregnancy protects the child in such a large proportion of cases that it seems unjustifiable to take its life merely on the small chance that it may turn out to have syphilis. Even if the child does show evidence of syphilis after birth, the outlook for health following effective treatment is good enough to justify its being given the chance for life

Conservative opinion suggests that with our present day knowledge, a syphilitic woman should be treated through every pregnancy, regardless of the duration of her infection, her serologic status, or the amount or type of antecedent therapy Treatment in any instance should be given only if well tolerated as described above

The reasons for this conclusion are as follows (1) Instances are known in which syphilitic women have given birth to diseased children as long as twenty years after they have acquired the disease. While a syphilitic woman with disease of long standing is less likely to give birth to a diseased child than one who has recently acquired her infection this is a factor of only relative importance and cannot be used as a basis for decision with respect to therapy (2) There is no diagnostic test which will insure that a pregnant woman (or any other individual for that matter) is completely free from the disease after she has been known to have acquired it. The relationship between mother and fetus is more intimate and for a longer period of time (nine months) than we meet under any other circumstance Even a transient spirochetemia may result in infection of the placenta and subsequently of the unborn infant. (3) As yet, there have been reported no extensive series of mothers clinically cured of the disease who have gone through subsequent pregnancies untreated to make a proper evaluation of complete treatment possible with respect to risk for the fetus in subsequent pregnancies. It is to be hoped that a more complete evaluation of some of the more intensive systems of treatment prior to conception may make some modification of this position possible.

Birnbaum (1927) has reported series of twenty-one women in whom syphilis was cured by appropriate treatment They later had thirty-four pregnancies, untreated all the while, which resulted in apparently normal children who remained free from syphilis, some for as long as six years at the time of publication.

Cole et al (CCG 1931) found that in fifty-two women ho became pregnant after being considered cured, their data did not furnish evidence of syphilitic child having resulted although births occurred up to fifteen years after the infection. McKelvey nd Turner (1931) reported in their series fifty-nine pregnant omen who had received minimum of 1 Gm. of arsphenamine prior to pregnancy but no treatment during the pregnancy none of whom gave birth to children with evidence of syphilis Rattner (1915) states that five patients of his series who had been treated by the five-day method, subsequently became pregnant and though no additional treatment was given, each has given birth to normal infant. Findlay's (1914) experience with adequately treated seronegative syphilitic mothers is such as to make him feel that "it is difficult to understand how

most writers recommend that further courses of salvarsan therapy should be carried out through any succeeding pregnancy

An essentially similar question is that as to whether a congenitally syphilitic woman who reaches adult life should be treated during her pregnancy In general we feel that the answer to this is *no* provided previous treatment adequate to control the activity of the congenital infection (not necessarily *to reverse the blood serologic test to negative which cannot be accomplished* in every instance) has been carried out. When confronted with a congenitally syphilitic woman who is pregnant we carefully review the previous medical handling. If this has been sufficient to prevent the development of interstitial keratitis (sixteen weeks of arsenical and thirty-one weeks of heavy metal after Cole *et al.*, 1937) and if there is no active central nervous system involvement we advise withholding therapy during pregnancy and observing the child postnatally If previous treatment has not been adequate, we advise treatment throughout the pregnancy more for the sake of the mother than the child. Third generation syphilis is excessively rare as discussed in a previous section

As a rule, if she has no infectious lesions a syphilitic mother may nurse her newborn child. We have never seen an exception to this statement, although Uhlenhuth and Mulzer (1913) have demonstrated *Spirochaeta pallida* in the mother s milk. It is necessary of course, that the mother with active syphilis be receiving treatment for her disease. Moore (1941) cites instances in which each of two infants developed a chancre of the lip through neglect of this precaution. Instances in which either mother or child has acquired the disease independently after birth may of course result in infection of the uninfected individual through nursing, and artificial feeding should always be resorted to in such cases.

The question occasionally arises as to whether antisyphilitic therapy given the mother prenatally may ever be harmful to the fetus. In general, we may state that the *amounts of arsenical and heavy metal which traverse the placental barrier with normal treatment are not injurious to the unborn child.* There has been considerable discussion in the older literature concerning placental shock (miscarriage resulting from arsenical therapy) When the fetus is already dead or grossly diseased introduction of arsenical therapy may result in sufficient reaction in the placenta to cause premature labor but this is seldom, if ever the case when the fetus is not grossly infected.

Type Cases *Management of Syphilis in Pregnancy* —*It is possible from* our general knowledge of syphilis to classify to some extent the treatment problems presented by the pregnant syphilitic woman, and to govern her treatment accordingly It must be remembered that in general the newly infected mother will not appear for treatment until florid eruptive manifestations have developed whether early or late in pregnancy

1. **Infection Coincident with Conception or Occurring Within the First Few Weeks of Pregnancy Chancre Present Blood Serological Reactions Negative.**—Such a situation, the most dangerous of all for the child, justifies also an attempt at radical cure of the mother for her own sake and that of her future pregnancies. The risk of inducing abortion by the use of a neoarsphenamine-bismuth system with five- to seven-day intervals at the outset is not great in our experience, though Buschke complained of abortions from the arsenical and by the time the pregnancy is far enough advanced to demand all her physical resources, two short (8-injection) courses each of arsenical and

heavy metal can have been given. Suppression of the infection without cure or with *postpartum* relapse must be guarded against by observation of mother and child and by the continuance of the mother's treatment through the full regimen for an early acquired infection and if possible up to the very end of the pregnancy. Should she in subsequent pregnancies be advised to take prophylactic treatment, even though supposedly radically cured? In our present knowledge of the problem the answer is yes.

2 **Woman Appears with Florid Secondary Syphilis Within the First Six Months of Pregnancy.**—In all fully developed infections in early pregnancy the mother whose condition is normal can sustain a moderate course of treat-

Fig. 849.—An illustration of the occasional failure of prenatal treatment of the mother to protect her child from uterine infection, and of the comparative robustness of a nonrelapsing syphilitic child. The mother received 10 injections of neoarsphenamine and 6 of bismuth between the fourth and eight months of pregnancy having entered with secondary syphilis. The child's cord Wassermann was positive, all subsequent tests negative until at seven months of age the eruption shown above appeared when the serological tests became positive.

ment for syphilis. No attempt should be made to shorten intervals and raise dosage beyond half the adult maximum. The treatment course should be so planned that the mother receives neoarsphenamine during the last two months of her pregnancy.

3 **Primary Lesion and Negative Blood Serologic Test in the Last Three Months of Pregnancy.**—In a case of this sort strenuous measures for radical cure are not justifiable for they may endanger both mother and child. Two-thirds the maximum adult dosage of neoarsphenamine intravenously once in five to seven days with a few injections of bismuth or small mercurial inunctions will protect both mother and child so far as our present knowledge goes. There need be no rest period allowed up to within a week of term.

4 **Florid Secondary Lesions and Positive Blood Serologic Test Developing Within the Last Three Months of Pregnancy**—Neoarsphenamine of known therapeutic effectiveness should be the mainstay and the later the pregnancy the less need is there for the intensive use of heavy metal. Immediately *postpartum* in these cases and the foregoing group, bismuth and arsphenamine should be pressed to forestall neurorecurrence or infectious relapse. Inasmuch as the child will have an outlook for complete escape, the closest attention should be paid to recurrence in the mother by both serological control and clinical examination, and the child should not be put to the breast unless the mother continues arsphenamine treatment.

5 **First Pregnancy in a Mother With Latent Syphilis of One to Five Years' Duration, Blood Serologic Test Positive.**—In this type of case the 8 to 10 injection neoarsphenamine course with weekly intervals between injections may be begun as soon as the patient comes under observation. Two arsphenamine courses alternating with bismuth timed so as to bring the patient to term while still receiving arsenical, and with the mercury or bismuth not later than the eighth lunar-month, may be arranged if time and condition permit.

6. **Multipara (More than Three Previous Pregnancies Carried Beyond the Seventh Month), Blood Serologic Test Positive.**—The protective effect of previous pregnancies if they occurred after infection may be anticipated and a single course of 8 to 10 injections neoarsphenamine in the latter half of the pregnancy preceded by bismuth and carried to term should protect the child. There is, however some doubt as to whether the arsenical should not be more prolonged if used at all.

7 **Woman Known to Have Had Syphilis, but Apparently Cured. 'Treatment for Life Insurance.''**—This is, of course, the type of case which lies just beyond the border of knowledge at the present time. We advise a 10-injection course of bismuth followed by an 8-injection course of neoarsphenamine "stretched to cover the last ten weeks to term and followed by bismuth intramuscularly for three months *postpartum*.

Postpartum Observation.—Adequate *postpartum* observation of both mother and child is a paramount obligation. None of the results as yet published can in point of time alone, answer finally the question as to whether the seemingly well child is actually well. The critical years, seven and fourteen, second dentition and puberty must be safely passed in a considerable group of cases before treatment of the mother can be evaluated for the child Under the conditions of public clinics a year or two of observation is all that most observers feel can be expected for the rank and file, but every effort should be made to extend this by those who have opportunity Nothing more than encouragement and evidence of symptomatic rather than curative effect can be drawn from the usual maternity service reports which embrace the condition of the child ten days to two months after birth.

Indications for Treatment of Congenital Syphilis in the Newborn Infant.—Recent developments in the diagnosis of infantile congenital syphilis make a brief summary of the diagnostic criteria desirable. In general, treatment should not be given unless a diagnosis of the disease is established in the infant.

Black (1930) has given an interesting summary of the pathognomonic criteria in the diagnosis of congenital syphilis. Ingraham (1935) has summarized from the literature the pros and cons for treating the apparently healthy offspring of syphilitic parentage without establishing definite diagnosis of syphilis in the infant. One of the strongest proponents of treating every in-

fant of syphilitic parentage at birth irrespective of antepartum handling is Hoffmann (1936). He feels that in resorting to such practice we are merely continuing therapy commenced via the placenta before birth. Perhaps the strongest argument against such procedure, of the several collected by Ingraham, is the fact that, as a result of treatment of the mother before birth, congenital syphilis is becoming so uncommon, that if treated all offspring of syphilitic parentage on the theory that they might be infected we would be treating largely normal children. Ingraham and Kahler (1934) have especially cautioned against the practice of treating infants of syphilitic mothers for a few weeks after birth, and then dismissing them, with or without periods of observation, if they remain symptom free. Such a procedure would succeed largely in curing those infants who did not have the disease and would give false sense of security to those cases be are harboring the micro-organism.

Many of the writings of a decade or more ago which attempt to evaluate the success of treatment of the pregnant woman or the infant with congenital syphilis have been rendered of little value by failure to understand the diagnostic criteria about to be summarized. We again emphasize that the adequate detection of congenital syphilis in infancy depends upon a knowledge of the existence of maternal syphilis and that the study of the mother must precede the study of the infant. The offspring of a syphilitic mother may be considered to be infected and eligible for treatment when

1. *Spirochaeta pallida is demonstrated* in skin or mucous membrane lesions or in scrapings from the umbilical vein.

2. *The blood serologic test for syphilis* is strongly positive on repetition *after the third month of life*. Prior to the third month, in the absence of clinical symptoms it is difficult to establish a definite diagnosis without a knowledge of the mother's and infant's serologic test at birth and without the use of *quantitative titered tests*. If such information is available then the following additional criteria for diagnosis are applicable.

(*a*) the titer of the blood serologic test of the infant is significantly greater than that of the mother (or positive when the mother's test is negative).

(*b*) the titer of the infant's blood serologic test rapidly increases after birth (or a test negative at birth subsequently becomes repeatedly positive).

3. *A properly interpreted roentgenogram* in a seropositive infant during the first eight weeks of life shows an unquestionable (preferably advancing) osteochondritis with or without periostitis.

Management of the Syphilitic Infant.—In general, a considerable pessimism has marked the literature on the treatment of syphilis in infancy and childhood especially in England and this country. This has arisen in large part from the fact that the disease so frequently developed symptomatically before it was recognized and treatment instituted. With the better management of the syphilitic pregnant woman and the wider application of the serologic test and roentgenogram in early infancy, the clinical cure of early congenital syphilis at least is becoming easier so that crippling and death from congenital syphilis at this age are the exception rather than the rule. The principles in the treatment of the syphilitic infant are summarized in Figure 850.

Persistence in therapy is necessary, at the same time controlling initial dosage carefully to correspond with the severity of the infection, in order to avoid damage from therapeutic shock or paradox. It is hard to escape the feeling that, in the past, too many clinicians have been too conservative, timid and not sufficiently persistent in their treatment of the syphilitic child. Early prenatal syphilis is virulent syphilis. The issue at stake is the child's life, and it seems better to adopt adult intensity in treatment even at some

risk than to give single courses or short (half) courses separated by long intervals of rest. The response to neoarsphenamine is known to be good and bismuth can be given, or mercury by inunction. Full weekly dosages of drugs commonly employed for the treatment of infantile congenital syphilis are given in Figure 851. The length and character of the treatment courses employed in the management of infantile congenital syphilis, or asymptomatic late congenital syphilis are largely the result of inference, by utilizing methods which have been found applicable in the management of adult syphilis. Treatment is ordinarily given in alternating courses of arsenical and heavy metal of six to ten injections each over a period of about one year. Before

Fig. 850.

PRINCIPLES IN THE TREATMENT OF INFANTILE CONGENITAL SYPHILIS

1. Do not begin treatment until the presence of the disease in the infant is established beyond question.

2. With definite diagnosis no infant is too small or too young to treat, with appropriate dosage of the drug.

3. With premature or malnourished infants every attention should be given to improving the physical condition by general medical care, but antisyphilitic treatment should not be withheld until the nutritional state improves.

4. Injection therapy is preferable to mouth medication or to mercury rubs, because of the greater ease in controlling dosage. A soluble heavy metal is preferable to an oil-suspended preparation for the same reason.

5. Because of the severity of the infection as it often occurs in the small infant, therapeutic shock and therapeutic paradox are to be feared, and may result in severe injury or even death of the infant if they are permitted to occur by injudicious choice of drug or too large dosage.

6. For this reason it is usually better to begin treatment with heavy metal rather than an arsenical and it is preferable to use from one-fourth to one-half the dosage calculated for the weight of the infant for the first two weeks, increasing to full dosage after the first month.

7. Dosage should be accurately measured for small infants in a tuberculin syringe with proper dilution of the drug.

8. Treatment should be continuous without rest interval for about one year if response is normal.

With newborn infants, the individual dosage of bismuth metal may be so small that with the normal concentrations of the standard preparations, accurate measurement may not be possible without dilution. With water soluble preparations this is easily accomplished, but with oil suspended preparations more difficulty is encountered. Active hospital services, where infantile congenital syphilis is a *frequent occurrence*, will find it profitable to have prepared in advance an oil suspended bismuth subsalicylate containing 20 mg. of bismuth metal per cubic centimeter by diluting the standard preparation with sterile olive oil or peanut oil.

the treatment is terminated a spinal fluid study should be performed. If both blood and spinal fluid examinations are normal, a year's treatment is considered to be sufficient. If the blood remains positive an additional six to twelve months of treatment are given, followed by a period of observation, preferably covering the next several years, but no more treatment is necessary unless symptoms of progression develop. Central nervous system involvement or ocular complications require special handling for which see subsequent sections. This is the type of therapy which we have used with good results both at the University and the Philadelphia General Hospitals. It is similar to that employed by Smith (1935), Cole (1937, 1941), Robinson (1937), Yampolsky (1938) and Howard (1939).

Choice of Drug—The choice of an arsphenamine in the treatment of prenatal syphilis will often be a matter of circumstance rather than pure therapeutic indications. **Neoarsphenamine** intravenously is readily available to the reasonably expert and, on the whole is satisfactory. Nothing compares in rapidity with the transformation brought about by "606" and "914." Arsphenamine is virtually never used at the present time in the treatment of infantile congenital syphilis because of the difficulty in its preparation and only rarely in late prenatal syphilis. Morgan (1938), Howles (1939) and Astrachan and Cornell (1943) have all reported upon the successful use of mapharsen in the treatment of congenital syphilis. Levin, Hoffman, Korasky, Richter and Gumbiner (1942) have used five-day intravenous drip with mapharsen in congenital syphilis, but favorable results were obtained in only 12 (37.5 per cent) of 32 patients. Dosages employed ranged from 1.6 mg. to 3.0 mg. per pound of body weight per day. Givan and Villa (1939) reported

Fig. 831

FULL WEEKLY DOSAGE OF DRUGS COMMONLY EMPLOYED IN TREATMENT OF INFANTILE CONGENITAL SYPHILIS BY INJECTION

(Initial dosage in active infections should be from one fourth to one half the amounts given below.)

Drug	Dosage (mg. per pound body weight)
Arsphenamine	3-4
Neoarsphenamine	5-8
Trisodarsen (trisodium arsphenamine sulfonate)	5
Mapharsen (meta-amino-parahydroxyphenylarsine oxide)	0.4-0.5*
Sulpharsphenamine	5-10
Bismarsen (bismuth arsphenamine sulfonate)	6
Bismuth (in terms of bismuth metal)	1-2†

* Experience in the use of mapharsen in the treatment of congenital syphilis is limited. There is feeling on the part of some that this dosage should be given at five-day rather than weekly intervals.

† Bismuth preparations vary greatly in content of metallic bismuth. If water-soluble preparation is employed one half this dosage should be given twice weekly.

the use of trisodium arsphenamine sulfonate (Trisodarsen) in the treatment of congenital syphilis with therapeutic results similar to those obtained with other trivalent arsenicals. Sulpharsphenamine, in a dosage of 20 mg. per kilo, has established itself with a number of observers as an effective drug, and the strong objections to its use in adults, because of the complications it produces, do not seem to be so applicable in the infant, who tolerates it better. Bismuth arsphenamine sulphonate has appealed to us as a moderately effective but not particularly impressive agent for the treatment of active tardive prenatal syphilis. It reverses approximately half the apparently fixed positive serological cases, but in interstitial keratitis is too slow and is comparatively ineffective in prenatal neurosyphilis. Beerman, Shaffer and Livingood (1942) conclude that bismarsen seems to be of value for the average patient with congenital syphilis. When used with infants, if response is normal, it may be continued with dosage recommended in Figure 831 for approximately

forty weeks without rest interval, terminating treatment with twelve weeks of bismuth subsalicylate.

The use of *acetarsone* in the treatment of syphilis in childhood is discussed in Chapter VII but is not recommended.

Bismuth in prenatal syphilis in infants is used as an adjunct to the arsenical much as in the treatment of adult syphilis. While it has largely supplanted mercury in all stages of the disease it is rarely used alone with satisfactory results. Wright has used bismuth alone successfully in the treatment of late congenital syphilis in certain stages.

Technic of Treating the Infant.—By the skilled technician, neoarsphenamine, and mapharsen, will be given intravenously in even the small infant by the technic described on p. 317 The jugular veins, scalp veins, and antecubital veins are all suited to this purpose. The frontal sinus should never be used. The less skilled will give the arsenicals intramuscularly or under the fascia in the parietal region of the scalp (Cole 1937) Bismarsen and sulph arsphenamine should be given only intramuscularly but it should be pointed out that the dosage for the infant under one year of age is so small that any of the arsenical preparations may be given intramuscularly Yampolsky (1938) in particular has remarked upon the use of neoarsphenamine intramuscularly in infants and Astrachan and Cornell (1943) upon the use of intramuscular mapharsen. Our experience is in accord with that of Robinson (1937) to the effect that concentrated solutions are better tolerated by intramuscular technic than are dilute ones. For intramuscular use the drug for the small infant need seldom be dissolved in more than 0.5 to 1 0 cc. of solvent. It is important to empty the needle by an air bubble with those small doses.

Reactions from Antisyphilitic Therapy in Infants.*—Aside from therapeutic* shock and therapeutic paradox which may be more serious problems with infantile than with adult syphilis, treatment reactions and their management follow the same general pattern as described in previous chapters. We have personally seen two instances of acute yellow atrophy of the liver, apparently from sulpharsphenamine resulting in the death of the infants treated at the age of five months and seven months respectively

Wolman (1940) has reported two cases of acute necrosis of the liver with death at the age of six weeks and nine months respectively following the administration of sodium bismuth thioglycollate (thiobismol) The older of these patients had also received sulpharsphenamine. In neither of these infants had a definite diagnosis of congenital syphilis been established which leads the author to remark, "One cannot condemn too strongly such a tendency to administer therapy to newborn offspring of infected mothers before signs of congenital disease become evident.

Friedman and Shinefeld (1941) report two cases of fatal hemorrhagic encephalopathy at the age of eight months and fourteen months respectively following sulpharsphenamine therapy One of these infants likewise probably did not have syphilis.

Infectiousness.—The syphilitic infant in florid eruption may be a source of infection and should be handled as such, though some observers feel that the risk to ordinary contacts is small. The early institution of arsphenamine treatment soon does away with the possibility of transmission. The congenitally syphilitic infant s ability to develop superficial infectious lesions is largely confined to the first year of life and almost never occurs after the fourth year By the time he reaches school age the possibility of transmitting

the disease to his playmates hardly needs to be reckoned with irrespective of his serologic status or amount of previous therapy

Adoption Problems.—The adoption problem of the syphilitic orphan or illegitimate child is not simple. The child should not be farmed out to an unsuspecting family or offered for permanent adoption without a full statement of the case to those who assume responsibility for it. In no case should such a child leave custodial care before it is two years old, and arrangements should be made to follow it by medical and serological examination over a period of years, if not until puberty The Welander home offers much the best solution of the problem. If a complication such as interstitial keratitis develops, adequate treatment should be provided by the state or county authorities, and the burden of a decline in independent earning capacity should not fall on the adopting family

Serological and Clinical Controls of Treatment.—The laboratory and clinical controls of treatment, both as regards the eye and general physical examination and the blood serologic test and spinal fluid examination, should be those for syphilis in general An early spinal fluid examination serves to lend direction to treatment. In no case should a child be sent out for adoption or raising without such a test. About half the patients with ordinary treatment attain and hold serological negativity of the blood and those who fail to do so should be interpreted more leniently in the absence of neurosyphilis than the acquired case. The ever present anxiety in the resistantly positive prenatal syphilitic is an outbreak or relapse of interstitial keratitis. There is, however a distinct type of prenatal syphilitic who carries a resistant positive test in robust health with no complications, probably throughout life and this type of patient, discovered in adult life, should not be overtreated, as he usually is.

The question of spontaneous remission in congenital as in adult syphilis, has been alluded to by a number of writers in recent years, and has been discussed in the light of their experience by *Ingraham, Shaffer Spence and Gordon* (1941). While the occurrence of this type of case does not alter the recommendations with respect to the adequate early treatment of every case of congenital syphilis, yet it is a factor which must be borne in mind in evaluating effectiveness of treatment.

The Management of Tardive Prenatal Syphilis.—The earlier in life treatment for syphilis can be begun, the better the ultimate result. Recent observations have even tended to show that treatment *in utero* through the mother makes even postnatal treatment of the child more effective. Tardive prenatal syphilis is, in general, late rather than early syphilis, and unless in the case of some fulminating complication can be dealt with by the more leisurely but very persistent methods adopted for the later years of the acquired form It is impossible to exaggerate the value of this leisurely but determined persistence in treatment in the securing of ultimate good results.

The basic methods used throughout the original Mayo Clinic series included (1) The repeated 6 to 8 injection arsphenamine course with simultaneous inunctions, (2) the four months interim at home on one month rest, 40 rubs and one month rest and (3) individualization of the refractory infection somewhat as indicated in Fig 338. The use of arsphenamine instead of neoarsphenamine as soon as the age of the child permits the combination with mercury by inunction and the rejection of insoluble salts; the prolonged use of moderate doses of bismuth and persistent leisurely treatment after the acute phase is controlled seem to us essential features of the technic. Bismuth in recent years has largely replaced the inunction.

Results of Treatment of Congenital Syphilis.—What such a mode of procedure accomplishes is shown graphically in Figures 853 and 854. In the former it will be seen that 82 per cent of our 170 cases achieved a good clinical result, and 62 per cent a serological reversal to negative. Only 18 per cent of our patients failed to obtain notable improvement. Serological results

Fig. 836.

EXTENSIVE OSSEOUS INVOLVEMENT IN TARDIVE HEREDOSYPHILIS WITH NEGATIVE BLOOD WASSERMANN REACTION. RESISTANCE TO TREATMENT OVERCOME BY COMBINING MERCURY AND ARSPHENAMIN AND USING ADULT DOSAGE.

Female, aged eight.

Date Examined 1/4/20.
Chief Complaint: Inherited syphilis.
History First living child. Wart developed at the anus when a few weeks old. Health good until two years ago, when an annular eruption and bilateral interstitial keratitis appeared. Six months ago the nasal bridge collapsed and painful swellings of forearm and leg developed. Perforation of the palate began six weeks ago.
Examination Parietal bosses, flat nasal bridge. Old bilateral interstitial keratitis. Hard palate inflamed and perforated. Serrated teeth, not Hutchinsonian. Osteitis of the radius and fibula. Liver and spleen palpable. Liver tender. Blood Wassermann reaction negative repeatedly (positive obtained seven months later). Previous treatment, neo-arsphenamin 15 injections, 300 mercurial treatments (rubs?)
Treatment Three courses, 8 injections each, neo-arsphenamin 0.2 to 0.3 gram. Mercury succinimid $\frac{1}{10}$ to $\frac{1}{8}$ grain. Total of 600 — 4 gram 30 grain inunctions. Nine injections $\frac{1}{4}$ grain mercury salicylate. Iodid by mouth.
Treatment Result. Complete disappearance of all osseous lesions and arrest of palate perforation, first course. Healing of gummatous septum, second course. Remarkable gain in weight and physical development. Weathered measles, sprained ankle, and fracture of formerly gummatous radius without slightest ill effect. Weight gain 44 pounds in twenty-four months.

Discussion

In spite of previous arsphenamin and mercurial treatment this patient presented an actively progressive osseous heredosyphilis. It was arrested only by
(a) Hospitalization with rest in bed.
(b) The synchronous use of mercury and arsphenamin.
(c) An arsphenamin dosage scale proportioned to the adult rather than to the child.
(d) The use of neo-arsphenamin in therapeutically and not arsenically equivalent doses.
(e) In addition to the above-mentioned factors an element of discipline was involved. This patient had previously received such treatment as she permitted her medical advisers to give her. Under kindly but firm and determined management she received the dosage and treatment which were adapted to her case.
(f) It is often extremely difficult to stop the progress of palatine perforation and to suppress gummatous osteitis of the septum and to bring a patient with this resistant type of osseous syphilis through a fracture without relapse. Gummatous recurrence is a good test of the efficiency of treatment.
Note that in spite of the active osseous syphilis and clinically undoubted nature of the condition the patient only once had a strongly positive blood Wassermann reaction. The spinal fluid is negative.
Little or no change was to be expected in the residua of the interstitial keratitis. The mother of this child has been repeatedly negative to syphilologic examination.

lag behind clinical results very definitely. Serological recurrence may be observed after several years of negative blood serologic reactions, and patients negative before treatment occasionally develop into resistant positive cases after treatment. The grading of clinical improvement is held below the best levels in a number of cases because of residua of interstitial keratitis

which mar the result. Very few patients indeed cannot be promised some degree of improvement in their general condition, and the gains in health, strength, personality and address which many of them make over a period of three or four years are most gratifying Figure 854 shows graphically the

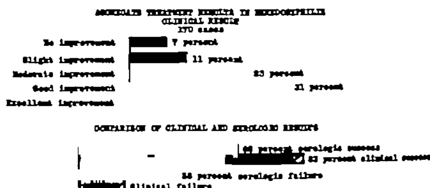

Fig 853.

relation of the grade of improvement to the number of courses of treatment received The rapid rise in excellent results with each successive course and the decline of mediocre results is an unmistakable index of the direction treatment must take in these cases.

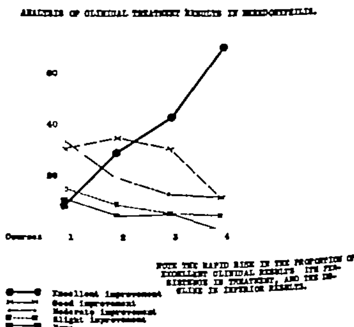

Fig 854.

Perhaps the most graphic portrayal of the results of treatment in congenital syphilis is to be found in the work of *F R Smith, Jr* (1933, 1936 based upon a study of the results of treatment in 621 patients with early congenital and 370 patients with late congenital syphilis. The earlier in 14

treatment is begun the more likely is the blood serologic reaction to become negative the better the ultimate clinical outcome and the less likely is clinical relapse to occur The tabular summary in Figure 855 is adapted from Smith's work.

Howard (1950) obtained complete clinical and serologic cure in 45 per cent of his cases with forty-nine weeks of treatment.

Significance of Fixed Positive Serologic Test.—Cole *et al* (Cooperative Clinical Group, 1937) found that a fixed positive serologic reaction in patient with late prenatal syphilis while he had acute lesions, or residual evidence of previous activity does not justify so good a prognosis as though the blood serologic test had reversed to negative. In the latent congenital syphilitic, it does not appear that serologic fastness influences clinical progression or relapse. The Cooperative Clinical Group studies with late prenatal syphilis showed that the amount of treatment did not appear to affect the reversal of the serologic reaction of the blood. More than half had fixed

Fig. 855

RESULTS OF TREATMENT OF CONGENITAL SYPHILIS
(After F R. Smith, Jr)

Age at commencement of therapy	Percentage cases. Seroresistant.	Showing clinical relapse.	Showing satisfactory clinical outcome.
1. Birth to 3 months	17 9	6 4	} 95 3
2. 4 to 6 months	26 1	10 9	
3. 7 to 12 months	27 3	15 1	
4. 13 to 24 months	38 3	19 4	
5. 2 to 4 years	41 3	4 4	93 7
6. 5 to 7 years	78 5	7 8	86 4
7 8 to 10 years	80 1	3 6	87 5
8. 11 to 15 years	86 2	8 5	91 5

positive serologic reactions despite treatment given. Howard (1950) also feels that positive blood serologic test after adequate therapy in the absence of other clinical signs is not of unfavorable prognostic import. Forty per cent of 45 children observed by him over ten-year period remained seropositive.

Special Problems—Interstitial Keratitis.—*Interstitial keratitis* should never be managed without the cooperation of the ophthalmologist. The delegation of the instillation of atrópine, so essential a part of local treatment to the parent does not appear to be satisfactory and iritis with synechia may result. Hot fomentations formerly much used seem less essential now Dionin is of distinct service. Salicylates internally are of some value in controlling pain and the secondary uveal involvement (Woods, 1943) The child must discontinue school and the eyes must be protected with tinted glasses. The tendency of children in this condition to sequester themselves indoors must be tactfully dealt with and every possible means taken to maintain the general health and morale

Adequate early treatment of congenital syphilis prevents the development of interstitial keratitis. Cole *et al.* (CCG) 1937 found that only 2 per cent of patients who received modern antisyphilitic treatment developed interstitial keratitis, whereas 90 per cent of patients who developed interstitial

keratitis had had no previous treatment. Effective systemic treatment has a rapidly favorable effect on the course of interstitial keratitis. In particular the effective use of arsphenamine will, in conjunction with a soluble mercurial salt intramuscularly used simultaneously bring surprising relief from photophobia and discomfort in four or five weeks This Stokes believes to be definitely superior at least to insoluble bismuth. The course of quite severe cases can be reduced from the usual period of six to eighteen months to from two to six months the rate of clearing of the cornea seeming less affected than the acute phase DeSchweinitz found arsphenamine in 0 4-Gm. doses most valuable Klauder and Vandoren (1941) have shown that contrary to previous practice, there is no justification for the customary use of iodides, either orally or intravenously in active or inactive interstitial keratitis. Careful analysis indicates that iodides may even be harmful It should be recalled that the use of small doses of neoarsphenamine at biweekly intervals without simultaneous mercurialization, which seems to be common practice is not regarded in this discussion as efficient treatment. Nonspecific methods may be invoked including especially because of its convenience boiled milk injections, 2 to 10 cc in older subjects for a series of 8 to 10 injections.

The results of our methods of treatment in a small number of cases which it was possible to completely recheck over a period of several years are given in Figure 85" to be compared with the better results of fever and chemotherapy (Klauder and Vandoren) Many of our patients came to us with chronic relapsing cases in which a high degree of opacity and vascularization already existed Had we been able to apply at the outset in all cases the treatment methods above outlined we feel confident that a shorter course and fewer residua would have been the rule. In patients seen within the first two or three weeks residual opacity and vascularization can often be absolutely prevented.

The attack of interstitial keratitis should be treated to an absolute standstill and no signs of activity should be detectable by the ophthalmologist before the patient is placed on any prolonged rest interval In patients who have a high degree of opacity and vascularization, measurable degrees of improvement can be obtained by the persistent use of arsphenamine and heavy metal over several years

Klauder and Vandoren (1941) found that chemotherapy was of limited value in improving visual acuity in inactive interstitial keratitis, less than 5 per cent of 115 eyes being benefited While both the Cooperative Clinical Group and Klauder's studies show that excellent results are obtained with the early use of chemother py in active interstitial keratitis, the latter studies also show that relapse is much better prevented [illegible]hen chemotherapy is supplemented by fever therapy Chemotherapy should consist of not less than twenty [illegible] eeks of arsenical with interim heavy metal When this treatment is continuous and commenced within t[illegible] months after onset between [illegible] per cent and 80 per cent satisfactory results can be obtained but relapse occurs in between [illegible] per cent and 18 per cent of cases. Routine therapy supplemented by fever therapy in [illegible] patients treated by Klauder resulted in only one relapse (1.8 per cent) and this patient had received only 2 injections of typhoid vaccine Visual acuity was best after the use of malaria, while typhoid vaccine produced less satisfactory results, and boiled milk was least effective

Woods (1943) discusses the value of roentgen irradiation in causing resolution of the infiltrate on the cornea, but points out there is a definite danger of damage to the lens and late effect, particularly if the roentgen ray is used. Theoretically of equal value [illegible]ith the roentgen ray and of comparativ[illegible] safet[illegible] is irradiation with the beta rays of radium. These penetrate only [illegible] or 2 mm. and do not reach the lens. They are given just short of contact and [illegible] total of about [illegible] gram 40 seconds in divided doses over [illegible] six week period, constitutes a full course. Each [illegible] infiltration of the cornea is followed by clearing of the infiltrates and irradiation has an inhibitory

effect on such vascularization, it is probably wisest to postpone any phototherapy until vascularization is fairly well established.

Deafness.—The heredosyphilitic child who has once developed a complete eighth nerve deafness does not respond in any appreciable degree to treatment as does the patient whose deafness is associated with an acquired neurosyphilis. The occasional premonitory tinnitus in childhood which

Fig. 836.

FEVER AND CHEMOTHERAPY RESULTS IN INTERSTITIAL KERATITIS
(After Klauder and Vandoren.)

Mode of therapy	Visual acuity 20–40 or better per cent.
Malaria	75
Hyperthermia	72
Typhoid or antigen H	50
Boiled milk	43

terminates in deafness at puberty should be more often the clue to diagnosis and treatment.

Neurosyphilis.—The prognosis of neurosyphilis, particularly if recognized in the asymptomatic stage, is better in the child than in the adult. Clausen and Jeans remark that the earlier a child with neurosyphilis is treated, the better the outlook and the quicker the desired result is obtained. They find this observation in keeping with the much larger amount of arsenic found in the spinal fluid of infants than older children, and the clinical fact that intraspinal therapy is rarely necessary in dealing with infantile neurosyphilis.

TREATMENT RESULTS IN 50 CASES OF INTERSTITIAL KERATITIS

	Cases	Per cent.
Improved	21	42
Arrested or unchanged	12	24
Improvement uncertain	9	18
Worse	8	16
Total favorable results		66
Doubtful or unfavorable		54

Fig. 837

Juvenile paresis is yielding to modern methods, though opinion is still in the making, and its high resistance is recognized. Its treatment is essentially the same as in the adult. Moore endorses malaria (1043) emphasizing its use before deterioration sets in, and the risks of tryparsamide. Tabes with crises or optic atrophy is as unmanageable as in the adult. In Potter's (1933) report on 38 cases, malaria and tryparsamide arrested 27 with complete remission in 5 partial in 0 cases, observed two to nine years. Potter found the prognosis better in patients normal before the onset of dementia who were past adolescence at onset who showed expansive and confused types of reaction or

whose paresis had not been of longer duration than two years. Menninger's (1936) monograph gives an excellent summary of this subject. In general therapy is similar to that which has been described for the adult (q.v.). Malaria is ordinarily the fever therapy of choice; tryparsamide is normally contraindicated unless visual acuity can be determined because of the danger of optic atrophy.

Asymptomatic Patient with Positive Blood Serologic Test.—The management of the patient whose only presenting symptom is a positive blood serologic test and whose spinal fluid examination is negative will depend largely upon the age of the patient. To be certain that the infection is congenital and not acquired, some definite stigma of the disease must be present in the absence of definite knowledge that the infection was present in early infancy. If such information is not available, then the patient should be considered to have acquired syphilis and be treated for such, irrespective of his age. Especially to be cautioned against, is the practice, still prevalent, of making a diagnosis of congenital syphilis, in a child or young adult, merely because no satisfactory history of the symptoms of acquired syphilis can be elicited.

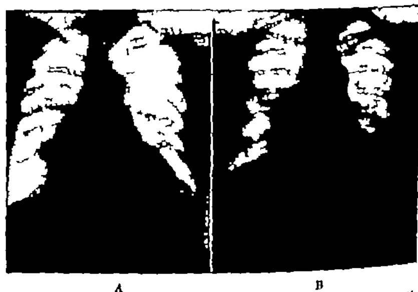
If the diagnosis of congenital syphilis is established, and the patient is less than twenty-five years of age, then minimum standard treatment to prevent interstitial keratitis should be given: sixteen weeks arsenical and thirty weeks heavy metal therapy. The likelihood of any serious late manifestation of congenital syphilis appearing after this age is reached makes further therapy inadvisable and it is questionable whether anything more than periodic observation is needed should the congenital syphilitic be over twenty-five years of age when first seen.

The Well Child in a Syphilitic Family.—The child who, though of syphilitic parentage, has a negative blood and spinal fluid, and no stigmas of the disease detectable by complete physical, ophthalmoscopic, and aural examination, is hardly in need of treatment. (See previous section on indications for treatment.)

The Marriage of the Heredosyphilitic Adult.—The victims of severe heredosyphilitic manifestations are probably best advised not to marry since there is still ground for fearing that they may impart abnormal diathesis to their offspring. On the other hand, the usual patient with a few stigmas, a positive serologic test, and perhaps an interstitial keratitis from which he makes a good recovery under effective treatment, is not ineligible for marriage. Sidler-Huguenin, who studied this question in the children of 250 persons whom he knew to have heredosyphilis, found that 28 per cent of the families were childless and the life expectancy was somewhat shortened, but that the children were normal and that there were no apparent drawbacks, other than those mentioned, to the marriage of those who have inherited syphilis. Hufer and Wiskott compared 40 patients with prenatal syphilis with controls, with reference to their descendants, and found no difference between the two groups in the incidence of abnormality or pathologic change. (See previous section on third generation syphilis.)

The Welander School-homes for Heredosyphilitic Children.—In dealing with the heredosyphilitic child, and especially the orphan or illegitimate, often bright and precocious but handicapped by some special disability or complication which demands expert attention over a period of years, one is impressed with the real worth of the plan developed by the Scandinavian syphilologist, Welander, for the raising of these children in school-hospitals

or homes in which the adequate treatment of their condition, demanding as it does unusual persistence, can be combined with formal education and healthful surroundings. Since the first home was opened by Welander through private generosity at Stockholm in 1900, with 4 children, the idea has extended into Norway and Germany and the original establishment has been greatly enlarged. The reported results (Balze, Müller and Singer Rondet) of this form of management for children who cannot have adequate home care are superior to any plan thus far devised and deserve consideration by child welfare authorities and agencies in this country



CHAPTER XXII

MISCELLANEOUS ASPECTS AND CASE MEMORANDA

The following brief summaries deal with relatively less common manifestations of syphilis to which restricted space is given in order to keep the foregoing material within the compass of single volume.

SYPHILIS OF THE LUNG AND MEDIASTINUM

Pulmonary Syphilis.—Syphilis of the lung has been admirably reviewed in extenso, with a summary of the literature, by Carrera, Wile and Marshall, McIntyre, and Levin. Acquired syphilis of the lung is regarded as rare, and seldom demonstrated short of the necropsy table. Pulmonary involvement in the form of interstitial pneumonitis is, of course, common feature of heredosyphilis. Of the acquired form Osler recognized 12 cases in 2500 necropsies. Carrera in Warthin laboratory found 12 cases among 152 necropsies of known syphilitic persons.

A B

Fig 838.—A, Syphilis of the right lung. Insofar as there is typical picture, this is it. Note the response to treatment in B (Courtesy of Drs. Stroud, Bowen and Bishop.)

Three important papers, those of Pearson and DeNavasquez (1936), Ha, Fraser and Hsieh (1939) and Levin (1940) bring the subject up to date. It must be conceded that differential diagnosis short of topsy and tissue examination appears more and more rather than less and less difficult.

Clinical pulmonary syphilis of the acquired form consists of solitary gumma, diffuse syphilitic fibrosis, and possibly diffuse syphilitic bronchopneumonia. Secondary involvement of the pleura may give rise to true syphilitic pleuritis. The boundary line between syphilitic involvement of the hilus of the lung and syphilitic mediastinitis is, of course, impossible to define in some cases.

Head and Seabloom have directed attention to pulmonary complication of syphilis associated with acute lobar pneumonia in report of 5 cases of delayed resolution, the fever and pulmonary symptoms persisting for days or weeks and giving the impression of interlobar pleurisy or empyema. The blood serologic reactions were positive the symptoms disappeared rapidly following the administration of arsphenamine. Subsequent to the above report, Farrell, Stanley Floyd, and Fitzhugh have discussed the subject, the last mentioned author reporting

3 cases. In case presented by FitzHugh and Anderson before the College of Physicians of Philadelphia massive infiltration of the right upper lobe had occurred with gumma of the right base. The symptoms disappeared rapidly following the use of mercurial inunctions and sodium iodide by mouth. While it cannot be said that syphilis is the first factor to be considered in interpreting unresolved pneumonia even in syphilitic subjects, it seems probable that the condition is more frequent than is generally recognized and that the presence of positive blood Wassermann test in patient with unresolved pneumonia should lead to treatment with mercury bismuth, and iodide before operative measures are considered. Even relapsing pleurisy with effusion may pparently occur in such cases and respond to treatment for syphilis.

Fig. 859

THE DIFFERENTIAL DIAGNOSIS OF ACQUIRED PULMONARY SYPHILIS AND TUBERCULOSIS

Syphilis	T berculosis
Concomitant evidence of syphilis.	N concomitant vidence.
Sputum repeatedly negative for tubercle bacilli (*Spirochaeta pallida* also not demonstrable)	Positive sputum.
Delayed resolution of lobar pneumonia in patient with syphilis.	
Right side most frequently affected.	Left side most frequently affected.
Lower or middle lobe involvement most frequent. "Pathologic changes in right lower lobe strongly suggest syphilis (Karshner and Karshner)	Apical involvement most frequent.
Pathology	
Spirochetes demonstrable (Warthin).	
Caseation not so marked.	Caseation more marked.
Blood vessels only occasionally ttacked.	Blood vessels often ttacked.
Anthracosis infrequent.	Anthracosis more frequent.
No epithelioid formation.	Epithelioid formation.
More pleural connective tissue scarring.	Less pleural connective tissue scarring.
Peripheral (subpleural) lesions common.	Peripheral lesions not the rule.
-Ray	
Calcification not common.	Calcification common.
Cavitation rare.	Cavitation common.
Gumma sharply circumscribed.	Margins of lesions more hazy
Lower and middle lobe shadows.	Apical shadows.
Fibrous tracts radiating from main lesion.	
Occasional polycyclic shadows.	
Often marked peribronchial sclerosis.	
Response to specific therapy excellent in pulmonary gumma, good in interstitial pulmonary syphilis if not too advanced.	Occasional nonspecific response to arsphenamine.

Much of the material on which this table is based is contained in McIntyre' article, and Levin in the Jadassohn Handbuch.

It is an interesting question whether pulmonary spirochetal crisis such as may occur in the brain in paresis or the heart muscle in acute syphilitic myocardial failure (Warthin), may not give rise to the clinical picture of acute pneumonia with delayed resolution.

The clinical symptomatology of chronic syphilis of the lung is nonspecific. In no case can a diagnosis be made without collateral evidence of syphilis, and autopsy or successful therapeutic test, carefully guarded against nonspecific misinterpretations. Gumma of the lung may pass for neoplasm, softened gumma for pulmonary tuberculosis with cavitation, and interstitial pneumonitis for nontuberculous lung infection, and even pulmonary fibrosis such as pneumonoconiosis.

The crux of the clinical undemonstrability of pulmonary syphilis lies in its masquerade as tuberculosis. It has been surprising feature of our personal experience to note the frequency of report of "healed apical tuberculosis" in association with active late manifestations of syphilis in th upper respiratory tract and the nasopharynx. From such cases we have derived the impression that pulmonary syphilis is perhaps clinically obscure, but not excessively rare.

The touchstone in diagnosis is the collateral evidence of syphilis, before mentioned, and the *repeated absence of tubercle bacilli in the sputum* over a considerable period, in cases whose clinical findings and roentgenograms suggest an open type. Fever, productive cough, bloodstreaked sputum, gastro-intestinal symptoms, weight loss, and even night-sweats are not impossible in pulmonary syphilis uncomplicated by active tuberculosis. Therapeutic tests should be performed with mercury or bismuth. Arsphenamine and iodide have too large margin of nonspecificity for safe interpretation.

Gumma of the trachea and of the bronchi (often diagnosed gumma of the lung) is quite rare and usually recognized late. It may be associated with gummatous involvement of the larynx. Inspiratory stridor and dyspnea with a dry brassy cough and paroxysmal attacks suggesting

Fig. 860.—Characteristic posture of the patient with mediastinitis producing venous and lymphatic stasis in the neck and arms. The crowding upward of the tissues in the supraclavicular fossae, with the thickening and edema, produces an apparent shortening of the neck and a frog-like forward thrusting of head and arms. There are numerous large *superficial* veins over the presternal region (obstruction of the superior vena cava) The eruption is tinea versicolor

asthma are common symptoms There may be scanty blood-tinged sputum. Roentgenography bronchoscopy examination of the sputum, and collateral evidence of syphilis with therapeutic test are essential to diagnosis. Bronchiectasis may follow upon or be associated ith the deeper lesions.

Asthmatic syndromes ascribed to syphilis, the diagnosis based almost entirely on therapeutic tests, are discussed by Mayer and Mossolin (1937) with summary of the literature.

Ayerza's Disease.—I 1901 Ayerza described disease complex in hich the pathologic changes consisted of chronic bronchitis, bronchiectasis, emphysema, and stenosis and obliteration of the pulmonary vessels. The pulmonary disturbances result in compensatory enlargement of the right heart and an erythrocytosis of degree approximating t times that seen in polycythemia rubra vera, with which the complex is sometimes confused. Herxheimer states that

cases in which the luetic nature of the arterial changes can be accepted have been reported by Warthin, and by Escudero, the latter stating that most cases are syphilitic. Herxheimer believes, however that the variable complex of Ayerza disease probably is dependent on number of factors including lues, malaria and chronic intoxications, and that the etiologic agent may be difficult to uncover in given case.

Syphilitic Mediastinitis.—Syphilis of th mediastinum has been presented and discussed to some extent in connection with cardiovascular syphilis (see especially case reports. Chapter XIX) Giffin summarized the situation on the basis of 5 ases seen t the Mayo Clinic, and Lemon discusses in full the differentiation of mediastinal affections.

Fig 861.—Thickening of the neck and venous compensatory circulation in patient recover ing from an extreme *grade of gummatous mediastinitis, with obstruction of both superior and* inferior vena cava

An uncomplicated mediastinitis is diagnosed with comparative ease when sufficiently severe to be responsible for marked pressure symptoms or to cause well-defined roentgenographic shadow The abortive forms, however, may give rise to no more than retrosternal pressure and slight pain, glottic spasm, hoarseness, fulness of the neck, and slight changes in the collateral circulation. A well-marked case of middle mediastinal infiltration presents striking picture. The edema of the neck, venous engorgement, swelling of the arms and tracery of vessels over the thorax, the bulging eyes and slight stoop with arms thrown forward akimbo, suggesting the attitude and appearance of frog, are recognizable on sight (Fig. 860) The possible extent of the mediastinal changes and the involvement of surrounding structures are illustrated in Fig 862. If the inferior vena cava be subject to compression in the process the symptoms may be suggestive of hepatic cirrhosis and the collateral circulation (Fig. 861) involve the superficial abdominal

Fig 308.

PULMONARY MALIGNANCY VERSUS PULMONARY SYPHILIS

Housewife, aged thirty-eight.

Examined 9/18/22.

Chief Complaint Hoarseness and pain in whole left chest and shoulder

No difficulty in swallowing, no dyspnea, no orthopnea.

Weight Loss 100 pounds in eighteen months.

Pain Requires Morphia.

Has Had a Diagnosis of Pulmonary Malignancy and Several Massive x-Ray Treatments Given Some Months Ago. No relief.

Wassermann Elsewhere Reported negative.

Examination

Clubbed fingers marked.

Exophthalmos slight

Left pupil slightly the larger

Enlarged veins left upper chest.

Restricted breathing

Blood-pressure same both arms. 180/70.

Breath sounds and voice decreased over entire upper half left thorax both front and back.

N pulsation, no diastolic shock, no tracheal tug

Temperature normal.

Heart negative

Liver and spleen palpable.

Leukocytes 23 400 Hemoglobin 80 Differential count 87 per cent. polymorphonuclears.

Blood Wassermann Reaction: Strong positive repeatedly

x-Ray of Chest: "Marked increased density over hole upper left lobe. Probably tumor Area over right diaphragm probably metastasis.

Re-ray Three Days Later: No change.

Left Vocal Cord in Midline.

"May be Necrosis in Tumor—Note Leukocytosis.

Clinical and Surgical Diagnosis: Malignant tumor left chest with metastasis on right.

Referred to Syphilologist: Unable to stay for treatment. Given forty 30-grain inunctions and potassium iodid, to take home.

One Month Later Reports She is Feeling Easier in Chest and Voice is Better.

Five Months Later Reports Cough is gone, has gotten her voice back and everybody who sees her says she "looks good.

One Year Later: Letter from home physician states patient died suddenly ith symptoms very suggestive of ruptured aneurysm.

Necropsy refused.

DISCUSSION

1 This patient well illustrates the problems that syphilis of the lung or malignancy may present. A negative Wassermann elsewhere, two positives in the clinic, afebrile but with leukocytosis, signs of pressure and mediastinitis, but no signs of aneurysm, and an extreme loss of weight ith lesions in both lungs. N response to x-ray therapy

2 It is rule worth bearing in mind that when malignancy or suspected malignancy presents anywhere in operable form, operate. But inoperable malignancy in situation such as the thorax deserves therapeutic test for syphilis with mercury and iodid. It is matter for debate whether x-ray therapy is entitled to precedence over syphilotherapy here or not unless the diagnosis of malignancy is borne out by absence of signs of syphilis, and, if possible, positive gland findings for malignancy

3. N suspected inoperable malignancy with positive blood Wassermann should escape having therapeutic test for syphilis. She had had negative test elsewhere

4 It is quite conceivable that pulmonary gummatous syphilis may be bilateral.

5. Softening may occur in a gumma in any location.

6. Weight loss does not make diagnosis of malignancy or speak against syphilis. Constant pain alone, irrespective of syphilis, can lead to marked weight loss from insomnia, etc and is common observation in aneurysm.

7 Note the clubbed fingers, of course not suggestive of syphilis.

8. The diagnosis on this case was by no means settled by the temporary outcome. It was entirely possible that she still had malignant process complicated by syphilis with partial relief

9 The suggestion of aneurysm contained in the physician death report was a complete surprise, and, while not established by necropsy, suggests the care which must be used in diagnosing non-pulsating masses in the middle chest ithout providing for therapeutic test for syphilis.

Fig. 863.

SYPHILITIC MEDIASTINOPERICARDITIS AND PNEUMONITIS; RECOVERY UNDER TREATMENT FOR SYPHILIS. COINCIDENT NEUROSYPHILIS

Housewife, aged fifty-two.

Examined 12/30/21

Chief Complaint: Cough and swollen fingers. One and half year duration, occasional bloody sputum, violent paroxysms of coughing. Dyspnea, orthopnea.

Fingers Clubbing for Past Three Months.

Attacks of Dizziness, girdle sensation, some taxia, paresthesias, etc., referable to the neurosyphilis.

Examination

Demonstrable neurosyphilis (pupils, etc.)

Deep dulness left base increased breath sounds, and whispered voice.

Click over apex of heart in fourth interspace. Otherwise negative.

Fingers markedly clubbed, pink color

N cyanosis on stooping

x-Ray of chest negative except heart enlarged and drawn to left.

Electrocardiogram left ventricular preponderance.

Sputum Examinations (three) negative for tubercle bacilli.

Blood Wassermann Reaction Strongly positive.

Spinal Fluid Strongly positive.

Consultant's Diagnosis Findings chiefly those of pleural thickening (involving pericardium?), but with dyspnea, chronic cough, bloody sputum, and clubbed fingers, should mean tumor or mass in chest.

Treatment for Syphilis Begun: Twenty injections mercury succinimid, sodium iodid by mouth.

Bronchoscopy Negative.

N Palpable Glands, neck or axilla.

Apical Retraction Noted, but no Broadbent sign.

T and Pre Apical Murmur (rub?)

Consultants Disagree to Whether Signs Justify Diagnosis of Adherent Pericardium.

By Tenth Day of Treatment marked improvement in all signs.

Fourteenth Day (mercury and iodid only) Cough gone, pain in side gone, fingers much smaller, general gain.

Neo-arsphenamin Begun Mercury continued. Further improvement.

Consultants Still Differ as to Cardiovascular Disease.

Neurosyphilis Resistant to Ordinary Treatment.

Patient Sent Home after 6 neo-arsphenamin, 5 intraspinal, 26 succinimid, 24 sodium iodid injections.

Heart Negative, Fingers Much Smaller Some Râles Both Bases, N More Apical Retraction.

Returns in Excellent Health for Observation N signs of pericarditis, heart negative as to physical signs, but -ray plate still shows enlargement and drawing to left. Symptoms gone entirely Will not remain for full course of treatment.

DISCUSSION

1. In retrospect while the diagnosis of this case remains undetermined, strong presumption of syphilitic pneumonitis nd pericarditis seems to exist.

2. The possibility of non-syphilitic lung infection forming the basis upon which the syphilitic lesion developed must be considered.

3. The therapeutic test as carried out as as nearly non-specific as possible. No arsphenamin was used to confuse the issue with pulmonary spirochetosis or non-tuberculous lung infection such as has been seen since the epidemics of influenza.

4. Blood-streaked sputum and slight fever are entirely compatible with syphilitic pneumonitis.

5. There was no sign of localized mass, which would t once have raised the possibility of malignancy though it might have been gumma.

6. Note that the clubbed fingers improved with the response of the pericardium and lung to treatment for syphilis. There were no -ray or clinical signs of periostitis or ostitis.

7 The Wassermann test and the finding of neurosyphilis really forced this diagnosis to the point of therapeutic test. More frequent use of non-specific therapeutic test in pulmonary lesions having repeatedly negative sputum examinations for tubercle bacilli and pulmonary spirochetes, would perhaps increase the prevailing estimates of the importance of pulmonary syphilis.

8. Arsphenamin has marked effect on variety of non-syphilitic lesions of the lung, and cannot be trusted for therapeutic tests.

as well as the thoracic veins. The most striking symptom in severe grades of syphilitic mediastinitis which Stokes has seen is the pronounced cyanosis which develops on stooping or lying down, as evidence of venous obstruction, of course, not specific for syphilis. It is not, however, invariably present.

Figure 863 illustrates the symptomatology of a probably syphilitic mediastinopericarditis, and the nonspecificity or rather lack of differential value of many of the symptoms commonly accepted as almost pathognomonic of aneurysm and other causes of mediastinal pressure. Figure 862, on the other hand with mass in the lung and a mediastinal shadow as regarded as malignant because of the coincident presence of the mediastinal shadow and the mass in the lung. The patient improved greatly under treatment for syphilis, and then abruptly died with symptoms practically conclusive of aneurysm. Tuberculous mediastinitis has twice been referred with anomalous Wassermann findings (weak positives) for therapeutic test. In one of the patients the abscess rapidly came to head and perforated the sternum during the latter part of six-week course of arsphenamine treatment. In the other case no significant improvement was obtained, and the case was regarded as tuberculous by inference.

The diagnosis of mediastinal syphilis would indeed be easy if it could be based merely upon a mass, a definitely positive blood Wassermann reaction, and positive therapeutic test. It is malignancy with coincident syphilis, syphilis and pulmonary gummas simulating malignancy with coincident syphilis, and solid mediastinal masses with negative blood serologic reactions which develop pulsation on therapeutic test for syphilis and become indubitable aneurysms, that

Fig. 864.—Clubbing of the fingers in syphilitic mediastinopericarditis and pneumonitis (Fig. 863) The clubbing disappeared as the mediastinal and pulmonary process involuted under treatment. There were no signs of osseous changes clinically or roentgenographically.

torment the diagnostician. In the presence of collateral evidence of syphilis and signs of mediastinal mass, then, the safest general rule is to approach the case as one of vascular syphilis, not because it is such necessarily but because such procedure gives the lowest percentage of temporary nonspecific results, if the process is tuberculosis or Hodgkin disease, and the greatest safety t the patient if the mediastinitis resolves itself into aneurysm.

GUMMA OF THE LYMPH NODES

This condition, pitfall for the unwary internist and surgeon, while not common, has not been rare in our experience. Hazen states that gumma of the lymph nodes is comparatively common in the colored race. Laymon (1934) and Herbert Fox (1936) have discussed the histologic differentiation of gumma of the lymph nodes in biopsy diagnosis, and the former found 15 per cent of 70 patients with early syphilis to present "tuberculoid" reaction in the lymph nodes, mostly inguinal. In the cervical region (Figs. 865–867) the only safeguard against error and unnecessary operation for tuberculous glands may be the routine use of the blood serologic test. Gummatous lymphadenopathy or at least local syphilitic lymphadenopathy may help to confuse diagnosis in aneurysm with mediastinitis (Chapter XIX), may produce clinical appearance of malignancy in association with abdominal lesions, including the stomach, the gallbladder and the rectum (Chapter XVII), and of the axillary lymph nodes (gumma of the breast). On the other hand, in the inguinal region Stokes has seen an inguinal adenitis due to Hodgkin disease submitted as *ipso facto* due to syphilis even though the blood serologic reaction and collateral findings were negative. Errors of the kinds described can be dealt with in only one way—by diagnosis to consider syphilis as possible complete explanation of an apparently nonspecific abnormality and by the thorough study of each and every case. Those who rely on these diagnoses exclusively

Fig. 865.—Gumma of the cervical lymph nodes mistaken for tuberculous lymphadenitis and twice apparently operated upon as such, with recurrence. The entire right side of the neck and the tissues posterior to the ramus of the jaw and over the parotid were brawny and indurated Following the finding of positive blood Wassermann reaction the entire process disappeared under treatment for syphilis. This patient oldest child had bilaterally symmetric hydrarthrosis of the knees (see Fig. 866)

for their opinion of an adenitis will make as serious mistakes as those who rely solely upon a blood serologic reaction.

LATE SYPHILIS OF THE KIDNEY URETER, AND BLADDER

Syphilis of the Kidney Ureter, and Bladder.—The kidneys of large proportion of syphilitic patients are found at necropsy to be abnormal in one way or another, especially with reference to chronic inflammatory change. The precise relation to syphilis is difficult to establish. Rich describes peculiar form of nephritis encountered in 9 per cent of 200 necropsies in which there was definite pathologic or serological evidence of acquired syphilis. I control series of 400 cases the lesion was never found in the absence of syphilis. The possible damage that may occur in the kidney during the stage of spirochetemia seems not to be appreciated fully Warthin has demonstrated numerous spirochetes in the tubular and epithelial tissues of the kidney in 5 cases of acute syphilis, 2 acquired and 3 congenital in origin Hermann states that trace of albumin or occasionally red blood cells may be found in almost 8 per cent of patients with spirochetemia. Miller and Hay have reported case of what may be classified as nephrorecurrence or renal spirochetal crisis. In their patient syphilis had been latent for some twenty years when evidence of an acute nephritis developed and death rapidly ensued. At necropsy the kidneys presented the picture of chronic nephritis on which an acute process had been superimposed affecting all the structures of the organ. Spirochetes were readily demonstrable in the tubules. Riviere believes that syphilis is sometimes the cause of albuminuria in pregnant women on the basis of his finding syphilis in only 8 per cent of women without albuminuria, while 23 per cent of the cases with albuminuria showed positive Wassermann reactions. From review of the literature and their own experience, Miller and Hay believe that syphilis of the kidney may be satisfactorily classified as follows:

I. Nephritis of the early stages (spirochetemia)
   (a) Acute glomerular nephritis, rare form characterized by low albumin content and numerous blood cells in the sediment (Hein, Zentral. f. inn. Med., 10 263, 1927).
   (b) Acute tubular or parenchymatous nephritis of which the lipoid nephrosis of Munk (Ztschr f. klin. Med., 78 1913) is type, characterized by very large amount of albumin, by hyaline granular and fatty casts with but few red blood cells. Most of the cases of acute syphilitic nephritis fall in this group.

Fig. 880

INTERPRETATION OF A SUPPURATIVE ADENITIS WITH A POSITIVE WASSERMANN REACTION

Male, aged nineteen, single.

Chief Complaint: Draining glands in the neck, enlarged glands in inguinal and axillary regions.
Father and mother dead, details unknown.
Six years of trouble with glands.
Cleared up temporarily by tuberculin (?)
Glands in the involved regions recurred and subsided t intervals up to one year ago, then marked recurrence in neck.
Tonsillectomy four years ago
Surgical removal glands right neck one year ago. Draining since through sinus.
Gonorrhea one year ago.
No history of Lues I or II
Chest negative. No T.B symptoms. No fever
SWR strong positive followed by negative.
Syphilologic Examination: N signs of acquired or inherited syphilis. Never been treated for syphilis that he knows. Provocative yielded negative, +++ +++ negative, negative, negative
Eye negative. Spinal fluid negative.
Neurologic Examination: Negative except slight nystagmus.
Full examination for tuberculosis negative except for glands (none excised).
Treatment: Six injections arsphenamin, 20 inunctions.
Four x-ray exposures coincidently ordered by another consultant.
BWR +++ after treatment
BWR negative after 60 more inunctions
Second arsphenamin course Six injections.
BWR negative, direct and provocative for two years.
No further treatment.
Spinal fluid negative.
Glands reduced 80 per cent., still palpable; sinus healed.

DISCUSSION

1 The patient is young for an acquired infection. If acquired with the gonorrhea ithout treatment, the BWR without treatment should be unconditionally positive

2. The cervical glandular enlargement which was operated on might have been the bubo of tonsillar lues I. This is unlikely in the absence of history of sore throat and ithout frank positive BWR.

3. If a childhood infection, the condition would be a gumma of the lymph-nodes This is usually localized to single group of glands and follow contributory cause such septic infection, i tonsillitis in the area of lymphatic drainage. Tuberculosis is more likely to invol several groups. Sinuses favor tuberculosis, but may be present ith gummas. They do not accord ith operated bubo of lues I.

4. Patients with tuberculosis may give false positive Wassermann reactions. These are usually partial positives (+ ++) They are pt to ppear ith little reference to treatment.

5. This patient may have had false provocative effect.

6. The therapeutic test with arsphenamin on gland masses is untrustworthy Tuberculous glands will often respond.

7 Th therapeutic test here was further vitiated by the us of -ray by another clinician. This alone might ha cured the glands, though seldom so promptly or with so few exposures as in this case

8. Great care in therapeutic tests must be used to avoid ( ) non-specific effects; (b) multiple procedures ith consequent inability to decide later hat did the work.

9. This boy must remain under observation indefinitely with an undetermined condition, probabl tuberculous.

10. A pathologic examination of an excised gland should have been made but would not have been absolutely conclusive. Animal inoculation could be used.

II. Nephritis of the later stages.
( ) Secondary syphilitic contracted kidney
(1) Chronic glomerulonephritis (Fordyce Miller and H y).
(2) Chronic interstitial nephritis, the end-stage of lipoid nephrosis (Munk)
(b) Chronic parenchymatous nephritis, syphilitic type of large pale kidney (Fournier) intermedi t stage of lipoid nephrosis.
( ) Chronic interstitial nephritis associated with vascular disease
(d) Amyloid kidney (?)

III Kidney of congenital syphilis.

Fig. 367

GUMMA OF THE LYMPH NODES, CONFUSION OF TUBERCULOSIS AND SYPHILIS. EFFECT OF ARSPHENAMIN ON OPTIC ATROPHY

A woman with a mass suggesting matted glands below the right jaw. Sinuses with ulceration.
Glands enlarged after tonsillitis.
The Scars of Two Operations for Tuberculous (?) Glands.
An arciform ulcerative lesion along the border of one of the scars.
Divorced six months after first marriage to "brute.
SWR Strongly Positive.
High myopia with primary optic atrophy.
CSF WR negative; Nonne negative; 8 lymphocytes.
Bárány positive.
No neurologic findings.
Treatment. Five injections arsphenamin, 3 to 4 decigrams.
No Herxheimer reaction.
Slow improvement.
Eyes Grew Rapidly Worse During the Course. Sixth Injection Omitted.
Lesion only partly healed when discharged, but healed completely while home on 40 injections.
Another Arsphenamin Injection Four Months Later Made the Eyes Markedly Worse ("Like a Cloud").
Fundus examination: Optic atrophy is progressing.
Patient can tolerate 1- to 2-decigram doses of arsphenamin fairly well. Eyes stationary under mercury.

Discussion

1. If the surgeon had noted the marital history and taken a Wassermann test the patient might have been spared two unsuccessful operations.

2. Gumma of the lymph nodes may come on after tonsillitis precisely as in the case of tuberculous glands.

3. The bubo of a tonsillar chancre does not break down.

4. False positive Wassermann results (usually one or two plus) may occur with tuberculous glands.

5. Tuberculous glands with sinuses may heal under arsphenamin, even in the absence of syphilis—a false positive therapeutic test.

6. The pathologic differentiation of gumma and tuberculoma is not always trustworthy.

7. The prominence of the cutaneous as compared with the glandular lesion, the repeated positive Wassermann over a period of months with final reversal under treatment, the slightly abnormal spinal fluid and the positive Bárány (inflammatory process in the brain stem) all speak for syphilis.

It may be impossible to make a differential diagnosis between syphilis and tuberculosis in certain cases without prolonged observation. Look for a tubercle bacillus.

Primary optic atrophy from whatever cause, may sometimes respond unfavorably to arsphenamin.

Stengel and Austin noted the presence of a double-refracting lipoid (Fig. 401) in a larger proportion of cases of nephritis associated with positive Wassermann reactions, than in nonsyphilitic patients. Paroxysmal hemoglobinuria is described in Chapter XXI.

Two reviews, those of Hermann and Marr (1935) and Baker (1939) have emphasized the need for a massive study of syphilis of the kidney with fuller case data, but without contributing anything radically new to the foregoing résumé.

Gumma of the kidney is a rarity although undoubted cases are on record (cf. for example Hunter, 1939). It may be suspected in patients who, in conjunction with a late syphilitic infection, develop a sudden hemorrhage with much detritus in the urine. Syphilitic pyelitis has been reported, but convincing proof of its syphilitic etiology is lacking. A proved case of syphilis of the ureter is not on record.

Posner states that 100 cases of syphilis of the bladder are found in the literature but objects to the sole criterion of therapeutic response as the evidence in many of these. Early syphilis of the bladder is exceedingly rare and takes the form of macular, papular and ulcerative lesions coincident with the secondary exanthem on the skin. Jovanovitch states that involvement is most marked in the more vascular regions of the trigone and fundus, and that the lesions are always submucosal and never ulcerative at the onset. Late syphilis of the bladder is usually gummatous or papillomatous, and more common than early syphilis, though even at that, decidedly rare. Hematuria and a slow course mark all the reported cases, together with a rapid

response to treatment and a resistance to other measures. No undoubted case was observed to Stokes's knowledge in the Mayo Clinic during the years 1916 to 1944. Finsterer's review (1930) of 158 cases in the literature since 1900 plus 2 of his own ends with the statement that not one measures up to the standard set by Young, that spirochetes must be demonstrated in the lesion. Neurogenous (atonic trabeculated) bladder of tabes has been elsewhere described (Chapter XX).

Syphilis of the prostate is also rare but well authenticated. The total of reported cases approximates 25 Warthin described the microscopical pathology and demonstrated the presence of spirochetes in a case of early syphilis, and Starry has outlined the gross changes occurring with late syphilis. Lobe states that the condition shows no distinctive features on palpation, and may resemble any type of prostatitis, prostatic tuberculosis, or malignancy the diagnosis resting entirely on collateral evidence and the therapeutic test.

LATE SYPHILIS OF THE CERVIX, UTERUS, TUBES, AND OVARIES

Gellhorn and Ehrenfest have published the most critical study of syphilis of the female internal genitalia. Parker review of early syphilis of the female genitalia is quoted in the chapter on early syphilis (Chapter XI) With the exception of chancre of the cervix, the syphilids of the structures mentioned are among the comparative rarities of medical and surgical practice. The pelvic satellite adenopathy of the cervical chancre can be recognized by palpation according to De Gregorio and De Biasio (1939) Late syphilids of the cervix are usually gummas, with necrosis and ulceration. The process may extend into the cervix or involve the vagina. The ulcers are firm, often elevated, may bleed or present profuse discharge and are painless. They may appear at some distance from the external os. Their outline is sharp, their surface covered with lardlike deposit, easily removed, leaving a characteristic luster The surrounding mucosa shows very little inflammatory reaction. The use of caustics on a simple erosion may produce a deceptive fatty sheen.

Actual knowledge of syphilitic lesions of the uterine body is extremely meager A few instances of gummas of the uterine wall have been recorded, and gummatous changes may occur in the endometrium, with excessive rarity The weight of evidence favors the belief that the uterus, like the prostate, is the most immune of all body structures, to *Spirochaeta pallida*. Gellhorn has described what he feels is a case of malignant uterine syphilis, with necropsy

Syphilis of the fallopian tubes may exist, but there is no clinical evidence of the fact, according to Gellhorn and Ehrenfest Syphilis of the ovaries is an as yet indefinitely defined possibility Hasen states that he has seen an undoubted case, but apparently no one has as yet succeeded in demonstrating the presence of *Spirochaeta pallida* in the adult ovary Gumma of the pelvic cellular tissue, mistaken for malignancy is also reported.

Uterine hemorrhage is an undoubted clinical associate of syphilitic infection in women. Gellhorn and Ehrenfest observed it in 40 per cent of 147 women with syphilis of the internal genitalia. Its cause is as yet unestablished and cannot be uncritically accepted as due to a syphilitic process in either the uterus or the ovary The mere cessation of hemorrhage following treatment for syphilis does not demonstrate the syphilitic origin of the process. Favel regards hemorrhage as the chief symptom of uterine syphilis. The one case on which Stokes has notes was that of a woman of thirty-four with a definitely enlarged and boggy nonpregnant and nonfibroid uterus who suffered from severe metrorrhagia with moderate secondary anemia and a positive blood Wassermann reaction. There was no history suggestive of gonococcus infection or abortion, and the response to treatment for syphilis was prompt, the hemorrhage ceasing and the patient improving rapidly in general condition. Such case history does not, as Gellhorn remarks, prove the metrorrhagia t have been of syphilitic origin.

Amenorrhea is occasionally observed as an incident of the onset of syphilis in the secondary period and in association with profound cachexia in the later aspects of the disease. It presents no distinctive characteristics. One or two menstrual periods may be missed during intensive treatment for syphilis without ill effects.

LATE SYPHILIS OF THE FEMALE BREAST

Early syphilis of the breast includes chancre and the rare form of acute syphilitic mastitis seen in the secondary period. Stokes has had a case under observation which, in addition to a mild mastitis during the secondary period, developed swelling and tenderness of the breasts without marked inflammatory signs, as a form of relapse on two different occasions, during rest periods in treatment, with immediate response to resumption of treatment. Late syphilis of the breast includes chiefly gumma, a very rare complication, usually mistaken at the outset for carcinoma and the even rarer condition of diffuse tertiary mastitis which may occur in prenatal

syphilis. Adair has recently summarized the literature of 40 cases and reports one case as appearing among 1674 carcinomas. The gumma is hard, painless, circumscribed, and presents cutaneous involvement as in carcinoma. *It differs from carcinoma in the bizarre involvement of the lymph nodes (gummatous lymphadenitis)*; in the rarity of "orange peel" pitting of the skin, in the more rapid growth of the gumma, the usual immunity of the nipple unless the lesion is very near the early fluctuation and breakdown of gumma, and the positive serologic reaction and confirmatory evidence of syphilis. In practice, *differential diagnosis from malignancy will be aided by tissue findings.* The most recent reviews are those of Ross (1938) and Braunstein and Woolsey (1940)

SYPHILIS OF THE TESTIS AND EPIDIDYMIS

The testis, in contrast to the foregoing rare conditions, is involved in syphilis with frequency that approaches that of the bones and the skin. Slight degrees of syphilitic orchitis seldom come to clinical recognition, however, except in the course of series of routine complete examinations. Palpation of the testis is too frequently overlooked, and there are no symptoms to attract the patient attention. Diffuse interstitial sclerosis and gumma are the two recognized manifestations. Marked degrees of the former give rise to the so-called "billiard-ball" testis, a slowly developing

Fig. 908.—Typical gumma of the left testis, of the type often spoken of as "fungus testis. Gumma of the testis before ulcerative breakdown occurs is most often confused with sarcoma and teratoma, and after breakdown with tuberculosis. The relative painlessness of the syphilitic testicle is not an infallible symptomatic guide. A blood serologic reaction should be taken on every tumor or enlargement of the testicle, and therapeutic test yields, as rule, very rapid results.

enlargement without marked symptoms other than dragging or aching sensation due to increased weight. The testis becomes insensitive to pressure and there may be an accompanying hydrocele. Involvement of both testes may occur though the process frequently remains unilateral. In this form of the disease the epididymis usually escapes. The tunica vaginalis may become adherent to the testis. The process must be differentiated from tuberculosis, which very rarely affects the testis except secondarily to the epididymis, and then follows course of breakdown and ulceration more suggestive of gumma. Sarcoma is favorite diagnosis in billiard-ball orchitis of syphilitic origin, and is relinquished sometimes with considerable reluctance by the surgeon in the presence of positive blood serologic reaction. The response to arsphenamine treatment is rapid enough to justify an intensive therapeutic test in such cases, softening and shrinkage following quickly on the administration of arsphenamine. Following the involution of the process varying degrees of shrinkage and atrophy may remain. The acute orchitides of mumps, gonorrhea, and septic infection are not likely *to be confused with it, although Hanon states that there is an acute syphilitic* orchitis which may be confused with gonorrheal epididymo-orchitis.

Gummatous orchitis is less common than the billiard-ball type, but may develop in association with it. The initial lesion is nodule which increases in size, becomes adherent to the tunica nd the scrotum, and softens and breaks down. Nodules may be palpated at other points. The differential diagnosis from tuberculosis is often not even considered. In no case should lesion of the

Fig. 869.—A moderate grade of syphilitic elephantiasis of the scrotum, in this case definitely associated with suppurating gumma of the inguinal lymph nodes. The condition responded rapidly to treatment. Late syphilitic elephantiasic changes in the labia and the scrotum, often with ulcerative lesions, are rare, though more frequently seen in the colored than the white race.

Fig. 870.—Gumma of the epididymis. This is a comparatively rare lesion, though nodular infiltrates of small size would be more frequently detected if search were made for them. The blood Wassermann reaction was positive.

testis or even hydrocele be treated without blood Wassermann test, and in any doubtful case, regardless of the blood Wassermann findings, therapeutic test is wise precaution.

Lymphedema of the scrotum may be secondary to syphilitic epididymo-orchitis with involvement of the coats of the testis. Pseudo-elephantiasis resulting from obstruction of gummatous lymph nodes is shown in Fig 869.

Epididymitis of syphilitic origin (Fig. 870), according to Michelson and Herman and Klauder is lesion whose rarity is more apparent than real. A very rare form, associated with secondary manifestations and following an acut course, is described. McLachlan (1926) demonstrated *Spirochaeta pallida* in the puncture fluid of 2 of his 3 cases with early syphilis. As rule the condition is chronic, coming on later in the disease and associated with sclerosis and permanent changes. The epididymis is easily outlined and not adherent, and is occasionally somewhat nodular There may be moderate hydrocele. The elimination of tuberculosis may be very difficult and should always include nonspecific type of therapeutic test even if evidence of syphilis be present.

Gummatous epididymo-orchitis usually begins in the testis as single or several grouped nodules, and results in the fusion of the two structures into an adherent mass which readily includes the overlying skin and breaks down to form crateriform ulcer Hernia of th testis may occur

In all lesions which have undergone softening and discharge, examination may disclose tubercle bacilli if the process is solely or partially tuberculous.

SYPHILIS OF THE PANCREAS AND SUPRARENAL GLAND

The clinical differentiation of syphilitic from other forms of pancreatitis is impossible, and the symptoms are not infrequently entirely masked by those of the hepatosplenic complex. An interstitial and gummatous type of pancreatitis are described, the latter being said t times to produce small cysts (Wile).

Warthin and Wilson in 1916 discussed the coincidence of latent syphilis in diabetes on the basis of the autopsy experience of the Pathologic Laboratory of the University of Michigan, giving in detail the histologic changes observed in the pancreas of patients with latent syphilis. Six of 41 cases showed marked changes in the pancreas and 2 of these were in diabetics. They suggested that latent syphilis may be chief factor in the production of form of pancreatitis most frequently associated with diabetes, but that diabetes is not always coincident with severe degrees of pancreatitis. I subsequent study Warthin placed the pancreas ahead of the central nervous system, liver and spleen in order of frequency of involvement in his autopsy material. His citations of the literature from the clinical side call attention to the general opinion that syphilitic glycosuria or diabetes is comparative rarity

Stokes has notes of only 2 cases in which the connection of the diabetes and the syphilis was established to the extent of an indubitably positive therapeutic test. Moore rates the condition as uncommon, but not rare. Both his patients were males in middle life with strongly positive blood Wassermann reactions and adequate histories, but no constitutional symptoms of the disease other than glycosuria. One of them was markedly overweight. The glycosuria disappeared in both cases under treatment for syphilis without dietary measures.

Syphilis of the suprarenal is well authenticated, but rare. Fite in careful study of syphilis of the adrenal based on autopsies of 250 syphilitic infants states that spirochetes could always be demonstrated in the adrenal if they were found elsewhere. In his cases 40 showed some abnormality of the gland, the most frequent lesions being the perinephritis syphilitica described by Simmonds. It may occur in association (see review by Wile) with secondary syphilis or as late manifestation. The symptoms are those of Addison disease, with or without the pigmentary features. I the case under J.H.S. observation (reported by Rowntree) the pigmentary picture was not typical; for long time there was doubt as to the actual involvement of the suprarenal glands, although the patient response to epinephrine settled the question antemortem He died suddenly and at necropsy was found to have suffered destruction of the larger part of the cortex and medulla of both suprarenal glands. Warthin in 2 cases found *Spirochaeta pallida* in the gland cortex.

LATE SYPHILIS OF THE THYROID

Mention has been made of acute hyperthyroidism in the course of early syphilis, of iodide hyperthyroidism due to the action of the drug on adenomas of the gland, of the improvement of symptoms of neurosyphilis under treatment for coincident hypothyroidism, and of symptoms of hyperthyroidism under treatment for syphilis. Gummatous thyroiditis is comparative rarity of which Stokes has seen 2 cases, one of which had been operated upon. Sensar (1918) and Netherton (1933) review the subject in the American literature. The detection of the condition must depend upon collateral signs of syphilis such as can be obtained by the use of routine blood

serologic test. Late syphilitic sclerosis has been described by Simmonds. Suspicion of syphilis or carcinoma should be aroused by the hardness or woody infiltration of the gland. Adherence to or ulceration into the surrounding skin occurs in a number of cases, but was absent in Stokes cases. The process, according to the literature, may involve any portion or all of the gland, and rarely gives rise to symptoms other than those of pressure upon the trachea, which may be serious, and of myxedema, which only occasionally occurs. Symptoms of hyperthyroidism are very rare. The response to treatment is excellent in reasonably early cases, and both those which Stokes observed sustained no serious consequences. The differentiation from malignancy cannot be made on clinical grounds alone.

Syphilis of the Salivary Glands.—Moore and Kemp state that involvement of the salivary glands occurred in 0.07 per cent of syphilitics seen at Johns Hopkins Hospital. Chargin and Rosenthal have recently summarized the literature on syphilitic parotitis, adding 31 cases to the 37 gathered by Gerber previous to 1914. It is apparent that many cases have been mistakenly regarded as Mikulicz syndrome, in which involvement of the lacrimal glands also takes place.

Involvement may occur early or late in syphilis, the early cases being bilateral and running an acute course, the late cases commonly being unilateral and running the slow course characteristic of gumma. Chargin and Rosenthal state that suppuration occasionally occurs in association with early syphilis, and concomitant involvement of the testes has been reported by Mohr. The response to treatment is usually good.

Mikulicz Syndrome.—*The chief symptom of this variable syndrome is a chronic symmetrical painless enlargement of the salivary or lacrimal glands. The etiology is probably a chronic infection, tuberculosis and syphilis having been demonstrated in some cases, with the etiologic agent unknown in the majority (Bunting).* Clinically early lacrimation occurs, with bilateral painless swelling of the lacrimal glands. Ptosis or exophthalmos is usually noted and there may ensue bilateral enlargement of the salivary glands, the parotids being most commonly involved. In a considerable proportion of cases general glandular enlargement develops, and definite leukemic blood picture has been reported. Rowe emphasizes the frequent enlargement of the liver and spleen. Howard states that, in the absence of glandular involvement, the course is benign. Syphilis is responsible for from 10 to 20 per cent of cases, the diagnosis resting entirely on collateral evidence and therapeutic response.

Syphilis of the Pituitary Body.—The literature comprises 30-odd cases, including the reports of Fink (1933), Kennedy and Fisher (1934), Williams (1940). The symptomatology is that of brain gumma plus pituitary disease, and symptoms of the latter may be lacking. Acromegaly does not occur (Fink), the symptoms being those of hypopituitarism. Involvement of adjacent structures may give rise to thalamic symptoms, etc.

Simmonds' Disease.—The syndrome of pituitary insufficiency first described by Simmonds may be syphilitic in origin. The cardinal symptoms of this bizarre disorder are emaciation, falling of the teeth and hair, thickening and loss of luster of the skin, listlessness and pathologic sleep. Affected patients have the appearance and actions of premature senility and Calder has remarked on the similarity to hibernation. In 1700 autopsies in which Simmonds examined the hypophysis there were found 17 cases of metastatic carcinoma, 9 with evidence of syphilitic changes, 9 of tuberculosis, and 20 cases in which the pathology was due to emboli. In the records of 70 cases abstracted from the literature by Calder 7 patients had syphilis of various types. One case showed improvement under antiluetic treatment, in one case the pituitary atrophy was believed due to syphilis and in two cases gumma was reported on pathologic examination. Mention has been made in Chapter XX of the syndrome of diabetes insipidus in association with neurosyphilis and changes in the hypophysis.

Relief of headache and visual disturbances in acromegaly following antisyphilitic treatment has been reported by Schlesinger and by Mingazzini but other symptoms have remained unchanged. Schlesinger also cites several cases of dystrophia adiposogenitalis of hypophyseal origin in association with prenatal syphilis.

Syphilitic Elephantiasis.—Fifteen cases of syphilitic elephantiasis are found in the literature, the process being limited to the genitalia or lower extremities. Fournier described the condition in his text. McDonagh recognized the possibility of confusion with Sabouraud's elephantiasis nostras in sporadic cases, and studied his case carefully for the presence of streptococci, with negative results. This patient recovered rapidly under mercurial therapy. Marshall and also Ingram have reported good response to specific treatment. Ingram's is the only case due to prenatal syphilis. Special care will be necessary after World War II to exclude filarial elephantiasis

CHAPTER XXIII

SYPHILIS IN PUBLIC HEALTH AND MILITARY MEDICINE

A Critical Field.—Under the explosive force of war a whole series of discoveries and critical evaluations of old principles and methods is taking place. It is easy to be optimistic as one observes the spread of serologic testing as a case-uncovering method the shortening of the time of treatment under intensive methods the reduction of risks of serious reaction by newly devised antiarsenical drugs impending improvements in prophylactics and the fall in venereal disease incidence rates both in the American civil population since 1936 and in those under military and quasi-military control. It is equally easy to be pessimistic as one views the enormous extent of the problem the recent rapid rise in incidence in special situations and in nations whose records have shown previous favorable progress the slowness of educational processes; the inertia, not alone in the public at large, but in those by whom the work must be done the unrealistic impracticalities of some of the most important control devices such as prophylaxis the tremendous disseminative influences of war via both the armed forces and the population shift of total mobilization, the perverse genius of alcohol and commercialized sexuality in keeping wide open and even enlarging the channels of dissemination, and the now critical problem of an expanding promiscuity

The Magnitude of the Problem.—The Surgeon General of the United States Public Health Service, Dr Thomas Parran has evidenced his intention of giving to the problem of syphilis during the next decade, or longer a very substantial share of the energies devoted to public health in this country From a recent forceful summary by Parran and Vonderlehr (Plain Words about Venereal Disease, Reynal and Hitchcock, 1941) we quote the most recent and authoritative statements covering the situation in this country

> The estimated prevalence of syphilis in the United States is three million two hundred thousand. The three and fifth persons with syphilis are divided, one for one, between white and colored races. The per cent of syphilis in the nation population is 2.4 to 1.3 for white; 11.9 for colored. One in every 44 persons in the United States has syphilis now The ratio is one in every 77 white, and one in every 8 colored persons. Syphilis is nine times more frequent in the colored than in the white race. It is slightly more frequent in white males than white females in colored females than colored males.

The statistical experience accumulated in thus defining the problem has led to some recent reinterpretations which are described by Vonderlehr and Usilton (1943) as follows, and summarized in Fig 871 quoted from Table V of their article.

> "The new calculated rates of prevalence are higher than the Selectee prevalence rates, the differential increasing with the higher age groups. For instance, among white males, age 21 to 25, the Selectee rate per thousand tested is 10 the calculated rate 14. In the 26 to 30 age group, the Selectee rate is 21 (20.9), the calculated rate 33 (32.6), and in the 31 to 35 age group, the Selectee rate is 36 (37.7), and the calculated rate 53 Again, the Negro rates follow the same general pattern except for the youngest group here the Selectee rate is higher than the calculated rate."

One must bear in mind throughout these discussions that rates are given in terms of number of cases per thousand population, that the incidence or attack rate is the rate of appearance of

new infections, that the prevalence rate represents all forms of syphilis present in the population under consideration at a given time including those uncovered by serologic testing. In interpreting the important Selectee statistics for this country it must be recalled that prevalence among Selectees is based on a count of individuals with positive blood tests, and excludes all those who had at one time acquired syphilis, but as the result of treatment or spontaneous cure, had negative blood tests at the time of examination.

Methods Employed in the American Survey Program.—On the basis of one-day cross-sections (reports from physicians in selected areas of the number of patients under treatment on a given day) and other statistical determinations, it is now definitely known that the minimum number of persons in the United States constantly in need of medical care because of syphilis is 683,000 or 4 per 1,000 population. Annually in the United States a half million cases of early syphilis seek authorized medical care. There is a large though undetermined number of individuals acquiring the infection who neglect treatment until some late manifestation forces them to have attention. As Vonderlehr points out, the disease is never thought of as epidemic in the United States, yet annually there are twice as many new cases of syphilis as scarlet fever, thirteen times as many as diphtheria, twenty-eight times as many as typhoid fever and one and one-half times as many as tuberculosis. The attack rate for syphilis based on a New York State survey is two and a half times as great in cities over ten thousand as in cities under ten thousand, being 414 per 100,000 in the larger cities. The urban attack rate was 40 per cent higher than that for upstate

Fig. 871

THE PREVALENCE RATE OF SYPHILIS AMONG WHITE AND COLORED SELECTEES; AND THE CUMULATED NUMBER OF PERSONS ACQUIRING SYPHILIS BY END OF GIVEN AGE PERIOD FOR WHITE AND COLORED MALES BASED UPON 1936 TO 1937 AND 1940 TO 1941 ATTACK RATES

Prevalence Rate per 1,000 Selectees Examined			Cumulated Number Acquiring Syphilis by End of Given Age Period				
				Using 1936 to 1937 Attack Rates		Using 1940 to 1941 Attack Rates	
Age Group	White	Colored	Given Age	White	Colored	White	Colored
21–25	10.1	191.2	24	19.9	220.8	12.2	136.4
26–30	20.9	293.7	29	40.8	318.6	21.9	243.6
31–35	37.7	357.2	34	58.4	375.2	29.3	301.6

New York. Incomplete reports substantiate the statement that the incidence of the disease is higher in the south (see Fig. 872) owing to the presence of a large infected Negro population. Analyses of the age, sex, and marital status bring out conspicuously the youthfulness of those infected. It is estimated that one fifth acquired the disease before twenty and even that on a national basis 11,000 yearly acquire it between the ages of eleven and fifteen.

The trend of the disease in this country has been investigated as a significant guide to what will be required in its control. From 1919 to 1930 there has, of course, been a gradual increase in the rate of reported cases for the country as a whole. Special surveys have been made to avoid the obvious error of statistics based on mere increase in reported cases. From such consider cessions in special communities aggregating eight and a half million in population, it is apparent that the prevalence rate of syphilis increased between 1927 and 1933, 6.4 per cent; between 1930 and 1934 in Massachusetts it increased 1.5 per cent. The rate for the female increased twelve times that for the male. The morbidity surveys of upstate New York have shown an increase in the prevalence rate for all stages of syphilis of 24 per cent.

In contrast to this increase in reported syphilis of all stages, surveys of special localities for early syphilis have shown such figures as a decrease of 15 per cent between 1927 and 1933 in seventeen selected communities, a decrease of 21 per cent between 1927 and 1933 in Massachusetts; and of 45 per cent in upstate New York during the same period. This decline in early syphilis, it will be seen, is accepted throughout the world as one of the most notable and hopeful

criteria of public health control for the infection. Reported late syphilis increased in the respective groups above mentioned 11 per cent, 19 per cent and 60 per cent. Syphilis in pregnant women, on the other hand, offers a hopeful contrast, with striking declines in certain areas, such as the state of Massachusetts, in which Hinton' examination of the serologic reactions of nearly 8,000 pregnant women between 1918 and 1919 and 17,000 pregnant women between 1930 and 1934, indicated a reduction of 70 per cent in positives and 76 per cent in doubtful serologic reactions, in spite of the employment of much more sensitive tests for a nine-month period in 1934.

Cardiovascular syphilis, so far as available figures indicate, is showing a downward trend in spite of the upward trend of heart disease at adult ages in the general population. In 1914 at the Massachusetts General Hospital, 18 per cent of a group of cardiac cases were due primarily to syphilis, while in 1928 the proportion due primarily or secondarily to syphilis was 5 per cent. The reduction of 20 per cent occurred in aneurysms in the same hospital, and aortic insufficiency and aneurysm have dropped 40 per cent in the United States Army in the ten years ending 1934.

In the field of neurosyphilis, first admission rates for paresis in 500 institutions in the United States show no change from 1922 to 1933, while first admissions for other causes than paresis

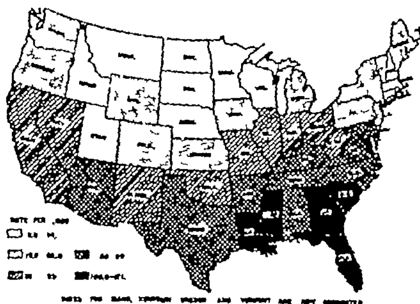

Fig. 372.—Two million selectees blood tested for syphilis. Rates per 1,000 tested for age, race and residence within each state. Reports received November 1940 through August, 1941 (Federal Security Agency United States Public Health Service).

have increased 17 per cent. In Massachusetts a slow decline in the rate for males has been apparent since 1920. Mortality data for paresis in the registration area of 1900 indicated a decline from 1916 to 1933. In New York and Massachusetts there has been a rapid decline from 1924 to 1927 but since 1928 the rate has remained stationary at 3.5 per 100,000 population. The death rate for tabes dorsalis declined from 3 in 1918 to 0.9 in 1933.

It is apparent then, that syphilis is a major if not the major national health problem. Vonderlehr and Usilton have summarized the pre-war status of the United States as of 1941 as follows

It may be reported that in the five-year period from 1936 to 1941, the chance of acquiring syphilis has registered a significant drop. It may be stated further that a new base has been established for measuring the effectiveness of syphilis control activities on the basis of prevalence, and that future measurements against the new base may be related to the pre-war chance calculations.

The precise extent of the gains made up to the onset of the war is summarized in Fig 871 The distribution of syphilis in the United States is graphically portrayed in Fig 872 and regionally summarized in Figure 873.

Smillie has published an interesting commentary on the significance of the foregoing types of figures syphilis as race problem. He contends that in the United States, it is neither an urban disease nor a disease of large cities and seaports; that industrial areas do not suffer to an unusual degree and that the extraordinarily high prevalence of syphilis in the Negro is the basic public health fact which permeates overwhelmingly all other data. The geographical distribution of the disease bears a direct relation to the distribution of the Negro population of the nation, and in those states having the highest syphilis rates in Negroes, there is concomitantly a higher-than-average syphilis rate in white men. The data indicate in his opinion also that syphilis may be brought under some degree of control in the Negro as well as in the white as in Massachusetts and Rhode Island for example. There has been tendency he contends, in official health circles

to gloss over or t ignore the high prevalence of syphilis in the Negro, and the sooner this truth is recognized, nd ppropriat steps are taken t deal with the situation, the better it will be for the Negro race and for the public health of the nation as whole.

Possible Sources of Error —The rapidly developing knowledge of the fallibilities of serologic testing should not be exaggerated as a possible source of statistical error but will undoubtedly require careful analysis. Certainly in figures which admit to consideration patients under treatment for syphilis in the practices of private physicians, there will be as there now very probably is in the armed forces, a significant group placed on treatment for biologic false positive blood tests. There is also some reason to suspect, though its qualifying influence may not be great that there may prove to be a special racial trend toward biologic false positiveness in the Negro that may influence statistics, as biologic false positives undoubtedly influence though slightly the general statistics, based on mass serologic testing It is hardly to be ex

pected however that these considerations will invalidate or reverse the important general principles above set forth.

Experience of Other Nations.—Declines in the incidence of syphilis have been experienced abroad especially in the Scandinavian countries in which the statistical evidence is most direct and Great Britain in which it is, in the main, indirect. It is wise to point out that declines in the incidence of syphilis demonstrable by figures are not necessarily due to public health practice. The existence of waves in the epidemiologic curve of syphilis has been pointed out by von Düring and Gumpert and suggested by Källmark's mathematical analysis. There has been no general demonstrable decline of syphilis throughout the world despite the modern advances in treatment control and educational effort. Substandard treatment has been responsible for bringing to a standstill programs and prospects such as the Belgian, which seemed at the outset certain of success (Schwers) The adverse influence of travel, of fluid population, of heterogeneity in language and race, and of the limited value over a period of years, of publicizing educational methods, has probably left its mark on the progress reports of many countries. The effectiveness of the Scandinavian program for the control of syphilis is conventionally estimated statistically from the incidence rates in three representative cities in 1919 as compared with 1934. In the city of Copenhagen the rate fell from 597 to 28 per 100 000 (divide by 100 for comparison with American rates) in Stockholm the rate declined from 450 to 7 per 100 000 in Oslo, the decline was from 350 to 30 per 100 000

In a country like Great Britain whose practice has had rather more in common with American procedure than the Scandinavian, there are unfortunately no absolutely definitive statistics. The number of cases dealt with for the first time in treatment centers throughout England and Wales has, according to the annual report of the Chief Medical Officer of the Ministry of Health for 1935 been reduced from the peak of 1920 (42,805 cases) to 19,535 in 1935 This represents a 55 per cent reduction and indicates that the volume of syphilis has declined within fifteen years, since the peak, to 45 per cent of the original figure. Known cases of syphilis with infections of less than a year's duration have been reduced from an incidence rate of 2.28 per 10 000 population to 1.47 per 10 000 population in the five-year period 1931–1935 This is a reduction of 35 per cent. The death-rate from infantile congenital syphilis has been reduced by 86 per cent from the peak year of 1917 to the low of 1935

The Effects of War.—The tradition, well established by experience, is that war increases the prevalence of venereal diseases in both civil and military populations. For the armed forces, as presently indicated, the rise in incidence during past wars is easily demonstrated. There are, however no figures at present available, or likely to become available until after the present war for the influence of this conflict on venereal disease incidence in American civil life. One must turn, therefore, to foreign experience, not too satisfactorily delineated, for some indication of what we may expect. Colonel Harrison states that the actual increase in venereal disease in the British civilian population in World War I is unknown, but some idea of it may be gathered from the number of service men who were infected (416 498 British and Dominion soldiers) and from the fact that in 1917 the mortality in infants certified as due to syphilis was nearly twice that in 1913 (ten times that in 1939) and that in 1938 the crude mortality rate of women from aneurysm of

large blood vessels, a disease most commonly due to syphilis contracted many years previously was two and a half times the mortality from the same cause in 1921 The Chief Medical Officer of Scotland reports for the period of World War II that the number of newly infected patients attending civilian treatment centers was 6 433 in 1939 6,851 in 1940 and 10,179 in 1941 The Glasgow figures for new infections were: 1939—300 1940—590 1941—909 The Edinburgh figures were 1939—199 1940—230 1941—444 This amounts practically to a doubling of the incidence of syphilis in Scotland in three years under war conditions. Colonel Harrison reports that in comparison with the rates for 1939 the incidence of early syphilis increased 31 per cent in 1940, 70 per cent in 1941 and 120 per cent in 1942.

While these are the facts, their explanation is as yet not completely determined. The state of affairs they depict should not be too readily ascribed to the presence of a nonresident or foreign army population from nations with differing or lower standards of sexual conduct and so forth. The problem

Fig 674.

OSLER'S REVISION OF BRITISH MORTALITY STATISTICS IN TERMS OF SYPHILIS

	Total	Estimated persons with syphilis
Diseases of the nervous system	58,000	
General paralysis	2,963	2,500
Locomotor ataxia	733	733
Other diseases of the cord	2,616	1,500
Cerebral hemorrhage (apoplexy)	23,485	5,000
Softening of the brain	1 478	[illegible]
Paralysis without specified cause	2,965	[illegible]
Other diseases of nervous system	14,000	2,000
Diseases of the vascular system		
Aneurysm and aortitis	1,141	1,000
Organic disease of heart	46,000	5,000
Diseases of arteries	10,000	2,000
Total	173,383	19 496

Syphilis is responsible for 11 9 per cent. of deaths from nervous and vascular diseases

reflects as much as anything the necessity for use of every resource at whatever cost for the control of the epidemic sweep of venereal disease in time of war The prevalence of syphilis in the armed forces of the United States will be summarized later but at this point it is well to emphasize the general principle that the civilian population is, broadly speaking the source of venereal disease and not the reverse. This makes the figures for the incidence of venereal disease in civilian populations particularly critical and makes the difficulty of securing them under war-time conditions of shortened budgets and reduced personnel especially regrettable

Morbidity and Mortality of Syphilis.—The importance of syphilis as a cause of death cannot be precisely defined. It has disappeared in a forest of symptoms ranging from apoplexy and chronic myocarditis, cirrhosis of the liver Banti's disease adrenal cachexia, uremia in tabes dorsalis, and some of the obscure pictures of syphilitic encephalitis In spite of this beclouding of the situation, attempts at reinterpretation of various categories of the listed

causes of death have apparently indicated that syphilis outranks both pneumonia and tuberculosis as a fatal disease Osler's revision of British mortality statistics in terms of syphilis still stands as probably the most suggestive estimate available (Fig 874)

While Osler placed syphilis, as result of this study first among the causes of death, Downing' reinterpretation of the Massachusetts statistics places it fourth (one death in eighteen) preceded by tuberculosis, pneumonia and cancer Salmon in New York State found that general paresis alone among the innumerable modes of death from syphilis to date stood eighth in the mortality tables, and that it is responsible for one out of every nine deaths between the ages of forty and sixty years.

An interesting study of principal reason why mortality statistics in syphilis are of little value was that carried out by the Westchester County Health Department in New York State (Nicol and Bellows 1934), in which it was apparent that hen physicians were assured that their death certificates were confidentially filed, the reporting of syphilis as cause of death was practically doubled over the original figures. A tabulation of deaths exclusive of stillbirths, and death rates in the United States in 1930, 1934, and 1935, quoted by Nelson and Crain (1938) from the United States Public Health Service Weekly Reports for April, 1930 shows that the reported death rate for syphilis, tabes dorsalis, and general paralysis of the insane was 13 4 per hundred thousand population in 1935 The rates for 1934 and 1930 were 14.0 and 14.1 respectively According to the Westchester County experience, these rates should be doubled to correct for incorrect returns.

The death curves for acquired syphilis have been computed for United States experience by Usilton and Miner (1937) Life expectancy of males with acquired syphilis is shortened from that in the general population from ages thirty to sixty by 17 per cent in the white males and 30 per cent in the Negro males.

Parran (*Shadow on the Land, 1937*) *estimated that syphilis caused 18 per cent of all deaths* from heart disease, but pointed out that this figure required revision because of the inclusion of Negroes, who have an exceptionally high death rate from cardiovascular syphilis. Syphilis accounts for 10 to 18 per cent of the total deaths from cardiovascular disease, and actuaries estimate that the verage patient with cardiovascular syphilis has twenty-two years less to live if untreated, than his normal contemporary Since persons with cardiovascular syphilis die sooner after the disease becomes apparent than other heart disease patients, the proportion of deaths is higher than that of other cases. Of 160,000 Americans with cardiovascular syphilis, 40,000 die each year death rate of one in four Of 2,340,000 Americans with other types of heart disease, 273,300 die each year death rate of one in eight and half In estimating the incidence of cardiovascular syphilis in latent and late syphilis Parran gives figure of 18 per cent based on 17 600 patients.

THE SOCIAL AND ECONOMIC COSTS OF SYPHILIS

The cost accounting of syphilis has the same elements of sketchiness as the estimates of its mortality The chief value of figures is impressionistic and bolsters campaigns for funds more than it illuminates the practice of public health *syphilology* On the other hand, the critical meaning of cost to public health versus private practice care of the disease the extension of laboratory testing facilities under modern standardization procedures which shows some of the characteristics of the production methods in industry the place of free drugs and hospitalization in a program and the costs of clinic, contact tracing and case holding, are real contributions to the brass tacks of syphilis control. In Fig 875 we have summarized the more important categories of figures in a résumé by Beerman (1940) which provides as much tangible information as is generally available.

Clinic versus Private Care and the Costs of Foreshortened Methods.—Attention should also be drawn in this tabular summary (Fig. 875) t comparisons of the cost of private and of clinic care,

as

and to the one available statement regarding the cost of foreshortened intensive treatment in early syphilis (five-day drip) These baseline figures constantly appear in the recent literature in arguments to extend the fields and methods concerned because of their cost availability For example, in the most recent acquisition t the treatment of syphilis, figures are already beginning to appear as to the cost of an eight-day cure in terms of gradually improving methods of manufacture of the agent employed. The ribald suggestion has already been made: "Make the cost of acquiring greater than the cost of cure.

Federal and State Appropriations for Venereal Disease Control.—The figures for the national program are the basis of extremely important estimates for appropriations such as the LaFollette-Bulwinkle National Venereal Disease Control Act passed by Congress in May 1938 This Act

Fig. 875

SOME "COSTS" OF SYPHILIS

1 Cost of national "curative" program, 518,000 cases per year		$14,000,000 to 25,000,000
2. Cost of Hospitalization		
Hospitalization and direct relief (Moore estimate, national scale)	per year	$53,000,000 to 80,000,000
New York City (Goldberg)	per year	$1,000,000
3. Cost in Labor Lost (man hours) in industry (estimate) at $5.00 per day standard treatment, national scale		$83,000,000
4 Costs of Laboratory Tests (actual)		
2400 tests per year	per test	$1.03
6000 tests per year	per test	.56
50,000 tests per year	per test	.29
200,000 tests per year	per test	.18
5 Costs of "Free" Drugs (Health Department purchases)		
Baltimore	per year	$7,000
Buffalo	per year	2,000
Philadelphia	per year	11 000
6. Direct Costs to Cities (special studies)		
Baltimore	per year	$170,000
Buffalo	per year	103,000
7 Per Patient Costs		
a. "Cure private care, standard systems		$300 to 370
b. Cure fresh infections, national program scale (Moore estimate)		25 to 40
"Cure, present clinic practice, at $1.00 per treatment patient visit		75 to 100
		75 to 85
d. "Cure, five-day drip		11.21 to 11.50
Contact tracing and case-holding per year		$15,500,000
8 Cost of Neurosyphilis, New York State, 1931	per year	$10,000,000
9 Cost of Blindness from syphilis, national scale.		
10 Cost of Cardiovascular Syphilis (hospitalized)		
Baltimore		$11,000
Buffalo		8,000
11 For City Budgets, see Fig. 880.		—

Summarized from Deerman, H. Am. J Med. Sci., 190 596, April, 1940. —

authorized $3,000,000 for Federal assistance t the states during the first year $5,000,000 during the second and $7,000,000 during the third year Parran relates that in Jul 1911, a budget bureau cut of more than 50 per cent of the authorized amount was immediately countered by action from the House of Representatives, practically restoring the entire appropriation. In the heyday of expenditure during World War I, have an interesting baseline for program estimates in that the National Government provided $2,700,000 for a single year's program. When recall that the Chamberlain-Kahn Act t its expiration left the program precisely the level, we can realize the really tremendous growth of national purse consciousness, each ascending year after year provisions, of the importance of venereal disease control in several years

An essential part of America's policy is that the states shall be dr to participate at

national program by dollar matching system. For example, in 1938 the State of Pennsylvania appropriated for venereal disease control the sum of $184,000 which was "matched" by $197,000 of Federal funds; Massachusetts in 1937 appropriated $300,000 which was then "matched" by $67,000 of Federal funds. According to Vonderlehr (1942) there was an increase of 24 per cent over 1940 in the budgets of Federal ($6,400,000), State ($3,000,000) and local funds ($3,800,000) for 1941, the third year of activity under the Venereal Disease Control Act of 1938. Of necessity Federal grants in aid must go in increasing proportion to parts of the country where the need is greatest and the per capita capacity to pay is least.

THE GENERAL VENEREAL DISEASE (SYPHILIS) CONTROL PROGRAM

Extent of the Field.—Syphilis should be considered with other venereal diseases because the program of its control extends far beyond merely medical measures. In fact, a major deficiency in syphilis control has been the tendency to focus so closely upon the medical and particularly the treatment aspects of the disease that the full front of the attack was lost in consideration of a single sector. In order to visualize the sectors of the front and the agencies over which syphilis control is distributed, Fig. 876 has been prepared as a teaching program guide against which it is possible to measure the coverage of any individual set-up as well as the direction and development of project plans.

The Grand Strategy.—While the grand strategy of control of a venereal disease may have a central headquarters from which directives issue regarding fronts and agencies, the essence of the control of venereal disease is a local and not a central problem. In the last war all those concerned with venereal disease control, and indeed the public at large, were vigorously impressed at the start by a tremendously positive expression of its intention by the Federal authorities, with the necessary implementing laws to back it. The local disease control agency had its arm strengthened often well in advance of the apparent need, by such implements as Sections 12 and 13 of the Selective Service Act of May 24, 1917, which provided a quick action mechanism for the clean-up of local bad spots. Impressed with the value of such central policy, one is apt to lose his awareness of the fact that local conscience and local practice provide the really lasting foundations of successful venereal disease control. No central policy directive such as this can entirely take the place of the way the home folks feel about it. Even under organizational discipline in the armed forces, the official in charge at a given point distant from the policy forming authority exerts a large personal influence on conditions for which he is responsible, orders from headquarters notwithstanding. Above everything else, a venereal disease control program leaning heavily on vice control and law enforcement in civilian life (Items 6–12 inclusive of the agency groups in Fig. 876) is almost completely at the mercy of local backing. It does not operate by general principles; it sidesteps central direction and is therefore a method with distinctly limited possibilities for the wholesale control of the spread of disease. Such considerations as these make the endless repetition of individual set-ups at individual points where venereal disease is a critical issue an unavoidable necessity. The detail of some of these local groupings is subsequently considered in connection with the armed forces.

Program Types.—Notwithstanding what has been said with reference to the essentially local character of successful venereal disease control solutions, there are program types on a national scale whose basic principles have wide application. A parallel column of the Scandinavian and British types appears in Fig. 877.

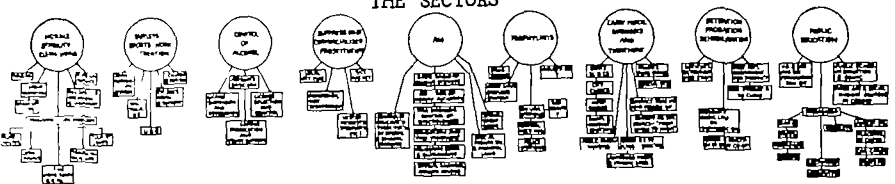

Fig. 876.—A blueprint of venereal disease control.

The United States is at the moment drawing its practice largely from the Scandinavian example. The Scandinavian plan of venereal disease control is probably the oldest in the world the most thoroughly systematized and rests on the most permanent foundation of national character national homogeneity and national intelligence of any body of health legislation in the world (Clarke, 1936) It is essentially an enforcement plan which takes education for granted. It is perhaps to be expected that from Scandinavian sources, the legislatively minded will draw inspiration which unfortunately is not always as effective in a new milieu as its proponents expect it is not received by nor has it the educational and constructive effect on a different type of mind that those who frame it, desire. In contrast with the Scandinavian technic stand the experiences of countries like Great Britain and the Netherlands, in which law and enforcement play a negligible part. While successive surveys of the situation in these two countries before the war tended to disclose results approximating those of the Scandinavian countries, the acid test is now in process of appli-

Fig. 877

PROGRAM TYPES IN VENEREAL DISEASE CONTROL

Scandinavian (Regulation) Type	British (Voluntaristic) Type
1 Complete basic legal structure and respect for law	1 Extreme or ultra-democratic voluntaryism (no compulsion)
2. Reporting and central registration.	2. No reporting or identification.
3. Complete compulsory authority vested in health authority and sanitary police	3. No contact-tracing or treatment attendance follow-up.
4. Treatment obligatory	4. Treatment not obligatory but made attractive as inducement (especial emphasis on convenience)
5. Treatment free for all.	5. Treatment free for all.
6. Advertising (full public)	6. Advertising (conservative).
7 Public education (conservative)	7 Public education (conservative)
8. Punishment for wilful transmission (seldom invoked)	8. No punishment.

THE AMERICAN TYPE IS DISCUSSED IN THE TEXT

cation and insofar as it is possible to appraise results, the shortcomings of a purely voluntaristic plan under certain war emergency conditions are for the moment more apparent.

The American Program.—The stage has been set for the American program by first, the development of standards of medical practice by the work of the Cooperative Clinical Group and the United States Public Health Service in association with the League of Nations Investigation repeatedly referred to in this work second the building up of prestige for the movement by the outspoken expressions and policy of Surgeon General Parran of the United States Public Health Service. Challenged at the start by the refusal of one of the national broadcasting companies to permit him to discuss the subject of syphilis over the air his persistent efforts in the matter have enlisted the interest and cooperation of even the most lethargic members of the medical profession, the press and the public. In fact, so active has the press become that "scoops" are occasionally in print almost before the originators of methods and ideas have clarified their own thinking. The third potent influence is, of

course the provision of the sinews of war in the form of funds under the Social Security Act and subsequent Congressional and State appropriations.

The general outline of the American program can be obtained from the report of the Advisory Committee to the Surgeon General, published by the United States Public Health Service in January 1936. This program provides that the state, municipality or health district which plans to open a campaign against venereal diseases should integrate this work with the Communicable Disease Division of its Health Department, but give it separate direction and a high individual autonomy implied by a full-time venereal disease control officer. A local advisory committee to the health department, coordinating the interests of the venereal disease division, the medical and allied professions and all voluntary agencies, is to be established in each of these jurisdictions. An adequately organized program and proportionate assistance determined by the state venereal disease morbidity rate, are provided for. Adequate treatment facilities in urban communities are to provide (1) for the diagnosis and emergency treatment of any patient who applies, or (2) of any patient who is referred by a private physician either for continued treatment or for consultative advice and opinion, (3) finally, for any patient who is unable to afford private medical care. The establishment of clinic facilities is to be made a matter of conference among various instrumentalities concerned, including medical school, local hospital, research and philanthropic societies with the local organized medical profession and the state and national public health service. Polyclinics are preferred to isolated clinics and the support of subsidized hospitals and health centers is made contingent on their cooperation in the state program. The admission of patients to beds when required for the treatment of syphilis and gonorrhea is made a condition of continued support. Provision is made for the development of a record system for transient and transferred patients. In communities with inadequate treatment facilities, surveys are provided for, followed by a conference of all concerned and a full discussion of the question of enlisting the cooperation of local practitioners, organized branch clinics, new clinics, health education and so forth. The need for abolition of quack remedies and drugstore prescribing is emphasized. In rural communities, emphasis is laid on subventionary assistance of properly qualified local physicians, the services of specially trained county health officers, special provision for transportation of patients to centers and the development of large special treatment centers in areas such as the deep South where many Negro patients are concentrated. Travelling health units are also suggested. It is stated that the free distribution of antisyphilitic drugs by the state to all sources of treatment is rational and proper, and it is advised that two arsenicals and one bismuth preparation be the minimum made available in such a program. The development of a venereal disease diagnostic and treatment center of high rank in each state is strongly urged to serve as a consultation agency for patients, the profession and the clinics throughout the state.

For the first time in its history the venereal disease control movement gives full cognizance to the great importance of epidemiologic work in the control of the disease. Coincidentally follow-up (case holding), long a species of stepchild in the majority of syphilis clinics, has received new and more serious recognition. Both these fields are now conceded to require careful special training for those who devote themselves to them.

In the matter of laboratory facilities the Advisory Committee has unhesitatingly urged the standardization by the state of all serodiagnostic procedures with the maintenance of a careful check even to the point of licensing of private laboratories performing this work. The effects of such recommendations and the results secured are more fully considered in the chapter on serologic tests. In the matter of morbidity and mortality reports, the American program provides for the reporting of all cases by a numerical system including a place of residence if not the name of the patient. Laboratory reports are not to be accepted as case reports. An exceedingly important feature of the modern venereal disease program is the informative and educational program for physicians. There can be no escaping the conviction after a study of this problem that the most serious difficulty confronted by a venereal disease program in a country such as the United States, where a large proportion of patients with syphilis receive treatment at the hands of private physicians, is that of raising the physician's standard of knowledge and technic to that of the modern clinic or above it.

Public Health Law — The issue of compulsion versus voluntarism which appears above in Fig 8— strikes through every question involving the control of venereal disease by laws. In the United States two sharply distinguished and opposed schools of thought exist, the majority we believe favoring legislative sanctions as essential parts of a venereal disease control program affect

they are to be used with discretion and with an appreciation of their educational as well as their compulsory worth. Broadly speaking however we subscribe to the belief that the voluntary approach should be permitted to do its utmost before any attempt is made to use the teeth which the program may provide. It has repeatedly been the testimony of experts who have had at their disposal every resource of police and other forms of compulsion, that the cooperation of the infected individual is vital to a successful epidemiologic approach. Unless the "from whom to whom" principle can be freely applied and elicit a generous and wholehearted response from the victims of the disease in whatever social category they may be found a program will inevitably suffer by the flight of the victims from the agencies which wish to help them.

Public Health Law in Venereal Disease Control.—The field of legal control is marked by two distinguishing facts the evidence of the American's liking for a law and the disposition to write a law on an isolated item or situation whenever such may be brought to a legislator's individual attention. The combination has produced a curious patchwork tissue of state enactments and fragments of enactments, many of them conflicting and anachronistic and many of them without adequate basis in either medical or public health knowledge. Moreover since syphilis has been the proverbial shocker of the legislative mind and the center of social hygiene activity most of the laws concern syphilis and as such fall far short of the requirements for general venereal disease control. The American Social Hygiene Association has been particularly influential in the effort to clear the confusion, systematize the requirements and formulate a standard form of law for the control of venereal diseases which can serve as a reference guide to individual groups making plans. This law is based on certain basic principles summarizable as follows with respect to syphilis. (From Stokes and Ingraham, J.A.M.A. 112 1113 1939.)

Laws regulating the control of syphilis should take account of the enormous variability in individual cases and the positive necessity for expert medical interpretation wherever serious question arises. Laws governing syphilis will tend to be too specific if drawn in too great detail. Insofar as they preserve the right of the state to allow its public health officers to decide by individual local or official regulation in a flexible manner the processes of enforcement and judgment, subject to cooperative interpretation by the court, they are likely to be good. Insofar as the enactments tend to define in days and weeks and to specify in degrees of positiveness and negativeness of the specific tests, they will tend to run into difficulties both in the infliction of injustice on individuals and in unenforceability in the light of expert testimony in the courts. A proposed public health law should be drawn in sufficiently general terms to permit an adequate exercise of individual expert medical judgment and to provide for public health expediency in the individual case without invading the province of morals. In thus allowing adequate exercise of expert medical judgment it is a further though unfortunate necessity that some provision must be made for the prevention of evasion through connivance between patient and physician. This contingency is well met in the New Jersey law for example, which grants to the health officer of the jurisdiction the power of review over medical decisions in individual cases, and even power to appoint his own medical examiner to check the original findings. No single test or single procedure uncontrolled or unchecked should be allowed to make a diagnosis of syphilis. This applies even to the darkfield identification of *Spirochaeta pallida*, a procedure in which even the reasonably experienced may make serious mistakes and over which some form of control and expertness in judgment should be exercised. The limitations of serologic testing have been adequately discussed and emphasis has been repeatedly placed on the difficulties encountered by the venereal disease control officer in his need for definitions of infectiousness and noninfectiousness and his attempts to obtain it (see p. 167). Special legislation for the control of venereal disease should then obviously not be written to depend purely and simply on laboratory tests.

The operability and effect of venereal disease control legislation is materially influenced by a number of considerations, some of which become evident only on an actual attempt at enforcement of previously framed legislation or ordinance. An excellent example and one of the oldest

course, the provision of the sinews of war in the form of funds under the Social Security Act and subsequent Congressional and State appropriations.

The general outline of th American program can be obtained from the report of the Advisory Committee to the Surgeon General, published by the United States Public Health Service in January 1936 This program provides that the state, municipality or health district which plans to open a campaign against venereal diseases should integrate this work with the Communicable Disease Division of its Health Department, but give it separate direction and high individual utonomy implied by full-time venereal disease control officer A local advisory committee to the health department, coordinating the interests of the venereal disease division, the medical and allied professions and all voluntary agencies, is to be established in each of these jurisdictions. An adequately organized program nd proportionate assistance, determined by the stat venereal disease morbidity rate, are provided for Adequate treatment facilities in urban communities are to provide (1) for the diagnosis and emergency treatment of ny patient he applies, or (2) of any patient who is referred by a privat physician either for continued treatment or for consultative advice and opinion; (3) finally for any patient who is unable to afford private medical care. Th establishment of clinic facilities is t be made matter of conference among various instrumentalities concerned, including medical school, local hospital, research and philanthropic societies with the local organized medical profession nd the state and national public health service. Polyclinics are preferred to isolated clinics and the support of subsidized hospitals and health centers is made contingent on their cooperation in the state program. The admission of patients to beds when required for the treatment of syphilis and gonorrhea is made condition of continued support. Provision is made for the development of a record system for transient and transferred patients In communities with inadequate treatment facilities, surveys are provided for followed by a conference of all concerned and full discussion of the question of enlisting the cooperation of local practitioners, organized branch clinics, new clinics, health education and so forth. The need for abolition of quack remedies and drugstore prescribing is emphasized. In rural communities, emphasis is laid on subventionary assistance of properly qualified local physicians, the services of specially trained county health officers, special provision for transportation of patients t centers and the development of large special treatment centers in areas such as the deep South where many Negro patients are concentrated. Travelling health units are also suggested. It is tated that the free distribution of antisyphilitic drugs by the state to all sources of treatment is rational and proper and it is dvised that two arsenicals and one bismuth preparation be the minimum made available in such program. The development of venereal disease diagnostic and treatment center of high rank in each state is strongly urged to serve as consultation agency for patients, the profession and the clinics throughout the state.

For the first time in its history the venereal disease control movement gives full cognizance to th great importance of epidemiologic work in the control of the disease. Coincidentally, follow-up (case holding) long a species of stepchild in the majority of syphilis clinics, has received new and more serious recognition. Both these fields are now conceded to require careful special training for those who devot themselves t them.

I the matter of laboratory facilities the Advisory Committee has unhesitatingly urged the standardization by the stat of all serodiagnostic procedures with the maintenance of careful check even to the point of licensing of private laboratories performing this ork. The effects of such recommendations and the results secured are more fully considered in the chapter on serologic tests. In the matter of morbidity and mortality reports, the American program provides for the reporting of all cases by numerical system including place of residence if not the name of the patient. Laboratory reports are not to be accepted as case reports. An exceedingly important feature of the modern enereal disease program is the informative and educational program for physicians. There ca be no escaping the conviction after study of this problem that the most serious difficulty confronted by venereal disease program in country such as the United States, where large proportion of patients with syphilis receive treatment at the hands of private physicians, is that of raising the physician standard of knowledge and technic to that of the modern clinic or above it

Public Health Law.—The issue of compulsion versus voluntarism which appears above in Fig 87" strikes through every question involving the control of venereal disease by laws In the United States two sharply distinguished and opposed schools of thought exist, the majority we believe favoring legalistic sanctions as essential parts of a venereal disease control program al…

is a species of understanding between courts and health officers as to the best method for meeting the hygienic purposes of the law with due regard for the rights and liberties of the individual.

The questionable value of routine food handlers examinations in controlling the dissemination of syphilis and other communicable diseases under the usual circumstances is well portrayed by Best (1937), who lists the reasons for abandoning this practice in New York City in 1931 after eleven years active trial, as follows (1) the average physician examination cannot be considered reliable. (2) The cost of adequate examination with attendant laboratory procedure is prohibitive and not commensurate with the public health benefits obtained. (3) Even though complete examinations are made, there is no assurance that the food handler will remain free of communicable disease during the tenure of certification. (4) The value of this procedure in preventing the spread of communicable disease such as syphilis is much over-rated.

What has been said with regard to food handlers' examinations applies with equal force to the again much discussed examination of prostitutes, for example, which recognizes them as an occupational class and presumes to indicate that their infectiousness is determinable at any and all times, or at stated times by an examination procedure of routine type. Conductors and dining car waiters, who for years were the only individuals in railroad personnel subjected to any type of examination specifically for syphilis, are probably as far removed from the danger field so far as the public is concerned, as any single group. Gross and improper extensions of the spread of law when it is freed from the individual case are well illustrated by a laboratory worker for example, with congenital syphilis, who because he worked for a milk processing organization was discharged from employment though his contacts were with chemical reagents and had nothing to do with food.

Under the legislation of the past decade, enforcement when projected into the courts has usually been at the expense of what might be called the relatively down-and-out types—persons of no reputation and questionable or "floating" standing in the community against whom it was relatively easy to secure authority from a court for summary action such as examination, detention, and quarantine. It is not to be concluded that the application of summary legislative procedure will be so readily accepted by persons of character standing and resource, as the spread of these laws increases. The question as to whether any person may be obligated under any conception of civil liberties, to undergo testing or examination for the mere existence of disease (and particularly disease implying rightly or wrongly moral turpitude) has had some consideration in the courts, and there have been decisions which have denied to a plaintiff the right to oblige a person under trial to undergo either physical examination or blood test to determine his status with respect to syphilis. It will, therefore, be doubly necessary in order to protect legislation against adverse judicial decisions, to place the responsibility for the interpretation of the blood test not with the law itself but with the physician or properly authorized public health representative.

It has been recognized for some time by claim and damage authorities that when a case involving syphilis as a contributory factor in compensation is brought before a jury it is fundamentally bad policy and likely to lead to adverse decision to force the evidence of syphilis in the injured person before the jury for adjudication. The jury apparently tends to take the view that in attempting to attach syphilis to the issue the defending attorney is endeavoring to besmirch the reputation of the pleader and to deprive him of just compensation on a character irrelevancy.

The question of secrecy and confidence always important in medical matters, has a double importance in all that concerns venereal disease. The mere statement of the law that the record of the test will be filed in confidence with the *state health authorities can be received as only* qualified assurance. Leaks unquestionably can occur and cannot be traced to their sources. The distrust of physicians for this confidential aspect of records is evidenced by their short comings in reporting. Privileged communication and record is an issue in the legal aspects of syphilis. Under Acts of the Pennsylvania Assembly in 1907 for example, hospitals, which are common sources of Fonting information on syphilis, have no right to give data from their records disclosing communications with physicians attending a patient in a professional capacity or information which would tend to blacken the character of the patient without the patient's consent. The sole exceptions are civil cases brought by the patient for damages on account of personal injuries. The constant violation of this law exemplified by correspondence between social service agencies for example, in which positive serologic reports are bandied about without regard to the responsibilities involved, or the protection of the persons concerned, is characteristic. Confidential privilege may be waived by the patient, and such waiver might conceivably be made a stereotyped part of a contract relationship as it now so generally is in life insurance policies.

The Individual Physician.—The individual physician who is medicolegally wise will not disclose information regarding a patient with syphilis to any source except under instruction of legal counsel, unless he is protected by a full release of such information over the signature of the patient. It is even well to be sure that the signature of the patient is genuine

THE PUBLIC HEALTH MECHANISM

General Principles of Control of an Infectious Disease.—The control of syphilis stems from fundamental public health principles which, if kept in mind make clear the purposes of the pyramid of organization which rests upon them and explains some of the avoidable and unavoidable conflicts between public health and private practice which too often stand in the way of disease control. An infectious disease is dealt with by (1) immunization, (2) isolation, (3) sterilization of the infected individual and (4) education of the public with respect to prevention Immunization against syphilis does not exist. Isolation and quarantine in the days of prolonged infectiousness and slow treatment at least, were a practical impossibility used only from time to time as an enforcement demonstration or for flash publicity in special situations. With the development of rapid methods of treatment, quarantine and isolation judiciously applied may grow in importance but since they violate the fundamental principle of voluntaristic control they are, wherever possible second rather than first choices Under war pressure such devices as rapid treatment centers will have their day and their need but their value as permanent constructive solutions of the transmission problem should be closely scrutinized Education of the public, as will presently be seen from a fuller discussion, has between inertia and impracticality an extremely difficult road to travel. There remains therefore, for the control of syphilis, the fundamental public health principle of sterilization of the infected individual. To devise the means for such sterilization, freeing the individual of the infective organisms as completely and rapidly as possible with the smallest possible risk to his life and health is the present *summum bonum* of public health practice in this field. The tremendous advances that are being made in this direction with the shortening of treatment requirements and the use of increasingly effective reactionless spirillicides may make unnecessary a considerable part of the present elaborate structure of public health control.

Organization, Costs and Budgets.—In order to draw adequate control plans, prepare the treatment set up and justify to the public and his constituency the organization and expense involved the health officer must have constantly before his mind the necessity for determination of the prevalence and distribution of the disease with which he is dealing As reporting is popularized and case uncovering more and more fully developed, the disproportion that exists between the cases that become matter of record and pursue uneventfully their treatment course towards infection control and cure and the vast unmeasured body of unidentified disease and suspected or recognized disease which evades or fails to obtain adequate treatment becomes increasingly apparent

As specific example of the importance of thus mapping the ratio between practice and ideals, the experience of Philadelphia is clear but probably not exceptional. Under Ingraham's administration of venereal disease control, the treatment prevalence of syphilis as it might be called (syphilitic persons under treatment) obtained by review of each of the established treatment agencies and 89 per cent of the practicing physicians experience in the community showed

Fig. 578.—Organizational Chart of City Department of Public Health Venereal Disease Control Program. The arrows indicate the directions of supervision or service from the central administrative office. Numerals within the squares show the number of locations or the strength of the staff in each position as the case may be. This is based upon the 1943–44 budget of the City of Philadelphia Venereal Disease Control Division with staff of 113 full time and part time individuals and an annual expenditure of approximately ten cents per capita as outlined in the text on p. 1206.

that in 1940–1941, 4.5 syphilitic persons per thousand population were under treatment. As a result of intensive work by the Division of Venereal Disease Control this had been increased to 7 per thousand by 1943. Contrast this, however with the actual prevalence of syphilis as shown by Selective Service examinations, surveys of occupational groups, particularly in war industries, and the result of premarital and prenatal legislation. The actual prevalence rate of syphilis in this area lies between 28 and 35 per thousand. Thus, despite great efforts and now approximately adequate financial provision for venereal disease control, only about one-fifth of the patients who should be receiving treatment are under medical care. In all probability part of the discrepancy is due to the fact that case-uncovering is a slow process that must be carried along over a period of years to be completely effective.

The type of organization deemed most effective for venereal disease (syphilis) control has already been outlined in general principle, on p. 1196. To give these general principles point, Fig. 878 has been drawn up by Ingraham to present a type of organization applicable to cities (Philadelphia) and in principle also to larger units. This set-up emphasizes what we conceive to be the modern requirements for case-finding in the form of contact-tracing mechanism and the liaison with various possible sources (e.g., the municipal courts) of infectious material. It also shows the

ANALYSIS PHILADELPHIA VENEREAL DISEASE CONTROL PROGRAM BUDGET 1943–44

			Annual Expenditure
1.	Central Administrative Office		$14,110 00
2.	Epidemiology and Attendance Follow-up		66,310 00
	a. Central Registry	$7,310 00	
	b. Central Epidemiologic Unit	33,500 00	
	Clinic & Field Service	14,000 00	
	d. Medical Social Work Consultation and Investigation	7,600 00	
	Consultation Court Cases	3,800 00	
3.	Treatment of Patients		91,731 00
	Medical Service	34,391 00	
	b. Nursing Service	18,400 00	
	Clerical and Janitorial Service	21,140 00	
	d. Drugs and Medical Supplies	17,800 00	
4.	Education Staff and Materials		5,700 00
5.	Miscellaneous expenditures (fixed equipment; replacements; repairs; rent; communications; stenographic, clerical and janitorial supplies)		11,400 00
	Total		$187,701 00

relatively large amount of effort necessary to classify and identify (under suitable protection) the infected individual and to see to it that he pursues treatment to a satisfactory outcome. In other words, a public health organizational set-up which consists simply of clinics for the treatment of individuals is inadequate by modern standards. A very large part of the budget will have to be devoted to reducing the discrepancy between patients under treatment and patients who ought to be under treatment, the quick identification of the infected individual on the street, and the permanent placement of the infected individual in the public health reconstructive program until he has ceased to be a danger either to the community or to himself. It will be recalled that the fundamental principle of free treatment will necessitate a considerable mechanism for the distribution of drugs both to clinics and to private physicians. It will be necessary moreover to expend time, personnel and effort in behalf of those functions of the private physician in public health relationship which he performs with difficulty or which he cannot perform at all (contact-tracing and case-holding).

The budget of an effective venereal disease control unit on a reasonably large scale as above outlined is illustrated in Fig. 879 and shows the tax-payer exactly where his appropriation goes. The largest single item is, of course, treatment, but the epidemiology and attendance follow-up is a close second, and uses 35 per cent of the total available funds.

In order to provide for the control of a large-scale infectious disease situation such as that represented by syphilis, it is desirable as early as possible to give the public some idea of what an effective program should cost. The studies of the past several years, represented particularly by the larger cities, are given in Fig. 880 The per capita basis of cost is now commonly set for an effective program at 10 cents. Cities, such as Chicago, which are trying expensive and important experiments in treatment centralization, easily demonstrate the quick rise in cost which an energetic campaign, involving centralized agencies such as treatment centers, may entail. One of the beneficent effects of war has been the quick acceptance by appropriating agencies of responsibility for bringing their per capita allocations in this field up to the ten-cent standard.

Significance and Appraisal of Educational Effort.—The venereal disease control officer should never give a merely casual acceptance to alleged educational methods and material. In the end his whole program rests upon the case that he can make for the seriousness of his problem, and the prospects of solving it. Accordingly while he subscribes to and uses propaganda, he recognizes its shortcomings, and labors unceasingly to bring to the potential and the actual victim of the disease the knowledge of how to avoid and how to meet the situation.

The last war (World War I) gave the United States an unusual opportunity to test the effectiveness of public education on really massive scale, in the attempt to saturate two million soldiers with what the constituted authorities considered adequate information on venereal disease. Direct methods of ppraisal lacking, an indirect clue to the effect of all this effort consisted in raising of the proportion of patients between 1916 and 1930 who reported t clinic within the first ten days of their syphilitic infections from 2.4 to 4.3 per cent. For examinations within the first fifteen days, the proportion rose from 24 to 35 per cent in fifteen years. It would be unjust, of course, to suggest that this glacial type of advance represents the best that can be done by didactic speech-making, lecturing and the leaflet type of informative propaganda. An attempt to carry the question more directly int the field made by the United States Public Health Service and the American Social Hygiene Association jointly (Edwards and Kinsie, 1940) dealt with the ill-defined but critical question of drug-store prescribing and the common man warenses of what to do if and when he acquired the venereal diseases. This paper (Venereal Disease Information, Vol. 21, p. 1 January 1940) should be read in the original by all those obliged to expend effort on the educational sector of the venereal disease front. Using "plain clothes observers, this study disclosed in 23 cities, 62 per cent of 1,151 drug-stores visited as willing to diagnose and sell remedies for syphilis or gonorrhea; 31 per cent would not diagnose but did sell remedies, especially if asked for by name; only 7 per cent refused to diagnose or sell. In this study it ppeared that the man in the street when asked for advice as to where to go to get fixed up for venereal disease, responded t the extent of 65 4 per cent with advice to the inquirer to seek drug-store, drug-store remedy or self-treatment. In 1935 similar questions had elicited "bad advice in 57.3 per cent and "good advice in 40 per cent.

Not only is there, then, the ever-present stolidity and stodginess of the established, the inertia of the human mind, but conspicuous lack of adequate study of which methods teach what, and how they do it. It is essential before education can mean what it should in the venereal disease field that, among other things, we better understand the human mind, and the modes and motives by hich it resists and absorbs new material. Whether educational forces must be brought to bear purely as matter between individuals or in the mass, through the eye, or through word of mouth is all still unclear The bursts of educational fervor in the press; the introduction *of syphilis int the status of "a cozy household word" as deKruif has put it, are worth a kile, but* partake unfortunately of wave-like ephemeral quality—a flash impressionism and passing worth. It is essential, therefore, that in his public educational work, the health authority be not satisfied alone with posters, moving-pictures and speakers, but shall concern himself with the systematized steady pressure of effort in the home, for example, in the school, in general hygiene education, and so forth. He must be constantly alert to the fact that while good influences are surely expanding and permeating, pornography lubricity and all the forms of literary and cinematic frankness and over-stimulation are not giving ground. No field places greater pressure

upon the public health officer to concern himself with all the broadly human relations of his disease problem than does that of venereal disease control. Though the effectiveness of educational methods in venereal disease control is estimated with difficulty when the public at large is the subject, the increasing budget, the increasing proportion of voluntary cooperation in case-uncovering, mass and individual, the increasing proportion of patients under treatment, as compared with infected individuals identified, provide basic measuring material.

The Cooperation of the Physician.—In the equally important undertaking of educating the medical profession to cooperation, the circular letter the personal questionnaire the activity of the county and state medical society in the field as a result of the venereal disease control officer s efforts to contact the physicians of his jurisdiction, the non-responsiveness on the part of the private physician frequently lamented by the health officer may be a matter of technic.

The public health authority in Philadelphia found, for example, that the placing of request in the bulletin of the county society for the names of physicians willing to treat venereal disease brought only approximately forty responses. When an adequate explanatory letter with reasonably framed and brief questionnaire regarding the physician practice interest and actual venereal disease clientele was mailed to every physician in the city 2600 replies were received from the group of 3300 practicing physicians. Of these, 1600 stated that they treated venereal disease, and 1100 expressed willingness to have patients referred to them by the City Venereal Disease Control Division. Contrast this with the forty replies to the notice in the Weekly Roster It is increasingly apparent that campaigns that consume their own smoke are direct appeals to the key persons in groups in the public health situation involved, and have much better prospect of return on the educational effort than fire-works discharged over the heads of the public at large

Mechanisms—Reporting Case-Finding, Statistics.—Two methods of reporting are at present in use. The first is the individual physician s venereal disease report card to State or municipal public health headquarters, which is so often a mystery even to consultants in venereal disease that a typical example with its appropriate instructions is given in Fig. 881 This form of report card provides for the (optional) use of a number instead of a name and address, the name and address usually being supplied only in the case of delinquent and uncooperative persons. Clinic reporting in a large proportion of the clinics of the United States is at present conducted through a central tabulating system developed and described by Usilton of the United States Public Health Service to whose description reference should be had (Venereal Disease Information, 21 61 March 1940) The information collected on the forms is transferred to punch cards which make possible the precise evaluation of the clinic material, the contact-tracing and the follow-up efforts included. Adequate reports of clinic performance are returned to the source on a monthly basis. The tabulating centers are allocated on a state or regional basis.

Case-finding involves the individual personalized mechanism for finding the infected person described under "patient control," below and the employment of mass serologic testing which has become prominent in the past few years. The first requisite to a wide employment of mass serologic testing whether legally sanctioned or voluntary is a dependable laboratory system. The really colossal mass serologic survey of the Selective Service System would have been impossible without the years of spade-work in the development of adequate state and municipal laboratories whose test results could be trusted. An approval system for private laboratories must be developed parallel. The public health officer controlling syphilis must not let his enthusiasm for case-finding lead to undiscriminating use of mass testing methods.

The margin of error is sufficiently serious and the interpretative difficulties sufficiently great so that he must provide for adequate evaluating mechanisms both for the sake of the individual case discovered and for his statistical records as a whole. In setting up mass testing demonstrations, it is necessary to make it clear to cooperating physicians that serologic reports are not case reports and that individuals with positive serologic tests must be examined. It is, we believe, bad practice to set up any mass testing demonstration in which the tested individuals are supplied direct with the results of their blood tests.

M.D.

Fig. 881.—Venereal disease report card. This report card serves a fourfold purpose and may be used to (1) report venereal disease; (2) report a delinquent patient for Health Department action; (3) report an individual who has been exposed to a venereal disease; (4) request drugs for the treatment of low fee patients, literature for patient education, and additional report cards. All information is kept confidential by returning in the enclosed business reply envelopes, postage to be paid by the Health Department.

Self interpretation under such circumstances is only too common, and the name of the home or referring physician to whom to send the report should be supplied by the patient or the patient should be told to visit a physician (preferably name and address given) to receive the interpretation of his result. The mechanism for the interpretation of serologic tests has been sufficiently discussed in Chapter IV.

The statistics obtained by the foregoing types of effort are the beginning and not the end of the venereologist's troubles. Discarding summary judgment, such as "lies, damn lies and statistics," it may well be insisted that the

public health authority should scrutinize and rescrutinize and publicize only after such scrutiny the results of all forms of case-finding efforts.

An excellent illustration of a typical problem in statistical epidemiology is provided by the experience of Philadelphia, following the reports of syphilis incidence based on Selectee statistics. In the Journal of the American Medical Association, an authority made the statement, "Philadelphia, with a rate of 41 7 per thousand, has the highest rate among the cities of one million population or more. Ingraham as Venereal Disease Control Director for the City conducted with the cooperation of the Public Health Service, which was the source of the statistics an analytical study based upon race, age and sex distribution figures from these same Selectee statistics, a survey which brought out the following facts: the rate through August 1941 for 14 of the largest cities in the country shows that Philadelphia with a rate of 8.5 per thousand among its white Selectees and volunteers, has the lowest rate in the country of any city of comparable size except Milwaukee, and with a rate of 182.2 per thousand among its Negro Selectees, is eighth from the top: San Francisco, Chicago, St. Louis, Los Angeles, Washington, D C., Buffalo, and Baltimore all having higher rates. In other words, a critical analysis of "flash" epidemiologic statistics, indicated that Philadelphia, far from having the highest, may have one of the lowest syphilis rates of the larger cities in the country

Spot mapping is often the highly useful visual aid that follows statistical epidemiology This type of pin-placement on a map provides the graphic inspiration for campaigns as well as a vivid demonstration to legislative sources of funds.

Sterilization of the Infected Person.—This, the key to the disease control situation in syphilis, must not only be clear to the venereal disease control officer and all his personnel, but must be sold as a treatment concept to the medical profession and to the public. The principles involved have been fully discussed under the control of infectiousness and in connection with the various drugs used in treatment.

The seriousness of a mistake in national policy in selecting an inferior spirillicide as the sentimental or economic choice over an arsphenamine was illustrated by the experience of pre-war France in which Jeanselme for example, was able to present to the French Dermatological Society evidence indicating that the national preference for bismuth, as a French discovery over salvarsan, as a German discovery had led to a serious prolongation of the infectious period of the disease in the individual patient. The struggle of the health officer to pin the syphilologist down to a "treatment to noninfectiousness" standard as a matter of budgetary economy and simplification of follow-up has been mentioned. Curiously enough "20–20" (20 arsenical and 20 bismuth injections), never actually proposed for the purpose by the authorities credited with it, has increasingly established itself as a fairly dependable amount of treatment for the reduction of the aggregate infective material to noninfectiousness. In the establishment of a time-interval between lapse or failure to report and time of reporting an individual case to the health authority the efficacy of an arsenical must be borne in mind, and two weeks is the maximum period (1 per of two treatments) that it is safe to allow before reporting by name is insisted upon. Similarly it is necessary to bear in mind, and to bring home to the practicing physician, the existence of treatment-resistant syphilis which fails of sterilization by the arsenicals, or expresses itself in repeated infectious relapse, particularly after a small amount of irregularly administered therapy. The oncoming of intensive treatment for early syphilis, plus the pressure of war emergency plus the prospect in the offing, of an extremely effective spirillicide whose administration is a reactionless nondangerous procedure compressible into approximately a week, is likely to transform many of our conceptions of the public health technic of sterilization of the infected individual. The rapid treatment center as a method of removing and "cleaning up" the most tarnished element of the community may ultimately find itself extended in the larger municipalities, especially to mass hospitalization comparable to the Chicago fever treatment center fully described by Sandeson, Bauer, Kendell and collaborators (J.A.M.A. 123:816, Nov 27 1943). Insofar as this simplifies or reduces the cost of multiple state management of the problem of infectiousness, it may be rated as an advance.

Compulsory Treatment or Quarantine.—Florid methods of dealing with the venereal diseases are of course, to be deprecated but compulsion must at

times be exercised This the health officer has authority to do under the general health law of the state or municipality through the use of a court order or bench warrant, either by incarcerating the person in a contagious disease hospital or quarantining him in his home under placard. Relatively little use is made of the last method mentioned, but the authority to do so is one of the most important of the resources of the health officer in dealing with the venereal diseases.

An essential element of this authority repeatedly supported by the courts is the doctrine of "reasonable suspicion," which makes possible the tremendously strategic examination of the patient as part or sequel of his quarantine or isolation as reasonably suspected" source of infection. The prostitute falls under special criminal classification in both the public health and criminal law and, upon conviction as a prostitute, she can be subjected both to examination and detention without further action. As will presently appear the examination and detention-on-suspicion technic is falling afoul under war emergency pressure of the many problems connected with complaints against a source of infection. In this country so generous has been the law's interpretation of the authority of health officer that almost anything not too palpably outrageous can be expected to work in an emergency but this does not justify the undiscriminating use of authority to force examination and detention as primary resource in dealing with local critical dissemination problems. It is always wise after the emergency is over to back-track; examine the legal standing of the methods employed, and then, if it seems desirable, to introduce by way of ordinance and enactment such measures as may make extrajuridical forcing of the public health authority less necessary

Free Treatment Clinic versus Doctor, and the Indigency Line.—In his obligation to provide free treatment (and incidentally free diagnosis to those who need it) the health officer in this country must take cognizance of the fact that 55 per cent of the physicians engaged in private practice do not treat syphilis at all. Slightly more than 50 per cent of all patients known to have the disease are treated in clinics. In some areas (St. Louis, for example), 65 per cent of syphilitic individuals are cared for by 5 per cent of the physicians. It is clear that of necessity therefore the clinic must be an important and indeed a major instrument in the treatment mechanism. A practical demonstration of its importance is found in the figures given by Vonderlehr which show an increase in the number of State Health Department clinics in the United States from 1 122, in 1938, to 3,245 in 1941 to meet an increase in case load from 140 434 to 340 615 This increase in number and responsibility is taking place despite the easily recognizable and to some extent inevitable limitations of the clinic as a mechanism for handling venereal disease. Clinic practice in the United States was rated in 1930 as only 25 per cent efficient, and for the potential case load only 10 per cent.

MacNealy and Pearson (1937) presented a devastating indictment of the venereal disease clinic practice of this country pointing out the lack of basic understanding of the problem, the limited scope of service the desultory extraclinical investigation, the incomplete recording of significant information the failure to utilize appropriate diagnostic aids; and the failure to control irregularities in treatment as primary and almost omnipresent defects. The international investigation by the League of Nations Commission disclosed not only inadequacies in diagnosis and treatment among the selected clinics of the world but that clinic chiefs themselves were unaware of the procedure of their own clinics and lived in dream-state in which their conceptions of ideal practice and the methods of their clinics showed no conformity whatever Notwithstanding all these strictures, however clinic practice can be made to align itself to a presentable degree with high modern standards and in many cases does better but it even at worst, than the general practitioner of the same area does at best.

The basic requirements for a good clinic may be listed as follows (1) a properly chosen head or director ideally full time or at least half time whose

personal enthusiasm inspirational power and standing as an expert are paramount. (2) The remainder of the staff must be not only professionally adequate but of a human type that enlists the cooperation not to say the affection and trust of the patients. (3) The physical equipment of the clinic should provide for privacy and if at all possible, the separation of the sexes. (4) Privacy is particularly essential in the preliminary history-taking and subsequent contact-tracing and case-holding interviews, and in the physical examination of the patient which should take place in an individual room or cubicle (5) Darkfield apparatus, in the present organization of most public health clinics, is essential (6) Equipment for the giving of treatment, which is plentiful enough and maintained in sufficiently good condition so that no disgraceful short-cuts can be justified and discomfort to the patient, that ever-present cause of lapse, shall be minimized. (7) Since it is preferable that clinics be part of general medical and diagnostic centers rather than *ad hoc* beds for the care of the more serious aspects of syphilis, for the isolation of the infectious case and for the treatment of neurosyphilis can and should be available. This does not mean however that every individual clinic for the mass treatment of syphilis should have electrocardiographic and fluoroscopic equipment. (8) Day and night clinics are essential. (9) So far as possible, infants, children and adolescents and congenital syphilis and pregnant women are to be taken care of in special groups.

McKneely and Pearson (1937) list, as evidence that clinic has obtained reasonable degree of perfection when there exists clear comprehension on the part of the administrators of the problem in all its aspects; an inclusive service reaching all types of cases maternity cases in particular an effective plan for seeking sources of infection, contacts and delinquent patients, and for observing temporarily those discharged an accurate system of records giving personal history physical findings, serologic tests and treatment response of each applicant; an adequate diagnosis based on history physical examination and appropriate laboratory tests, and the use of an accepted scheme of treatment adapted to the needs of the individual.

The indigency line cuts directly across the clinic s organization and problems, and is the chief source of controversy between private and public health practice in this field at the present time. Unquestionably if the health officer will temper his zeal for ideal results by accepting and indeed seeking private medical cooperation, extraordinarily effective response may be forthcoming Suspicion and misunderstanding, on the other hand will lead to a stymie which is sometimes extremely serious, especially when a medical society with a well-organized legislative program and floor representation takes the field. The result of a personal approach to a large group of physicians in a city area has been presented on p 1205 Consistent assurance that the case-uncovering methods employed are not intended to recruit patients for state or city clinics, but that uncovered cases will be turned over to private physician cooperators who are genuine cooperators, very quickly opens the door to better understanding. In addition, an active effort to make available to the busy practitioner consultative service and instructional programs, usually meets with excellent response. The teaching methods employed should be preferably those of case-teaching, individual consultation, demonstration *before small groups in a suitably* equipped setting—rather than lectures, orations and formal scientific papers, though the latter if reinforced by visual and printed summaries and material, may be made effective. The popular radio broadcast, the use of lantern-slides and moving-pictures, are, in our

opinion, distinctly second in worth to methods based upon the actual demonstration of case or technic.

Consultation by correspondence has been presented t some extent on p 136 to indicate the type of question in which the practitioner is interested. Such consultative aid is unquestionably desirable, but may be limited by the malpractice laws and interpretations of the locale in which it is to be developed. A study of medical educational requirements for students suggests that fifty-six teaching hours, 250 pages of text, and demonstration of 80 to 100 actual patients in the third curricular year are reasonably effective. The minimum which the student needs for a public health program is the ability to collect and mail specimens, interpret reports, prepare and properly inject the best spirillicides and heavy metal preparations; ability to control and prevent reactions to master schedule for early and prenatal syphilis; t keep out of trouble in latent and lat syphilis, and cooperate willingly with the state and individual consultants in their special responsibilities and procedures.

Patient Control.—Some of the most important developments in the past decade of public health practice have been in this field, and the whole subject needs to be understood better by the private physician, in order that he may avail himself of state service, and thus contribute enormously to the control of the disease Case-finding has been discussed in its mass-testing aspects. Individual case-finding or contact tracing is an art rather than a science Effective case-finding like effective case-holding or follow-up, begins not as the patient leaves, but as he enters the physician s office or the clinic. Upon the impress made in the first interview and specifically the impress made by the physician quite as much as the specialized worker depends all the future success or failure of the effort to find out, from whom to whom" the infection has passed and to induce each and every source and carrier to begin treatment and pursue it to recovery

The original contact tracers were first, public health officers, such as Munson, ho deserves the credit for originating the present-day emphasis on the epidemiologic approach to the disease, and ho hunted it from point to point as the carrier moved, in what he called "mole-leather epidemiology His work and principles were taken up and expanded by social orkers such as Jal MacPhillips nd Louise B Ingraham. Their work made it clear that the contact tracer is not an occupationally classified individual ith diploma and certification, but an adept who combines number of qualities not necessarily confined to medical or nursing public health personnel. It has been one of the interesting observations of World War II that wide variety of people, provided they have human—one might almost say salesman or salesman-detective—approach, make excellent contact tracers The most strikingly original work done by physicians in the United States has been that of Smith nd Brumfield at the University of Virginia. Studies of the technic and problems of contact tracing and follow-up have indicated superiority of the voluntary approach over compulsion or enforcement tactics which ca be stated in percentages, as summarized by the Ingrahams. Their ork indicates that the employment of confidential persuasive approach to elicit voluntary response from the patient, in the hands of trained individual, is about half again as productive of usable epidemiologic information as is the untrained coercive approach. This applies also to persuasion of the contact to submit to medical examination. The natural" who does this work most successfully has the true sleuthing and portrait-classifying type of mind. Clues such as bent lamp-post at an assignation corner a cast in the eye tint of hair some quirk in the method by hich the prostitute contact "rolls" the victim, provide the basis for building up identities in remarkable fashion. When it is considered that the source of much contact tracing material is the befuddled if not intoxicated individual, the difficulties which the verage doctor may encounter in tracing the source can be imagined.

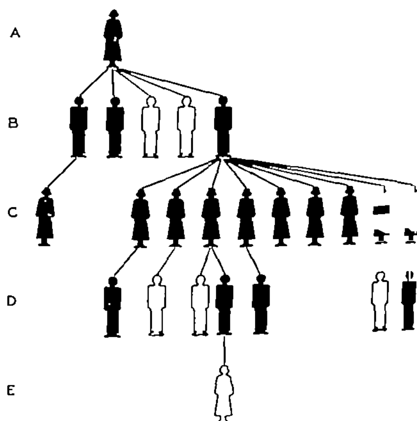
In order to make clearer the picture of the contact tracer as one of the most important instruments of present public health venereology Fig 83! has been prepared

Individual case-finding has revealed, as nothing else has ever done before, the trickle of venereal infection, syphilis specifically through all strata of the community and over the entire country-side. Particularly effective diagrams in the trousers and skirt pattern are reproduced in Figs. 883 and 884 The latter by E. Gurney Clark, illustrates the interweaving of husband, wife and children into the fabric of prostitute and prison over the country-side from state to state and town to town. It is clear despite the obvious duty of the physician to whom an infectious patient presents himself to find out "from

Fig. 882.

THE CONTACT TRACER (EPIDEMIOLOGIC WORKER)

1 The contact tracer is person, male or female, who has, or can develop, the knack of (a) getting venereally infected person confidence; (b) getting the names and whereabouts of the sexual contacts before and after development of disease; (c) persuading all persons exposed t come in for medical examination.
2. A contact tracer must be trusted and trustworthy in the estimation of wid range of people including ( ) the family (b) the young beginner (c) the frightened or the nonchalant, (d) the merely weak, (e) the amoral and asocial, (f) the vicious, (g) those ho have social and personal stake in concealment.
3. A contact tracer must be voluntarist—must think of force last, not first, as contrasted ith enforcement practice. In this lies the secret of his capacity and power
4. A contact tracer must know something of the diseases, the gonorrhea, "the ropes (local, political, legal, professional) and in war the military and naval channels and set-up.
5 A contact tracer must have catalogue mind and photographic memory comparable t that of the best enforcement and detective officer
6. A contact tracer must know his "territory" intimately if he is responsible for regional problem—the whereabouts of infected persons (treatment register), of local infection groups, of treatment facilities, etc.
7 A contact tracer must be incorruptible preserve the professional confidence, be entrustable with records.
8. A contact tracer must have the personality art and persistence to get his man (or woman) in whatever situation he (or she) may be found; on the street, in the taproom, in the brothel; in the parked car or over the kitchen stove, behind the counter or at the machine; in the dra ing room or the hot spot, in the hospital or clinic.
9 A contact tracer may be "natural, intuitively equal to all these roles, or trained specialist in one or more of them, as the visiting or public health nurse is in the family
10 The principles of effective contact-tracing can be taught but personality is the key



The qualities of training that make good contact tracer make good person to induce patients to continue treatment until cured. This is called case-holding" or "follow-up" and where the duties are combined one speaks of "contact-tracing and case-holding personnel.

whom to whom," that unless he is himself adept, he will need an interested specialized assistant to unravel even the more ordinary chains of distribution.

I "The Management of Syphilis in General Practice, the United States Public Health Service has outlined the commoner types of investigation of contacts, emphasizing the obligation t present fully to the infected individual the reasons hy it is necessary that he be requested to expose the details of his personal conduct, of his sexual experiences and partners. He must know that his contacts may not experience warning symptoms such as his which indicate the need for medical care an inadvertent tragedy may follow his failure to share his knowledge and his warning with them. Resentment against his supposed infector may be reduced to minimum by showing him that he voluntarily risked infection and that the individual from hom he has acquired his infection is likely as blameless as he is in illfully spreading the disease. I the case of marital partners, the question of infidelity presents complication of more serious nature, but tactfully handled it is by no means insurmountable. The promiscuous husband can often seek safety in

admitting premarital exposure; others must find their means of inducing husbands or wives to be examined through various ruses when overt confession seems impossible. The contact is best approached through the informed original patient, but when this means fails, other methods may be resorted to, and the health authorities called in. To provide the patient with even the phraseology with which to approach his contact, to meet the family complications where infidelity has occurred, through established round-about approaches to a problem seemingly in-

HOW SYPHILIS SPREADS

BLACK FIGURES PERSONS EXAMINED AND FOUND INFECTED
OUTLINE FIGURES CONTACTS EXAMINED BUT NOT FOUND INFECTED

Fig 883.—A physician in a middlewestern city asked the State Health Department to trace the source of infection in 5 cases of newly acquired infectious syphilis in his practice, all men (*B*). The infection of all 5 was traced back to 1 woman, *prostitute* (*A*). Then the inquiry turned to persons whom these men might have infected. It was discovered that 1 man had infected 1 girl, and another man 9 girls, of whom 8 were under 18 years of age (*C*). Of these, 4 girls in turn infected 4 other men (*D*). In all 21 persons were examined and 18 were found infected and placed under treatment. (Data furnished by the Minnesota Department of Health. Chart by the American Social Hygiene Association.)

surmountable directly, may require more time and ingenuity than the physician cares to give to it. In such case, absolutely no hesitation should be felt in requesting the city or state authority to supply a confidential investigator. Modern practice has achieved sufficient dependability so that no one's interest will be violated by such an intervention.

Case-holding or follow up, as has been previously pointed out, is not likely to lose in importance with any changes immediately to be anticipated

in the management of syphilis as a disease. It will be as important to follow the recipient of five-day drip or other foreshortened procedure as to hold the patient who must take sixty-five weeks of standard treatment to a tedious regimen. The same qualities that make a good contact tracer tend to make a good follow-up worker

Fig. 264.

The follow-up is controlled from the clinic by tickler calendar or by the central tabulating system which warns specifically that given individual has lapsed treatment. The very common practice of sending out letter protected by various devices against falling into the wrong hands, or non-return if undeliverable, is the least satisfactory of all effort of this kind. It usually brings return of not more than 10 per cent of the lapsers. The problem of false address, always difficult to meet, may be approached by mailing letter to the individual on the day he gives the address,

and then attempting t straighten out the false address muddle if the letter is returned unclaimed, before the patient disappears completely Where a tickler reminder fails to provoke a response, a more personal letter may follow perhaps more peremptory in tone and then the next step must be personal visit by a follow-up worker Public health urses, as follow-up workers, are excellent, particularly in the domain of the family and visiting nursing organizations also furnish valuable aids. In the pursuit of infected individuals into the underworld, objection has been made to the use of the public health nurse, but much depends upon the characteristics of the worker, and one who can perform adequately in the contact tracing field rarely fails in case-holding. The question as to when compulsion shall be invoked to oblige the recalcitrant to return for treatment cannot be categorically answered In the verage clinic, according to Ingraham's study of the problem, 70 t 90 per cent of patients disappear within a year Adequate instruction of the average new patient, as to the public health implications of his disease, is capable of improving clinic attendance only about 5 per cent. An active follow-up service ith threat of compulsion when necessary and the occasional pplication of the teeth of the law to bite the recalcitrant offender is capable of holding 70 per cent of the early infectious cases for the required period of time. Colored patients conform t treatment standards much less readily than the white. The hit man is the most susceptible t obligatory treatment methods, the colored man and woman next, and the white woman least of all.

The employment of the public health nurse in this field has been supplemented during the inadequacies of the present war by the so-called male investigator an advanced type of contact tracer often with an exceptional preparation, who is capable of organizing a considerable field, developing n acquaintance with an entire state problem and pursuing individuals not only ver the network of his own state but into surrounding states and over the country at large Such individuals are particularly important when large bodies of the population, military and civil, are on the move as in World War II, nd there are reasons to believe they should form part of the permanent venereologic establishment.

The community resources vailable for contact-tracing and case-holding are numerous and complex, nd are enumerated below The practicing physician who senses the need for study of other members of the family for example, may appeal to another physician who knows the family better than he does, but when the investigation gets beyond this point, he is wisest to ask his city or state health authority for the assistance of confidential investigator

Study and Control of the Carrier and the Reservoir.—Much of this material falls under the control of prostitution dealt ith below The question as to just how far the health officer shall go in his study of conditions hich create infection foci in community is difficult to say He rapidly finds himself becoming amateur and not too effectual sociologist or police officer Nonetheless, it has seemed to us essential that the public health officer have at least some acquaintance th the conditions in his terrain that create carrier foci, and that he shall map as precisely as possible and study the set-up of such foci. I cities in hich segregated districts do or have existed the location of clinics and prophylactic facilities often depends on an intimate survey of such conditions. The health department should therefore not leave holly to the police its knowledge of the hereabouts of distributors of disease, and should not too readily accept the st tement made by the police authority that all is quiet on the Western front. Nothing assists more to comprehension of the focal distribution of carriers nd reservoirs than does the action of ell coordinated contact tracing group which quickly demonstrates not only the center from hich trouble is coming, but the infinite network over which it flows into the community t large (see Figs. 883 and 884)

THE USE OF COOPERATING AGENCIES AND RESOURCES

The Enforcement and Probation Authorities.—The relation of public health practice to the law has long been a bone of contention. What one might call the old-line health officer repudiates vigorously any idea that he should assume responsibility for or even have guilty knowledge of the legal borderland of his terrain Nonetheless it is inescapably true that many of the most effective workers in the public health field have had almost an intimate knowledge of the functioning of law and court in an harmonious relationship with the health authority Reference has already been made to the necessity for such an understanding in the enforcement of the newer types of law (p. 1211) One of the justifiable reasons why even those health officers who have had guilty knowledge of law enforcement are showing a disposition to retreat from

the idea of participation has been the growing observable tendency on the part of the courts to absorb the functions of medical judgment in deciding whether or not a person accused of crime or sex delinquency shall be held for having or being suspected of having a venereal disease. This substitution of a medical for a legal basis of decision has several disadvantages, chief among which is the disposition to discharge all undoubted prostitutes and *ipso facto* disseminators of venereal disease from custody (isolation) upon a negative medical examination report. The venereal disease control officer especially in times of emergency like the present, may justly contend that a prostitute should be convicted for the legal crime of prostitution and detained accordingly leaving the question of the significance of her positive or negative medical findings wholly to the health authority With the incertitude attaching to negative serologic tests and negative smear examinations for gonorrhea, it is easy to understand the necessity for this contention. The court should stick to the law the health officer to the medicine.

In order to clarify to the law enforcement group the present situation with reference to venereal disease, a summary of some new and old principles was presented by Stokes (Ven. Dis. Inform. 23:303 November 1942) These are incorporated in the following summary and will serve as a practical basis of discussion for those physicians and health officers who are expanding their contacts with the enforcement authorities.

WHAT A LAW ENFORCEMENT GROUP SHOULD KNOW ABOUT VENEREAL DISEASES

A Summary of Some New and Old Principles

1 Emphasis should be shifted from "prostitution (solicitation and price) to promiscuity in sexual relations, as the basis at law of enforcement procedure. How does the law under which you work define the potential transmitter of VD as one whose sex is "for sale or one who is merely promiscuous The latter legal definition of "prostitute is closer to what you want.

2. Changing times have brought changing customs. Electricity gasoline, and rubber have dressed Venus in new clothes, provided whole new court and retinue. The telephone, the automobile, the taxicab, trailer and bus lines to everywhere; modern business organization from hot spot to card catalogue, to call girl, to chain service, city to city have promoted accessibility elusiveness, and concealment. The condom index (inspect the dooryards and pavements in the morning) in apartment house districts must now be studied rather than the count of doors in the out-dated "red-light district. The drugstore booth, pinball and telephone service and their patrons, the dog-walkers, cruising cars and convention get togethers quite as much as the bars, the taverns, clubs, hotel lobbies and bus terminals, need surveillance.

3. The purveying of sexual pleasure used to be professional specialty The hip flask, the automobile, and the scarification of young and old during and since "prohibition, have made it amateur sport. Under the emotional tensions of war the players become innumerable, and women especially may abandon themselves to relations under cloak of duty good-will, "last fling that put the enforcement mechanism y out on the edge of the problem. The girl-friend becomes anyone, anywhere, out for good time. The zipper the simplification of clothing, the car the tourist camp, the invariable presence of alcohol—the ounce too much—has spread the transmission of the venereal diseases all over the place. The gas and rubber shortage is actually card in law enforcement hand.

4 Today the field or generalized formula of VD control problem presents the following elements:

( ) Youth—desired, desiring emotional, unstable, mobile and unattached, roving, financially without stake or resource. VD is youth problem. The younger the carrier and the younger the infection, the more dangerous. The "boiled owls are more apt to be harmless.

(b) A get-together contact or dating mechanism, by which boy meets girl—e.g school, club, phone, park, dance, taproom, local groups in neighborhood contacts, job and work contacts, eating, boarding and rooming contacts.

( ) A brake-remover—usually alcohol, playing the unvarying and monotonous prelude to venery

(d) A place to do it. Where shall we draw the line? Where the lights are more than 50 feet apart, up the elevator shaft of the hotel five miles out on the state highway between the servant's bedroom on the top floor and the living quarters?

5. As a problem (and it is always a local one) is tested or analyzed by this formula it becomes clearer where the preventive or controlling emphasis must be placed, and the agencies that must be called on to deal with each subdivision. Where is youth in the picture (juvenile court, probation, the policewoman) what the get togethers how does the brake-remover enter the problem (don't forget local standards and morals) where is the place and how can it be dealt with? An all-out program deals with all.

6. Into those parts of the formula that enforcement cannot reach, the contact tracer carries the individualized confidential approach. He (or she) discovers the garage that is the rendezvous for a group of perverts who have been introduced to the spiral germ of syphilis by one infected member—the five families in one blind alley stirred into a venereal omelet—and so on.

7. Well-considered experience indicates that the health department or officer through the stories obtained from patients in the clinics to which year in and year out they go for treatment, uncovers from 20 to 40 times as many sources or carriers of venereal disease as does the examining mechanism associated with the courts. Nothing shows more clearly that prostitution is no longer, if it ever was, the principal commercialized source of venereal infection. Nothing shows better the need for close cooperation between courts and health departments in the effort to control the spread of disease. The contact tracer can usually add new infection carrying links, even to a court chain, in persons never brought to the attention of the law.

8. Every infectious case, every person complained of as a source of infection whose identity can be secured in an enforcement procedure, is a priceless lead to the VD control officer in following up the trickle of infection, the secret rills of disease transmission that never come to enforcement notice. No greater service can be rendered public health than for the court and police authorities to keep the contact tracer and his Health Department VD chief always in mind, always at their elbows, constantly informed and utilized. They will do their work confidentially and well.

A second important field of public health and enforcement contact, is that concerned with the bringing in of suspects for examination. Reference has already been made to the use of almost extrajudicial procedure in emergency conditions, to bring in from all directions, possible disseminators of venereal disease, particularly women and young girls. Justification for the use of devices like the loiterers statute and the curfew enactment is found in the undoubted shift of promiscuity in sexual relations from the professional of old-line prostitution to the amateurs of the modern joy-ride. Here again, the principle of rigorously applied scrutiny in behalf of human civil liberties deserves consideration, and judges who are sensitive to it not infrequently incur the disapproval of other agencies in the protective and preventive field which desire to extend the examination of suspects to its widest limits.

A device which bears an almost surely emergency stamp is examination on complaint. This procedure reluctantly accepted in tracing contacts among the armed forces, has not reached the point thus far in the United States where fewer than three witnesses to the identity of the source of infection is sufficient to force examination. In Great Britain however a, for the British, truly astonishing structure upon the rights of the individual, has been promulgated in Regulation 33-B, added to the General Defense Regulations of 1939. This regulation requires that any physician treating a patient with venereal disease must fill out an appropriate form concerning the suspected source of infection and this complaint been repeated by a second person permits the medical officer of health to conduct a physical and laboratory examination of the accused, under compulsion if necessary. The efficacy of this regulation as teeth has been greatly hampered if not largely nullified by the fact that the infected person is required to name not his sexual contact, but the person from whom he believes the infection to have been acquired, and heavy penalties are attached to false accusation when demonstrable. This, of course drives all information into hiding at once.

The Council of Social Agencies.—This, or its equivalent, is part of the social service organization of practically all large cities, and serves as the coordinating center for a variety of aids which the health department may invoke. It is, however in the main a policy-determining educational and social service exchange type of group whose support should be enlisted but active

utilization of its components can only be obtained by direct personal approach.

The visiting nurse is of especial service in establishing family contacts, and in organized care of the pregnant woman, with respect to venereal disease. She should especially be schooled to the principle that syphilis in the pregnant woman does not end for either her or the child with the mere fact of delivery or discharge from the maternity hospital. The visiting (*i.e.*, public health) nurse should be familiar enough with the course of syphilis; have seen some of its infectious lesions; have an index of suspicion with reference to blindness, cardiovascular disease, and neurosyphilitic manifestations, and be familiar with the requirements of the law with regard to prenatal and premarital blood-testing. Th school medical authority and with it, the school nurse, usually comes into direct contact with syphilis through the occurrence of acquired infections in young persons, hich are commoner than is often supposed; congenital infection, manifested in interstitial keratitis especially; and sex delinquency with its risk of venereal disease transmission manifested in illegitimate pregnancy The schools further bear an important part, more it must be conceded, in prospects for the future, than in present achievement, in the morale and educational front of venereal disease control. Especially appointed school counselors, high school principals, and the physical education instructional staff have particularly good opportunity to deal with juvenile transmission problems. Th family nd maternal child health societies have titulary interest in syphilis and its control and may be enlisted if they have active health centers or clinic establishments. Family clinics are valuable segregative division of venereal disease and have valuable segregative function within the general syphilis clinic. A mother with young child is demonstrably far more willing to accept treatment herself, and carry through for her children, when one visit will take care of both.

Th pharmaceutical associations and the pharmaceutical profession hold key position in the front against venereal disease. The drugstore is often the social center of neighborhood; it is often a gathering place and refreshment spot for young people at the age when the start towards venereal disease is most often made. The socially-minded head and personnel of such establishments can (*a*) discourage off color frequenters looking for pick-ups and trouble; (*b*) give friendly advice and even sober counsel to some who are obviously on the way to going wrong; (*c*) urge blood tests and medical examinations on persons who are known to have exposed themselves. The pharmacist can, if he will, maintain center for public health and preventive medicine, comparable in some ways even to the physician office. From behind the counter he has the first chance to give or sell prevention to the person who may be exposed to venereal disease. H can be sure that the prophylactic or the kit is top-grade approved product. He can emphasize the importance of time in postexposure prophylaxis, and warn the victim of "the ounce too much, of the need for immediate action. The pharmacist above all can sell the basic idea of prompt, accurate diagnosis and immediat treatment to the person who describes the symptoms or asks for treatment or relief; the person who asks for or purchases proprietary for venereal disease treatment *tells the story that shows he is taking risks he doesn't realize*; has consulted quack; or has no medical care. If the physician interested in venereal disease control will establish reciprocal contacts ith the pharmacist, he will find him much more cooperatively minded, than if the arrangement is only expected to work one way—from the drugstore to the doctor office.

The medical societies and specifically the county and state associations, have shown wide regional variation in their responsiveness to the responsibility for venereal disease control. Where public health practice was popular as ith the profession in Detroit, under the leadership of Henry Vaughan, the practicing physician was one of the most eager of cooperators, and his county society fully reflected his attitude. In certain states and municipalities the schism between medical society and public health authority has not progressed beyond stolid refusal to cooperate, on the one hand, and indignant sputterings on the other In fortunately limited number of instances, the medical society has placed an active lobby in the stat legislature to block free diagnosis and to see that free treatment is given to none but the indigent. It has even appeared that the profession, through carelessness, no doubt, has on the one hand, utilized the free diagnostic service of the premarital examination la n, to secure free blood-tests for patients nd been willing to certify them as indigent while charging for the certificate. Broadly speaking, it may be said that the profession either has nothing to lose by an increased assumption of responsibility by the health authority or can expect positive gains therefrom. For example, the institution of mass blood-testing has demonstrably in certain cities in this country increased, nd to striking degree, the privat practice of physicians willing to treat venereal disease. This is the usual rule. There is more tha enough for all, if all is uncovered. Generally speaking, the health authority should at the earliest possible moment, and consistently and repeatedly thereafter seek the counsel of the local medical society take it into his counsels preserve personalized and intimate

rather than a distant high and mighty approach to the individual practitioner and in every possible way convince the everyday doctor that he is a vital element in the control of syphilis.

The American Social Hygiene Association has supplied a generous share of the initiative in venereal disease control, particularly in its relation to social hygiene and the war effort. The national association has a number of local chartered branches, and through its central organization will supply ideas, educational material, cooperative liaison, with national groups such as pharmacists, and investigative services, particularly in the law-enforcement field which are an important part of civilian or private initiative in venereal disease control problems. If the health authority genuinely desires participation of all the people in the solution of what is all their problem, it will utilize and strengthen the voluntary agencies of this type in venereal disease control.

THE PREVENTION OF THE VENEREAL DISEASES

Fundamental Principles.—In May 1942 all vehicles of the Philadelphia Transportation Company including streetcars, buses, subway cars and trains and trackless trolleys, carried in behalf of the City Defense Council's Venereal Disease Subcommittee an advertisement which epitomizes the principles of prevention of venereal disease. This card is reproduced in Fig. 885 An alert

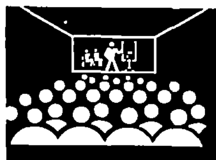


Fig 885 —Street Car Advertisement—see text.

observer will note the one omission—public education—of one aspect of which the card itself was an exemplification.

The Morale Front.—*The British Army Bureau of Current Affairs* in its Handbook revision for 1943 supplies what might well be quoted as the Magna Charta of the morale front "Morale depends on knowledge There is a widespread ignorance among soldiers about current affairs an ignorance not peculiar to soldiers, but a chronic condition among the citizens of this country An ill informed or indifferent citizen or soldier is a menace to national safety Morale is a matter of discipline which in turn, is a function of understanding. It is not enough to apply these principles to military matters only the citizen-soldier should realize Cromwell's definition of one who must know what he fights for and love what he knows.

The car advertisement purposely placed clean living clean sport and recreation first under the controlling influences, in the belief that the summated experience of a century has clearly shown that the positive moral force of a people or a community and the agencies which encourage it are the groundwork of that self-control which controls the venereal diseases. Sexual misconduct

duct begins at the point where the individual, lacking inspiration to clean living and with excess energy and money to spend, follows the aberrant track of an emotion uncontrolled by intelligence to an unsound solution of a basic need. The basic need being inescapable, and variable in its intensity from individual to individual, the classification of influences leading to the undesirable solution will be difficult, but fortunately the classification of the influences restraining him will be relatively simpler Granted that the hereditary background and childhood associations and experience are not too prejudicial (and these are large grants) the majority of human beings will (*a*) work out a not too discreditable solution of the individual sex problem by the end of adolescence and (*b*) if given sufficient play to offset worry and sufficient hard physical work to discharge tension, will be able to employ reason and ideals in meeting an impulse to sexual indulgence. It follows therefore, that to control loneliness and homesickness, to provide adequate substitutes for temporarily severed human associational ties, especially with the other sex· to provide a cause, ideal or aim which validates effort and assures the future and to keep the individual working hard towards it, will tend to reduce the morale problem of sex conduct to the most controllable terms.

In World War I, for wars are always crises in these affairs, it has been pointed out that the compensatory forces got under way early· in the Commission on Training Camp Activities they had full encouragement and support, and the influence of the American Social Hygiene Association, and General Pershing uncompromising stand on the matter made real what might otherwise simply have remained paper.

The generation between the first war and the second has seen number of important changes —perhaps one might almost say leaks or breaches in the morale front. The experiment of prohibition unenforced, simultaneously with the advent of the automobile, put youth to test in which its morale survival values are not yet established. Delays in bringing to bear some of the control influences early evolved in the last war have doubtless influenced an early unfavorable trend in venereal disease incidence both in civil and military life. But far more important are the serious elements of difference in the morale problem of this war as compared with the last. Scientific discoveries may and in fact are already enhancing the effect of general loosening up of sex standards. As evidence of the loosening, we witness shift of the infection source from professional prostitute to casual amateur which has delayed and even defeated the approach to control at number of important points (see below). W find the girl-friend or pick-up performing her uncertain offices without cost, which confounds the police ttack on prostitution, and we find among omen and girls of the most unexpected types an almost vid desire to show the boys good time. Solicitation seems to be climbing to unheard-of proportions in many cities, and in other countries as well as our own, and the dating mechanism developed during peace is superfunctioning in time of ar Some peculiarities of our national effort are important too. W are concentrating troops overwhelmingly in the South in areas where both white and colored races have phenomenally high incidence of venereal disease. The color-line is thinning, drawing on the Negro reservoir of infection, the highest in the country Transportation has done things to peripheral cantonment control which worked in the last war but is far less effective in this. The population as well as the armed forces is on the move, and civilian equally with the soldier and sailor is swept into the morale-wrecking effects of change, break-up of home and stabilizing influences, loneliness, unrest. Liquor has been less effectively dealt with later in the game than in the last war And now scientific discovery—the one-day cure of the maligned but often effective fear-producing deterrent of disease—is knocking out the props from under our platform.

It may then well be asked where shall turn, in situation like this, if not to the rediscovery of old truths and their reemphasis in education. The scanty grace now accorded clean way of living; continence dismissed in five words followed by "but, in the current official instructional films—only impresses the more intensely the need, the imperative need for moral rejuvenative and positive force t replace growing cynicism in this whole business. Perhaps it is intended to leave all that to the chaplains. Earnest and effortful though they may be, they will fail. The control of venereal disease, the clean conduct of the sexual life cannot be made effective by ecclesiastically coated pills. It is man-to-man and day-to-day affair. In civil life its exponents should be the parents who are the living examples; the teacher who is too often perforce the official in-

structor In the armed forces, it is the business of the commanding personnel from squad corporal to colonel and general on the land, and up the Navy's staff to the top-most admiral on the sea. The attitude of the physician, more important by far than he may realize, should be uncompromising. The medical officer in particular owes the morale side of this problem an unbrisking and wholehearted allegiance.

The man on whom it fell to summarize the record of the American Expeditionary Forces in the last war is not too incorrectly quoted as saying that the sense of being set apart for a great destiny raised the proportion of continence in our Army far above the expectancy for armies in general and that continence and not the barbed wire of St. Nazaire kept down our rates. This being set apart for a great destiny belongs not alone to the heroic moments of life, but to the everyday drudgery of living. As such, it must be made a part of the fabric of our being, and the venereal disease control officer must insist that this is so. Of the here and now it may truthfully be said that if ever there was a day when the bodies of men, equally with their souls, are set apart for great destiny this day is it.

Education.—It has been indicated that much educational effort in the prevention of venereal disease falls under the condemnation of Ecclesiastes—of the making of many books there is no end and much study is a weariness let us hear the conclusion of the whole matter Fear God, and keep His Commandments Education is a supplement and elaboration of example example begins in the home and is merely carried forward by the school and all those forces and agencies which under the guise of organized play and association try to make the square deal and the do unto others the basis of behavior Precisely as it has become clear in the educational effort among soldiers and sailors that the small group the eye-to-eye talk, the vivid and dramatic instructional episode iterated and reiterated time after time finally teaches something so it appears the more intimate and direct approaches in preventive educational technic at large may be expected to be the most effectual Such education is not successfully carried through by the inexperienced or by all who may feel the urge to attempt it. Accordingly along with sound general direction, educational programs require specialized and again adept personalities to carry their message across.

This type requisite has stood out of all the varieties of educational experiment that have marked the past twenty-five years in schools, YMCA s and other groups Much of the reluctance which has been apparent to transfer sex education to the school as against the home has been based on the contention that the contact cannot be so intimate, the example is less clear the precept more formal and potentially embarrassing and the teacher too often himself an unadjusted individual unfit either as an example or an instructional agent. Despite these strictures on sex education in the schools, it has become increasingly apparent that something in this field must be invoked to head off the increasing trend toward juvenile promiscuity

The earlier conceptions of sex education tended either to etherealize on generalities or to specialize in prophylactic frankness Special situations may of course require the latter but the general situation now appears to require first, an integration of instruction in matters of sex with the general content of instruction in health and hygiene at large Second, the range of such instructional effort has been extended from the original application to the teen-age high school group, to the parents, even the prenatal parent so to speak, and the child from infancy to and through the college years. Thus sex education becomes in the term applied to the preparatory instructional course for teachers and counselors given in 1913 by the Institute for the Control of Syphilis at the University of Pennsylvania a course in "Health and Human Relations." A third principle is that of central full-time guidance for the program wherever and however instituted in the school system A fourth calls for the utilization and preparatory instruction of persons of special aptitude from the teaching staff itself This includes school counselors, school principals, instructors in physical education and others who have demonstrated special capacity for dealing effectively with the problems of youth.

Special information on the educational plans of the Philadelphia School System and the curriculum of the course in Health and Human Relations for counselors and teachers may be obtained from the Board of Education, 21st and the Parkway Philadelphia, or the Institute for the Control of Syphilis, Hospital of the University of Pennsylvania.

A surprisingly large part of educational effort in this field at the present time is represented by the moving picture. Typical and worth while films include "Know for Sure" (United States Public Health Service), "In Defense of the Nation" (American Social Hygiene Association) and the various instructional films of the Army and Navy. In our opinion these are essentially stop-gap devices, creditable though several of them are, to meet special situations in what must ultimately be a broadly organized program. They are under fire of criticism from groups in the church which believe that they underestimate, if they do not actually damn with faint praise the morale aspects of venereal disease control. Certainly one feels this lack in the instructional films used by the armed forces in the early part of this war, and in some of the franker pamphlet literature, especially on prophylaxis, which has had high and wide sponsorship and circulation.

The question of reading matter for educational purposes is often referred to the physician. A particularly good summary of the worth while social hygiene books and pamphlets, and the function and equipment of the public library with reference to sex education, is given in the *Journal of Social Hygiene*, volume 29, June, 1943. Excerpts from this material and advice on these problems may be obtained from the American Social Hygiene Association, 1790 Broadway, New York, and the United States Public Health Service Division of Venereal Diseases, Bethesda Station, Washington, 14, D. C. It is necessary to remark that the educational front of venereal disease control has as deep a lunatic fringe as any in the calendar. By no means all who feel themselves called, should be chosen to the business of inspiring and educating the public in this field particularly. The health officer should scrutinize; the physician should gravely question each and every one called to missionary effort lest he find himself and his program encumbered by deluded crank.

The Control of Organized Prostitution.—Organized vice or prostitution has so long held the center of the stage in venereal disease control thinking that it requires a basic analysis, even though it seems in the process, for the present war at least, of being displaced as the major infectious source by the nonprofessional promiscuous individual. In a considered statement, the Subcommittee on Venereal Disease Control of the Philadelphia Defense Council and the Pennsylvania State Venereal Disease Control Committee laid the present situation with reference to prostitution before its public, and this statement seems worth quoting in full.

A STATEMENT ON PROSTITUTION

Two schools of practice have existed since the beginning—segregation and tolerance or repression.

As medicine progressed it added the notion of safety to the segregation, by inspection.

As medicine progressed a little further it found inspection unreliable because of difficulties in diagnosis and uncertainty as to continuity of the negative or disease-free status. This is the still unsolved carrier problem, active and passive.

As it progressed still another step, it proposed to keep the infected or infectable individual free of infectious lesions by chronic treatment, so to speak. The bismuth plug, the periodic sulfonamidization are examples of this technic.

Meanwhile science had stepped in from another angle and proposed the local use of antigonococcal and antispirochetal disinfectants plus devices for keeping infective organisms away from susceptible and exposed parts—in other words, post and preexposure prophylaxis.

The latest contribution is that of epidemiology—the art and science of the contact tracer.

Study of contact tracing results and the sex habits of infected persons seems to show that:

1. *Most males and many females* have worked out some individual sex solution or compromise by early adulthood, either continence, masturbation or one or another kind of sexual relation. A relatively small proportion are inactive. The Army's impression seems to be: 15 to 20 per cent won't, 15 per cent will, 70 per cent shift back and forth under the influence of this or that circumstance including upbringing, availability, companionship, mass or group morale, work interest and fatigue, normal recreation and distraction, feeding, and above all, alcohol. It is to be expected therefore, that the soldier or sailor viewed realistically will have a sex life subject to these influences and influenced by what we do about them.

2. *The old symbolic concept of prostitution* as organized house and solicitation activity gov

Colonel Ashburn at the close of the last war (1919) estimated that 30 per cent of the A.E.F. remained absolutely continent during their service in France.

varying facilities for sexual intercourse with the shift from professional to amateur. This makes doubly important the emphasis which Williams, who has a singularly effective record in the clean-up of Vancouver and the seaport towns of British Columbia, puts on the suppression of what he calls the "facilitator" as distinguished from the woman victim of the prostitution situation. The beginning of an attack on facilitating agencies is in an adequate contact tracing technic. The aim is to find the place at which the exposure occurred and then to trace the place to its ownership, and to persuade the ownership to active cooperation in extinguishing the place. Such efforts, of course, bring contacts with other facilitative agencies including the distributors of alcohol, the call mechanism for summoning girls, and so forth. The emphasis on the place is, of course, longstanding prostitution control practice, but Williams' emphasis on the person as distinguished from the legalist approach, is new. The attack on the facilitator is emphasized in the foregoing summary of prostitution control by the italicized items 7 to 10 inclusive, under "How Can Prostitution Be Repressed."

Colonel Ashburn at the close of the last war (1919) estimated that 30 per cent of the A.E.F remained absolutely continent during their service in France.

tractor. In the armed forces, it is the business of the commanding personnel from squad corporal to colonel and general on the land, and up the Navy staff to the top-most admiral on the sea. The attitude of the physician, more important by far than he may realize, should be uncompromising. The medical officer in particular owes the morale side of this problem an unshrinking and wholehearted allegiance.

The man on whom it fell to summarize the record of the American Expeditionary Forces in the last war is not too incorrectly quoted as saying that the sense of being set apart for a great destiny raised the proportion of continence in our Army far above the expectancy for armies in general, and that continence and not the barbed wire of St. Nazaire kept down our rates. This being set apart for a great destiny belongs not alone to the heroic moments of life, but to the every day drudgery of living. As such, it must be made a part of the fabric of our being, and the venereal disease control officer must insist that this is so. Of the here and now it may truthfully be said that if ever there was a day when the bodies of men, equally with their souls, are set apart for a great destiny, this day is it.

Education.—It has been indicated that much educational effort in the prevention of venereal disease falls under the condemnation of Ecclesiastes—"of the making of many books there is no end, and much study is a weariness ... let us hear the conclusion of the whole matter: Fear God, and keep His Commandments." Education is a supplement and elaboration of example; example begins in the home, and is merely carried forward by the school and all those forces and agencies which under the guise of organized play and association try to make the square deal and the "do unto others" the basis of behavior. Precisely as it has become clear in the educational effort among soldiers and sailors that the small group, the eye-to-eye talk, the vivid and dramatic instructional episode iterated and reiterated time after time finally teaches something, so it appears the more intimate and direct approaches in preventive educational technic at large may be expected to be the most effectual. Such education is not successfully carried through by the inexperienced or by all who may feel the urge to attempt it. Accordingly, along with sound general direction, educational programs require specialized and again adept personalities to carry their message across.

This type requisite has stood out of all the varieties of educational experiment that have marked the past twenty-five years in schools, YMCA, and other groups. Much of the reluctance which has been apparent to transfer sex education to the school as against the home has been based on the contention that the contact cannot be so intimate, the example is less clear, the precept more formal and potentially embarrassing, and the teacher too often himself an unadjusted individual unfit either as an example or an instructional agent. Despite these strictures on sex education in the schools, it has become increasingly apparent that something in this field must be invoked to head off the increasing trend toward juvenile promiscuity.

The earlier conceptions of sex education tended either to etherealize on generalities or to specialize in prophylactic frankness. Special situations may of course require the latter, but the general situation now appears to require, first, an integration of instruction in matters of sex with the general content of instruction in health and hygiene at large. Second, the range of such instructional effort has been extended from the original application to the teen-age high school group to the parents, even the prenatal parent so to speak, and the child from infancy to and through the college years. Thus sex education becomes in the terms applied to the preparatory instructional course for teachers and counselors given in 1935 by the Institute for the Control of Syphilis at the University of Pennsylvania, a course in "Health and Human Relations." A third principle is that of central full-time guidance for the program wherever and whenever instructional in the school system. A fourth calls for the utilization and preparatory instruction of persons of special aptitude from the teaching staff itself. This includes school counselors, school principals, instructors in physical education and others who have demonstrated special capacity for dealing effectively with the problems of youth.

Special information on the educational plans of the Philadelphia School System and the curriculum of the course in Health and Human Relations for counselors and teachers may be obtained from the Board of Education, 21st and the Parkway, Philadelphia, or the Institute for the Control of Syphilis, Hospital of the University of Pennsylvania.

8. *From the owners of property* used for prostitute and affiliated activity or their estat representative—the "vested interests.

9 *From all sorts of persons and sources who believe*

( ) That stopping prostitution leads to increase in rape.

(*b*) That the sole or chief source of disease is the "institution of prostitution and the "prostitute, who can be caught, confined, controlled, inspected, treated—forgetting all the other sources mentioned.

(*c*) That repressing prostitutes drives them into hiding and scattering—forgetting that this very thing enormously decreases their accessibility and contact frequency—especially to soldiers and sailors, who as strangers, if looking for sex, strike out for the sex district if there is one.

What happens when prostitution, in the institutional or house sense, is vigorously and effectively repressed? There are some recent excellent demonstrations—a notable one in the Pacific Northwest, Washington and British Columbia for example.

1 *Gonorrhea* is often greatly reduced in incidence almost at once.

2. *Syphilis is less rapidly influenced*, for unknown reasons, but possibly because more of the syphilis of the established prostitute (this does not mean merely blood-test syphilis or latency) is past the infectious stage or controlled by treatment. The "prostitute is less dangerous source of syphilis often than the casual" and the ignorant but promiscuous "girl friend.

3. *The house of ill fame* is broken up as criminal resort and hide-out with corresponding improvement in the criminal and liquor control situations.

How can prostitution be repressed and infective exposure of all sorts reduced to the lowest terms?

1 *By developing an uncompromising public demand for clean-up.* A process of education.

2. *By all-out medical acceptance* and endorsement of the epidemiologic facts and the viewpoint on which repression is based (see above).

3. *By punishment*, legal and otherwise, of violators of the health regulations regarding inspection and certification of prostitutes if such regulations exist in the statutes of the state or municipality If no law against inspection and certification exists, let the community or state be persuaded by the physicians to get one.

4. *By as wide an application of the examination of males and females* caught in the toils as local sentiment and law permits—release to probation on positive findings to include treatment and follow-up of infected persons.

5 *By long-term imprisonment* (not fines) of the repeatedly convicted prostitute, imprisonment meaning commitment to an institution where ( ) adequate treatment carried to cure is given (not the average thirty-day county jail sentence) and (*b*) probationary rehabilitation placement work is effectively carried out.

6. *By invoking the May Act* through the military or naval authorities if the exposure of soldiers and sailors is an important element in the situation, and local inertia blocks action.

7 *By "padlock" law*, closing properties rented for or by prostitution or its agents, to all uses for year or more.

8. *By publicizing recalcitrant and reactionary conduct or noncooperation*, on the part of all agencies such as hotels, and hot-spots, real estate owners and agents, liquor dispensers (taverns, etc.) frequented or used by prostitutes.

9 *By cleaning up the police administration* if corrupt.

10. *By starting an FBI investigation* of the "higher-ups via the income tax, where officially tolerated corruption exists.

11. *By cooperating with the armed forces* in the identification of sources of infection in the community

12. *By establishing prophylaxis* (preventive treatment) (station, dispensing, etc.) on locally satisfactory basis, for post exposure and if possible pre-exposure technics.

13. *By enlisting the help* in controlling mobile and casual prostitution, of the following agencies:

(*a*) *The State Health Department' Division of Venereal Diseases*, whose expert contact tracers (epidemiologic workers) are trained to trace venereal disease to its source, quietly confidentially unobtrusively and to bring it under treatment.

(*b*) *The Beverage Control Board*, which can help to identify and control the alcohol factor especially by strict enforcement of the Liquor Control Act in licensed premises.

(*c*) *The automobile licensing authorities and State Highway Department* which can help control the taxicab, the parked car and the trailer

(*d*) *The State Motor Police*, usually of higher than average morale, who can help control the road house and the tourist camp and dine-and-dance.

It would be mistake to suppose that organization is disappearing from the business of pur

varying facilities for sexual intercourse with the shift from professional to amateur This makes doubly important the emphasis which Williams, who has a singularly effective record in the clean-up of Vancouver and the seaport towns of British Columbia, puts on the suppression of what he calls the "facilitator" as distinguished from the woman victim of the prostitution racket. The beginning of an attack on facilitating agencies is in an adequate contact tracing staff and technic. The aim is to find the place at which the exposure occurred and then to trace the place to its ownership, and to persuade the ownership to active cooperation in extinguishing the place Such efforts, of course, bring contacts with other facilitative agencies including the distributors of alcohol, the call mechanism for summoning girls, and so forth. The emphasis on the place is, of course, longstanding prostitution control practice but Williams s emphasis on the persuasive as distinguished from the legalistic approach, is new The attack on the facilitator is emphasized in the foregoing summary of prostitution control by the italicized items 7 to 10 inclusive, under "How Can Prostitution Be Repressed.

Appreciating the force of the horrible example, particularly under American conditions, Parran and Vonderlehr (Plain Words about Venereal Disease, Reynal and Hitchcock, 1941) tersely described several situations representativ of regulationism and prostitution on the loose, from which we quote. Salinas, California, a city with normal population of 10,000, had from 200 to 300 women engaged in prostitution at the beginning of 1941 Thousands of troops are being concentrated in Monterey County nd the cities of Monterey Salinas, and other nearby towns are outdoing themselves in providing "entertainment for the boys. The prostitutes were separated in two areas, the cribs and the regulated houses.

Such disorder resulted when men visited the cribs by the hundreds, that the Army authorities found it necessary t put these places out-of-bounds. It was easy to take this action because the crib girls were free lances, had no procurors, and kept what they made after they paid the exorbitant rent of hundred dollars month for wooden shack divided into a bedroom and toilet. Seventy-five to hundred of these shacks constituted the crib area. The bedrooms opened directly on a walk-way and the military manpower paraded past while the girls sat in the brightly lighted bedrooms where the prospective customers might get good look at them. Two or three blocks way was the so-called segregated area of Salinas. Half dozen houses were on ts sides of single block and several more on an adjacent side street. Several houses were under construction and one of the oldest was being remodeled while occupied. The Madame extended a warm greeting t the investigator nnouncing that she had twelve nice girls, was increasing the number of rooms and modernizing the plumbing equipment, and expected to have the most sanitary house in the town hen the job was finished If the Army camps nearby continued to grow she expected to bring in as many as thirty girls if necessary The segregated area of Salinas is typical of many cities in the U ited States It represents so-called effective segregation in this country, which still is advocated as solution of the venereal disease problem It is significant that the only prophylactic station in the town for the Army in early 1941 wa in an alley back of the crib area in which had been installed the apparatus for what may have been well administered prophylactic treatment, if the exposed man would walk through the mud in the unpaved alley to get it.

While most of the horrible examples citable today will be cleaned up tomorrow or have been cleaned up yesterday there is no escaping the fact that similar solutions" for local venereal disease problems may arise at any time in any place in the country or the world where local public sentiment, official corruption, the indifference or cynicism of the medical profession, and the anachronistic notions of medical and line officers, encourage them.

Alcohol.—Liquor is the Siamese twin of venery and no operation has yet been devised which can separate the two without the death of the one or the disappearance of the other A distinguished medical officer expressed the situation aphoristically—'Only to a drunk does a whore look good" Knowledge of the influence of commercialized liquor on prostitution is essentially old stuff buried in papers of the preprohibition era, among them Kneeland's classical study (Social Hygiene, 1916, volume II 00–00) and Clark (*Ibid.*, 1917 3-5-00) From 30 to 80 per cent of exposures by various estimates take place under the influence of alcohol, and it has been sourly remarked by the sergeant in charge of a huge prophylactic station, that a man must be slightly drunk to submit to prophylaxis. It is quoted as axiomatic that prophylaxis stations should be so placed that "a drunk will not walk uphill" Under the ordinary

conditions of venereal disease control, the Beverage Control authority deals with the liquor factor along three lines prosecution (1) for sale to minors, (2) for keeping open beyond established hours (usually midnight or 2:00 a.m. or Sundays in some leave areas) and (3) for sale of liquor to intoxicated individuals. The law also usually intimates that bar keepers and owners are not expected to permit known prostitutes to frequent their premises, but this is extremely difficult of enforcement. Each of these provisions recognizes the principle of keeping alcohol out of the hands of inexperienced and emotionally dominated persons (youth) limiting the time of its availability to those hours when people would rather drink and sit in public than, drunken, fornicate in private. Midnight closing cuts off a considerable accession to the exposure field in the persons of those who go from bar to room on the same premises. At what point the intoxicated person reaches his maximum susceptibility to prostitute solicitation is, of course, undetermined but there is little doubt that the succumbing point gets nearer and nearer as the ingestion of alcohol increases. While the cleaning up of a wide open town or district with respect to liquor violations does not of necessity clean up the prostitution or venereal disease dissemination situation at large, a shut-down on alcoholic over-indulgence is practically always the first step in genuine reform.

Other Forms of Commercialization of Sex.—Pornography in pictures, postal cards and magazines; the "cheese cake" or photographic leg work, which is alleged to sell the nationally known illustrated magazines; and shading upward, the pulp and sexy story magazine, probably act more directly upon the adolescent than upon the older age groups in the stimulation of promiscuous activity

Prophylaxis, Mechanical and Chemical.—Prophylaxis in this sense is pre-infection or preventive treatment. It is subdivided into pre- and post-exposure categories, into personal and station prophylaxis. The indubitably tremendous effectiveness of station prophylaxis under discipline and uniform application has encouraged an incautious optimism as to its universal applicability to the control problem of venereal disease. Preexposure prophylaxis provides a choice between the condom or sheath and the prophylactic packet. Preexposure prophylaxis without control of the alcohol factor is hardly worth the paper on which it is described.

The condom specifically may be available and be found still in the pocket after the get-together Many condoms prior to the intervention of the Food and Drugs Administration of the Department of Agriculture, which set standards of manufacture and testing, were imperfect. The condom, no matter how perfect or effective, will be rejected after its first employment unless an adequate technic is taught, because it spoils the act "like washing your feet with your socks on. Instruction in the use of the condom by films and others is almost invariably fails to mention that lubrication should be on the inside as well as the outside. At best the condom is, of course, only partial protection in the act itself, and provides no protection in sex play or to uncovered areas. Nevertheless, especially if women could be induced to insist upon its use, it could and very possibly does provide one of the chief barriers against the present day acquisition of venereal disease. Lubricating oils and jellies to be introduced before exposure, and, of course, cervical caps and similar protective devices for the women, are as yet unsatisfactory unstudied, and in their present form, unusable in the casualness and opportuneness of much sexual exposure today The ideal preexposure prophylactic is not a messy ointment or an awkward and repellent mechanical device, but a penetrating, inconspicuous and even colorless substance, which when applied will fix itself in skin or mucous membrane for a considerable period, and may therefore be applied when intelligence can dominate the situation

Post-exposure prophylaxis is stymied by the elements of time inconvenience and discomfort. If and when it is universally enforceable after actual or

assumed exposure as in troops or ships crews returning from leave in a notoriously infected area, they can be subjected to station prophylaxis with astonishing results.

A classical example is Walker's experience at St. Nazaire in World War I, when an incidence rate of 625 per thousand per month was reduced in three months to 110 per thousand by the compulsory application of prophylaxis to all men returning from leave, whether admitting exposure or not. Further application of prophylaxis, and more efficient guards around the camp, reduced the incidence to 35 per thousand. Estimates of the efficiency of station prophylaxis based largely on World War I experience, include such figures as 1.3 per cent failure in 244,000 treatments one infection in 37 exposures without prophylaxis as against one infection in 274 exposures when prophylaxis was taken.

The standard recommendation in all instructional films and lectures for the armed forces in the present war places the optimum time of use as from one to two hours after exposure or sooner if possible the critical question of how large a proportion of exposures is likely to be followed by prophylactic treatment, even if facilities are provided is met by various informal estimates of 1:3 1:5 and even 1:9 prophylaxis taken to exposures made. Washing facilities which recent work indicates are less important than their conspicuous place in instruction suggests, are of all things, most difficult of access under the prevailing casual circumstances of exposure.

It would appear then that the essential conditions of effective mechanical and chemical pre- and post-exposure prophylaxis, are difficult to satisfy They include a measure of intelligence in their application too easily destroyed by the customary or common use of alcohol discomfort and inconveniences discouraging their use even under favorable circumstances nonparticipation and lack of control of the situation by the woman inevitable, almost physiologic delay in the time element of application and evasion of the obligation to take prophylaxis for a variety of reasons if the compulsory or disciplinary use of the method be not employed

An official procedure reduced to formula has been provided as preliminary statement by the special joint committee appointed by the American Social Hygiene Association and the United States Public Health Service published in Venereal Disease Information, 21:311, October 1940 and is quoted as follows: (1) Safest method ( ) use a condom of standard type; (b) thoroughly wash the genitals and adjacent parts with soap and water as soon as possible (the sooner the better but within one hour at most) after removal of the condom. (2) In the absence of condom, ( ) thoroughly wash with soap and water as already described, (b) after urination, inject 6 cc of 2 per cent strong protein silver solution or other efficient nonirritating germicidal solution into the urethra and hold for five minutes, (c) rub 33 per cent ointment of mild mercurous chloride (calomel ointment) into the genitals and adjacent parts. A two-tube formula officially recognized by the Surgeon General's Office United States Army includes 4 grams silver picrate jelly 0.25 per cent strength and calomel ointment 6 grams (this is the official 33 per cent) in separate different colored tubes with appropriate directions, together with a soap cloth and protector for the clothing

The great importance of chemical prophylaxis to the armed forces has led to the recent institution of a number of important studies whose nature and results cannot be disclosed. It is to be expected, however that such studies must include the investigation of penetrant, the incorporation of sulfonamides, the testing of other mercurials than calomel, though it still to date remains supreme and the significance of such ritual procedures as washing with soap and water, the time factor and the local employment of spirillicides of other than heavy metal types. The physician must of necessity therefore, turn to the literature when it becomes available for the recent advances in this field A combined formula of experimental type already published is that of Taylor (U S. Naval Medical Bulletin, September 1943) as follows mercury oxycyanide 0.1 gram sulfathiazole 5 grams, starch (corn) 5 grams, distilled water to 100 grams. For this formula the author claims 100 per cent protection in group of 187 exposed cases, while calomel protargol standard prophylaxis administered to 287 exposed persons failed to protect in seven.

Systemic prophylaxis for syphilis has made no advance and has in fact, retrogressed since the last edition of this work. The history of the procedure including the bismuth plug and the use of stovarsol is given in the second edition. The use of the arsphenamines has succumbed to the uncertainties involved and its further employment is discountenanced. Those who for any reason wish to insist on post-exposure treatment in anticipation of the risk of infection, should carry through the full therapeutic procedure for an established diagnosis of early syphilis.

It is in view of these statements of particular interest that Mahoney and Bryant satisfied themselves that an important, and perhaps the major element in the efficiency of calomel prophylaxis, is the systemic effect of the small amount of mercury absorbed in the procedure. Subsequent studies have tended to show that calomel prophylaxis at least does have an important systemic phase.

Systemic prophylaxis as applied to the control of gonorrhea by the oral use of the sulfonamides, pre- and post-exposure is not here discussed, since it is not within the field of this text.

Prophylaxis and the Professional Infection of the Physician.—On this point so many questions are asked and one is so frequently the recipient of requests for telegraphic and other emergency advice, that two summaries contained in Figs. 213 "To Avoid Professional Infection with Syphilis," and 214 "In Case of Suspected Accidental Infection with Syphilis in Medical Practice," would seem to have practical usefulness. In the majority of cases it is the finding of a positive serologic test in a patient after an accident which inspires alarm. The status of the serologic test here as in all other aspects of the infectiousness of the disease, is, of course beside the point, although the presence of a positive serologic reaction of course directs attention to the risk. A syphilologist who has had any considerable experience with the reaction of his brother physicians towards syphilis in themselves, cannot but regret that a more preventive attitude on this subject and better teaching in regard even to the relatively unsatisfactory procedures available do not prevail.

OCCUPATIONAL AND INDUSTRIAL SYPHILIS

Occupation and industry marshal human beings into aggregates more effectively perhaps than any other agencies except the armed forces. For this reason there has been an almost traditional pressure to induce industry especially to interest itself in the problem of syphilis, not only because of its significance as an industrial hazard, but because of its power as an educative influence in behalf of public health. In time of war occupational shifts, induced by the mobilization of industry have tremendous spreading power as far as venereal disease is concerned, and man-power losses and economic costs due to disability mount in a spiral that compels attention. Industrial losses, destruction traceable to incompetence from diseases, have qualities of sabotage, and this aspect of the matter receives poster recognition in times of total mobilization.

The interest of industry in problems of personnel syphilis has been a slowly progressive and not too easy task. The autonomy of industrial medical groups, their problem in developing their bailiwick to its full possibilities in the face of hard-headed examination of their every claim by management, has probably led to some hesitancy in taking on an additional mass responsibility for what seems to be a matter of general health not to say morals, rather than one of industrial accident and injury. The movement however championed by persuasive and realistic personalities such as Surgeon General Parran of the United States Public Health Service, and Russell, whose special contributions are well known, has in this country had a most beneficial effect.

Industry in fact, in many areas, is "rarin to go" but the supportive public health mechanism still occasionally lags.

That some of the "rarin" is in management rather than in industrial medicine as such, must occasionally be conceded, for the problem undoubtedly seems simpler the greater the distance of the moving agent from the medical problem as such. The lag in public health cooperation is to a large extent result of the elaborate preparation that must be made for an effective industrial policy From the start a mass case-uncovering mechanism in the form of reliable serologic tests in such vast numbers as really stagger the laboratory imagination, is inescapable. For the Philadelphia area for example, it is reasonable estimate that for preemployment tests alone, facilities for 500,000 tests would be necessary within the first year load which the existing public facilities could not possibly undertake to carry without very large expansion and subsidy On similar scale throughout the country the load thrown on the laboratory network could not be met within several years, if not a decade of planning and building. This situation, of course, has been met by certain large industrial groups (*i.e.*, the du Pont de Nemours Company) by the development of adequate intramural laboratory facilities. The relatively small employer is more of a problem than the large one, and the disposition of all employers to "let George (*i.e.* the health authority) do it has been made clear by at least one survey (Pennsylvania Bureau of Industrial Hygiene) The approaches thus far successful have been largely through manufacturers associations and through management and personnel. It remains to be seen how much if any more can be accomplished by laying the baby directly on the knees of its putative guardian—the industrial medical organization as such.

The Prevalence of Syphilis in Industry —Parran and Vonderlehr have graphically presented the situation in a table quoted in Fig. 886. This is the serologic survey approach. A fair picture of the serologic plus the clinical approach is represented by an older study—that of Stokes and Brehmer published as a discussion of syphilis in railroad men.

The industries included in the Parran-Vonderlehr summary may be rated as "heavy Some additional interesting figures include the Endicott-Johnson shoe manufacturing interests, which in 1928 reported 3.7 per cent syphilis in 4117 workers the Seattle City Health Department, 1927 1931 reporting among milk-handlers and drivers of public conveyances 3.7 per cent syphilis among 29,408 persons barbers in Oklahoma in 1938 rated t 13 per cent syphilis; unemployed casual laborers, Minnesota 1931 8.4 per cent syphilis; Eastman Kodak figures, 1.1 per cent syphilis (quoted by Parran, "Shadow on the Land, 1937). Nine railroads requiring tests on routine application for jobs, gave among 21 026 applicants, 7.8 per cent syphilis (Parran, as above) The U.S. Coast Guard (Robertson, 1937) showed an interesting differentiation between personnel in the sea service and the life-saving service 8 7 in the former and 0 4 per cent in the latter For agricultural and industrial labor in the south the estimates run higher (12 to 25 per cent, according to the U.S. Public Health Service surveys) (Lewis, 1937).

The Costs of Syphilis to Industry and Labor —Figures of this sort have still a somewhat speculative character Many of them are old and possibly outdated based on industrial surveys in industries whose identities are concealed and whose representative character for the problem in general over the country at large cannot be determined

Among the most quoted estimates are those of Parker (1934) including 18 per cent syphilis in a group of railway employees, exhibiting delayed convalescence and disability whose total loss of time represented 13,940 day and $48,711 A large industrial concern, unnamed, how personnel efficiency had dropped below expectations, found that one in ten employees had gonorrhea or syphilis 60 per cent of the noneffective employees were on the sick list because of these diseases, and those venereally diseased had lost three times as much time as persons not affected. Each person with syphilis or gonorrhea was paying out an verage of $75 year for such treatment as was being given.

In an ttempt to present the picture graphically Fig 888 was developed as part of the material laid before a conference on industrial syphilis called for the Philadelphia area in 1911 The figures are self-explanatory and are of course, based on the older or standard treatment systems

Fig 896.

SUMMARY OF RECENT INDUSTRIAL SEROLOGICAL SURVEYS*

Location	Period	Number Tested	Number Positive	Per cent Positive
Chicago, Illinois (Average of 350 plants year)	1939	44,015	2,198	5 0
	1940	78,639	1,839	2 4
West Virginia (New River Coal Company)	1931	3,325	302	9 1
	1931 38	8,478	636	7 5
	1938	3,270	220	6 7
du Pont de Nemours & Co. (18 plants, 10 states)	1934–35	27,154	1,063	3 9
	1937 38	50,519	2,030	4 0
	1940–41	35,974	363	1 0
Cincinnati.	1939–40	29,518	1,301	4 4
New Jersey	1939	15,910	267	1 7
Buffalo, New York.	1935–40	4,450	177	4 0
Peoria, Illinois (Caterpillar Company)	1937–40	20,000	160	0 8
Alabama (Alabama Fuel and Iron Company)	1937 39	3,146	333	10 6

Fig 897

SYPHILIS IN VARIOUS OCCUPATIONAL TYPES (Stokes and Brehmer)

Occupational Types	Men Only		Husbands and Wives	
	Cases	Per cent Syphilis	Cases	Per cent Syphilis
Railroad employees	128	11 7	184	10 3
Laborers.	243	6 1	297	8 8
Business men (tradesmen, merchants)	236	3 8	311	3 2
Farmers	536	1 3	863	1 4

The low percentage of farmers with syphilis accords ith Parran reports of the U ited States Public Health Service figures and the synopsis of the final report of the British Royal (Sydenham) Commission, which indicates that agricultural laborers are relatively free from the disease. Of 1145 men examined i the M yo Clinic survey 4.2 per cent had syphilis; and of 514 women, 2 6 per cent had syphilis. The relatively low proportion of syphilis in these figures is probably affected by the source of the clientele of the M yo Clinic, which is drawn from the population of the section of the United States in which the survey of the second million drafted men in World War I showed the incidence of venereal disease to be very low

which can undoubtedly be materially reduced by the adoption of duty-status technics as they develop. The cost figure for syphilis at estimate of $8 per 10-hour day which is obviously low for many important categories on a war wage-scale, amounts to $7 440,000.

The cost of syphilis in the key person is emphasized by the last caption of Fig. 888 "and it depends on the man." This point is repeatedly and justifiedly emphasized in propaganda, and the enormous—indeed the immeasurable—cost to business in the "nervous breakdown" initiating paresis in important executives and business heads can be substantiated by example. More graphic for the commonalty however are some of the examples from the publication of Stokes and Brehmer on syphilis in railroad men, and Stokes and Ingraham in "Syphilis and the La

A yard-master whose last routine medical examination preceded his symptoms by approximately five years, but who had been under the care of railroad physicians for fourteen months, came to the Mayo Clinic for supposed laryngeal tuberculosis. He had never had a Wassermann test according to his statement. On the finding of a positive test, he was placed on treatment and made a remarkably rapid and satisfactory recovery. His history showed that he had developed a mass on his shoulder probably gummatous, following injury in line of duty through which he was endeavoring to collect compensation from the road. He had at a previous time received compensation for complications following another injury which suggested the influence of syphilis

Fig. 888.

MAN-HOUR COSTS OF VENEREAL DISEASE

Disregarding loss of efficiency slowdown and critical mistakes from illness with, or the effects of treatment for venereal disease, the hours potentially lost per infected and treated man may be estimated conservatively as:

Syphilis	500 man-hours in 65 weeks
Gonorrhea	*80 man-hours in 10 days*

Using the rate of 30 per thousand for syphilis in industrial workers recently established by surveys covering 267 000 employees in a national industrial personnel of 10,000,000 men:

Syphilis Can Cost.	93,000 000 man-hours spread over at least 65 weeks
Gonorrhea Can Cost.	7 000 000 man-hours spread over 8 weeks

100,000,000 man-hours

A 100-Hour Battle by One Million Men, LOST

And syphilis alone keeps on costing at a minimum of 15,000,000 man-hours a year—

AND IT DEPENDS ON THE MAN

A screwy pilot (with syphilis of the brain, or taking "tablets" for gonorrhea) can crash 400,000 man-hours of bomber in one motion.

as a cause. In addition to the foregoing he had been a continuous source of expense to the railroad for fourteen months during the treatment of a nonexistent tuberculosis, only to have the real nature of the trouble identified by a Wassermann test. A locomotive engineer age thirty-six at the time of his physical examination in the Mayo Clinic complained of difficulty of urination, for which a physician had been treating him with sounds, on the supposition that he had a stricture. On examination he was found to have a positive Wassermann, neurologic findings fairly distinctive of taboparesis. This patient was under observation and intensive treatment for one and a half years, in the premalarial era entered a definite remission, and during a period of about six months successfully carried his usual run. Suddenly however he returned to the clinic for observation, and it developed that he had been given "90 days" for his responsibility in a passenger wreck. As the patient expressed it one of his "spells" (lapses of memory) had come on him while on the engine and he had passed a siding where his orders were to meet another train. An examination of his spinal fluid at that time showed a rapidly advancing process in his central nervous system apparently unaffected by the treatment he had received. We could find no evidence that the railroad employing the man had made any effort to identify a possible medical factor in his responsibility for the wreck. Still another locomotive engineer in charge of a large superheater was suddenly seized with an irresistible impulse to ram the trai he was about to haul to the yards. He forced himself to close the throttle set the emergency air turned the engine over to a fire-

man, and following treatment for his neurosyphilis subsequently discovered, recovered sufficiently to go back to work. Still another yardmaster hit on the back by a brake-club, was catheterized for two weeks in a railroad hospital without a definite diagnosis. He was proved ultimately to have neurosyphilis, responsive to treatment.

The Definition of an Industrial Policy—Industrial policy must take on the color of the individual situation without doubt, as in most venereal disease control problems. There is, however, a fabric of underlying principles, which, from our experience and the literature, we have endeavored to summarize in Fig. 889. The first three captions, referring to the serologic test, are self explanatory, but Item 5 properly emphasizes that there is existing case material to justify—namely, the obligation of an industry which establishes its own laboratory or uses any laboratory facility, to see that such a facility measures up to all the national and state standards of approval now in exist-

Fig. 889

SOME INDUSTRIAL SYPHILIS PRINCIPLES

1. Serologic tests in preemployment examination and periodic reexamination are not the whole answer.
2. Serologic tests on candidates for employment should be routine and routinely a part of physical examination.
3. The serologic test should conform to all accepted standards as to laboratory fitness and procedure.
4. The possibility of false positives should be considered and checked.
5. Identified syphilis should not be dealt with simply on a blood test, but classified by fuller study—i. e., early, latent, CNS, cardiovascular, special sense organ.
6. For the community the first two, for the job, the last three are the most important.
7. Syphilis does not, as such, disqualify for a job (even as a food handler) nor does it justify a fire-on-sight policy.
8. The industry has a powerful leverage, in the job, for holding the employee to treatment which can insure fitness.
9. Such treatment, either given or positively arranged for, is an industry's duty.
10. Cooperation with organized labor is desirable and of great assistance in securing 8, if 7 is adhered to.
11. The industrial medical staff should utilize the services of the public health authority, report cases to them and make use of this assistance in contact-tracing and in the control of recalcitrants.
12. A very moderate expenditure of effort yields large returns in (a) increased safety, (b) less compensation costs, (c) increased employee confidence and cooperation, and (d) reduction in syphilis.

ence. The harvest of false positives and false interpretations where this is neglected can be large and serious. Industrial physicians, responsible for the interpretation of test results, should be familiar with the necessary checks on positive tests (which should always be repeated) and should be familiar with the causes of biologic false positives as now understood. They may require expert assistance and interpretation, which *should* be available *through* the public health authority.

Great stress should be laid on the classification or work-up of all syphilis identified in an industrial group.

Moore (1937), in his editorial expressions on this problem has particularly emphasized this point, and Cochrane and Kemp (1937) have shown that industrial disability and possible compensable injury may actually develop on the job from cardiovascular syphilis in unrecognized victims of the disease. For the public health, syphilis should be classified into early (infectious),

late symptomatic and asymptomatic types. It is the symptomatic syphilis, of course, which is critically important, but it should be pointed out that asymptomatic neurosyphilis, especially should be identified by spinal fluid examination whenever the individual case seems to justify it. This, for example, is the practice of the Baltimore and Ohio Railroad, as reported by Mulholland, and is particularly necessary in this type of industrial work.

All policy formats for industry to date begin with the positive assertion of Item 7 even more vigorously and uncompromisingly phrased. Reference has already been had to the fundamentally unsatisfactory character of job or occupational syphilis-finding activities, because serologic tests do not define either infectiousness or competence with respect to the particular work in hand, or in prospect. That there is such a thing as job fitness with respect to the presence of syphilis, however, should not be minimized or denied, and whereas an individual may be permitted one type of work in the face of one type of syphilis, he should be denied it if the type of syphilis either involves risk of inadequate performance, risk of extension under strain; risk for fellow-employees, or risk to the public health.

All proponents of industrial cooperation in syphilis control appreciate the tremendous leverage exercised by industry in behalf of adequate treatment and feel that industry should recognize its power by a corresponding sense of duty and should arrange for, supervise and assist in holding to treatment all individuals for whom it accepts any responsibility at all. Some of the difficulties that industry may encounter in trying to carry out this duty are vividly described by Gehrmann of the du Pont organization, and justify the suggestion that if private care is inadequate, the public health authority, through its clinics, should be drawn into the picture.

Many of the initial difficulties in the industrial field arose from an antagonistic attitude on the part of labor, which felt that blood testing was a discriminatory device containing an element of unfairness to the employee. That this reaction can be largely disposed of by a full statement of the situation and frequent conference with organized labor has now been clearly demonstrated. In fact, the influence of organized labor is a potent means of controlling the floater and the recalcitrant.

Sayers (1939), of the Division of Industrial Hygiene of the National Institute of Health, lays an excellent foundation of principles, some of them already alluded to with reference to the significance of syphilis for various types of occupation. He points out that while broad administrative policies may be defined, the decision as to what shall be done about syphilis of the employee in industry must be based upon a consideration of the individual case. In doing this, two groups of variables appear: (1) the particular job, its requirements and responsibilities, and (2) the particular syphilitic, the stage of the disease and the treatment taken. When one considers the job, there seem to be four principal sorts of human relationships involved, three of which concern industry. The other, or the individual job, is more or less distinguished by the fact that it is not integrated into a larger enterprise, such as the job of the farmer, the artist, or the prospector for example. Sayers divides jobs as follows: the personal contact job, in which it is important to keep alert for early syphilis. Among these he classes food handlers, hotel workers, barbers, beauty parlor workers, pullman porters, matrons, nurses and school teachers. He might well include all classes of domestics. His second classification is the job of responsibility: air-pilots, engineers, operators of switches, train dispatchers, crane operators, financial executives, for example. Among these, late syphilis as recognized by special tests and special examining acumen is highly significant. The third classification is that of the routine jobs such as clerical workers, laborers and so forth, in which he rates syphilis as of less importance but still a factor.

With reference to infectiousness, Sayers' emphasis deserves amplification. It is a concern of the employer, for example, that the waitress in the company restaurant, who is acting as the disseminator by clandestine prostitute activity with employees, shall be rated as an industrial hazard, precisely as is the employee who handles the lettuce or passes the towel from one person to another. D. C. Smith (1930) has emphasized the practical importance of the intramural carrier in a large group centering about a small industrial plant employing young men and women. The plant was thirty miles from the clinic. Fifty-seven names of exposed persons were obtained by messages of patients and correspondence. Twenty-four persons were examined in the clinic and gave negative reactions, and fifteen were found to have acquired syphilis. In fact, it is quite conceivable that the syphilis transmitted through the intramural sexual contacts of syphilis-infected employees is a more important issue than the transmission of syphilis through the medium of food, articles of common use and the like.

In all consideration of industrial syphilis, trauma looms large and the discussion of the topic in Chapter I should be referred to. Klauder and Solomon (1931), and Klauder individually point out that industrial compensation laws now abolish the defense of contributory negligence. Hence, it is no defense for the employer to show that preexisting disease brought about accident. In fact, Klauder's (1933) contribution on interstitial keratitis and trauma should be read by

every industrial physician, and its principles become familiar to industrial executives and medicolegal counsels. Eliet, under the professorship of Jeanselme laid down in 1936 a summary which is constantly quoted by persons concerned today with the influence of trauma in syphilis (Besson 1936). His classification of its effect includes (1) single and violent trauma; (2) single mild trauma; (3) mild trauma repeatedly applied. For all of these the industrial physician should be constantly on his guard in evaluating the potential significance of syphilis in an employee for his company. The activation of neurosyphilis, particularly by trauma (Urechia 1936, Barthelemy 1930) is often startling and serious. The question of infectiousness is an angle of the trauma issue, for *Spirochaeta pallida* may appear in early syphilis in lesions induced by vesicants and other traumatizing agents (Frankl 1936, May 1931).

Serologic Misinterpretation and the Job.—The foregoing discussion has related largely to the use of serologic tests, and some reference must be made to its abuse, especially where the law intervenes in a compulsory role. These misinterpretations are the not unjustifiable basis of labor opposition to extensive applications of blood testing in industry. A typical case, illustrative of the arbitration of individual issues, medical merits and personal rights by an incompetent arbitrator and the misuse of a positive serologic reaction as a pretext for a discharge actually based on other and personal ground, is illustrated by the following case.

A kitchen worker attached to the staff of college training table, who without preliminary medical examination had been employed by the college for six months and proved to be thoroughly efficient, was then subjected to routine serologic and physical examination; the blood reaction was found to be positive by the State laboratory. As was proper under the circumstances, he was referred to the College medical clinic, having charge of syphilis, and was found to have a seropositive latent infection of probably not less than twenty-six years' duration, the patient being at this time forty-six years of age. Before it was possible to work up the case or have competent medical opinion on his status, the nurse attached to the training-house squad discovered in some way that the patient had been referred to syphilis clinic for study, and without further information on the matter took the information to the lay superintendent of employees in this group. The lay superintendent and nurse, again without referring the matter to the physician who had originally recognized the presence of syphilis in the employee, proceeded directly to the syphilis clinic in an effort to obtain information as to whether this employee had syphilis. Information was properly refused them on the ground that they were laymen, and that the patient was privileged in the matter of communication. Thereupon these two lay persons, considering further reference of the matter to medical authority unnecessary, took it on themselves to discharge the employee on the ground that he had syphilis and that his association with food-handling work on the training table made him public health menace. Thereupon the clinic in which the man's infection was under study went back to the physician in charge of the case with its report, and by conference with him, and with the cook in the kitchen, succeeded in securing the employee reinstatement, since the syphilitic infection was absolutely without significance for the transmission of the disease.

The Reduction of Syphilis by Industrial Action.—A valuable table (Fig 890) from data in Parran and Vonderlehr "Plain Words about Venereal Disease" (Reynal and Hitchcock, 1941) shows graphically why the public health authority and the syphilologist desire the aid of industry in the control of infection, and why industry is justified in rendering such aid.

One of the industrial concerns mentioned previously as having noted conspicuous lack in personal efficiency which, on investigation, was ascribed to the prevalence of venereal disease, established clinic within the industry for adequate treatment, and discovered that it promptly offset the cost of the establishment by increased production. A West Virginia manufacturing concern, as result of the installation of clinic for venereal disease, costing $5000 to $6000 for the first year sustained an increased efficiency of 25 per cent. Undeniably the cost-accounting and personnel divisions of large industrial concerns could make stimulating and important contribution by closer study of this question.

Fig. 880

THE REDUCTION OF SYPHILIS IN INDUSTRY IS POSSIBLE WITHIN A PERIOD OF A FEW YEARS*

(1931 1934)

	Size (Number Employees)	Years	Prevalence of Syphilis in Employees
New River Coal Company West Virginia	3,300	1931	9 1%
		1931 36	7 2%
		1936	6 7%
du Pont de Nemours Company (18 plants, 10 states)	40,000	1931–33	8 9%
		1937–38	4 1%
		1940–41	1 9%
Caterpillar Tractor Company Peoria, Illinois	20,000	1937	4 6%
		1941	0 8%
General Electric Company Schenectady New York	14,000	1932	4 4%
		1939	1 8%
		1941	0 7%

ORGANIZATION FOR AN EMERGENCY VENEREAL DISEASE CONTROL SITUATION—CIVILIAN PROGRAM

A preliminary bow of credit should be given in such a discussion to the importance in time of emergency of the preemergency forces and set-ups which have been concerning themselves with the entire front of venereal disease control (Blue-print Fig 876) In direct proportion as a community or a nation has concerned itself with the problem before it becomes acute the result of emergency effort will be distinguished or mediocre From the civilian standpoint, at the present day much of the organizational effort expended on venereal disease control has followed the "association and education technic" as it might be called. In other words, it has undertaken to gather interested persons into chartered groups, serving as centers of influence and distributors for what is essentially propaganda or educational material. More infrequently such associational activity has concerned itself with the building up of intramural cooperation among the various groups or elements in the agency category confronting the sectors in Fig 876 When an emergency develops, the pressure for getting something done quickly results in a distinct shift towards what might apologetically be called the Fascist phase of a democratic procedure This means a resort to the key persons of high initial energy and acquaintance with the field who are given mandates under Defense Council authority either to head or to organize small committees which thereupon proceed to a further search for and enlistment of key persons, and the repeated and systematic employment of conference in an effort to galvanize and knit together the activities of the more central members of the agency front. The key to the key-person technic is of course influence and acquaintance as well as knowledge of the field As the civilian committee unit expands its activities, it undertakes to inform the public of the course it is pursuing but it relies on the public only secondarily and wastes as little time as possible in torchlight

processions and propagandistic publicity The earlier contacts made by the civilian VD defence group with the health authority the courts, the police, the prosecuting attorney and the liquor control agencies, are its contribution towards what might be called "the gang-up approach" to concerted effective action. This gang-up should, of course, follow a rather careful consideration of the precise nature of the local field, and a decision as to the points on which greatest pressure must be exerted to produce maximum control effects. The maintenance of adequate continued pressure is, of course, the chief problem for all public movements in or out of emergency situations have the initial emphasis of the rocket and a tendency to final flop

The selection of important social and industrial units through which to exert pressure or initiate movements is often determined by the finding in such units of key individuals who are both interested and active or willing to become so. Thus traction authority may be induced to publicize on tremendous scale, as in the car advertisement shown in Fig. 885 which through key person approach was placed in all the vehicles of the Philadelphia Transportation Company Industries may be induced to lend few minutes of industrial time to forceful moving picture; department stores may participate in employee and public education. The County Medical Society must be approached in manner to enlist its support and give it due place and importance; *broadly speaking no single agency has so much power to bog down movement so dependent* on the fundamental public health principle of treatment of the infected individual as does the medical profession. *Pari passu*, no single influence, probably has greater power to activate public sentiment when once it is willing to take the field. The technic of the original organizing and stimulative VD defense group should include the invitation t membership of representatives of the gang-up agencies. It should scrupulously preserve both the open forum and freedom of discussion technic, within its own membership, and absolute privacy and respect for off-the-record communications The importance of military and naval uniforms cannot be over looked in war emergencies and their presence often makes the difference between action and desuetude.

Thus, comparatively small group can provide the yeast for considerable rising of substantial bread in the emergency control of venereal disease. Such groups usually find to their astonishment that they are by no means alone in their efforts and desires, and that the front is closely defended, not to say at times obstructed and bestrewn by other groups intent on similar laudable purposes. After such statement the mention of any specific groups might be considered invidious; but unquestionably local sentiment not being too jealously isolationist, the state and national resources indicated in the blueprint should be invited to participation early in the work. In fact, it has been said that nothing gets to nowhere in the local infection control problem until the FBI takes *over the scrutiny of bank accounts and income tax returns. This points the moral* for the prosecuting attorney and for all others, that finding the vested interests, isolating or reforming or punishing the facilitator is one of the chief works of long range civilian cooperation and program control.

The disposition in old line thinking to leave venereal disease control to the police and the courts is sometimes an explanation of a halting and jerky raid-punctuated program Common sources of difficulty are of course familiar enough to the slightly cynical reader The police throw out the dragnet, gather in the known prostitutes, and then are chagrined to find them discharged though undoubtedly guilty of violation of the criminal code on the basis of a negative medical examination. The prosecuting attorney finds it difficult to prepare cases in the absence of witnesses, many of whom wear uniforms. Politics dominates many of the smaller centers of legal decision, and interest pulls every leg that it can find. The liquor control authority as has been many times indicated, holds one of the critical strategic positions without, unfortunately in many cases, a sufficiently extended power to enforce. The health authority too often is looked upon by the old-line workers in the field as an interloper respectfully addressed as "doctor" but regarded as one who

should stick to his statistics and let the vice squad and the wagon do their work unhampered. The disposition to adopt stop-gaps and chase dogmatized solutions particularly such as the wholesale incarceration of prostitutes, appears and reappears, and the press, too often enlisted with great difficulty in a sober and well-thought-out presentation of any problem will quickly make a sensational issue of a nonessential Broadly speaking, in the present emergency press cooperation has been so far as we have observed, more difficult to obtain than that of any other publicising agent.

VENEREAL DISEASE IN THE ARMED FORCES

Army and Navy Rates.—The student of venereal disease control owes a lasting debt to Colonel J F Siler whose monumental analytical study of venereal disease in the Army of the United States of America throughout its history is literally a textbook unsurpassed in the world literature From this source from the statistics of diseases and injuries for the calendar year 1939 in the Annual Report of the Surgeon General of the United States Navy (with comments) published in 1941 and from a statement read by Commander Carter before the Special Committee on Enforcement of the National Advisory

Police Committee on Social Protection (Journal American Medical Association, 122:311 May 29 1943) we have collected the figures to place the venereal disease incidence problem of the armed forces in their American perspective (see Fig 801) From Colonel Siler s monograph, Figs. 802 and 803 are reproduced the former because it shows, together with incidence in the Army as a whole the striking effect of foreign service on venereal disease incidence controlled and uncontrolled, and the latter because it correlates the ups and downs of incidence in an armed force with important events and regulations in the control situation. From these figures and summaries it will be apparent that the United States Army has been able to introduce into human experience as determined by wars, the paradox of a drop in venereal disease incidence of the most striking proportions in complete violation of the experience of history our own included that venereal disease rates in armies and navies should rise enormously during wars. The Navy has in World War II accomplished a similar feat (Fig. 801) In the case of the Army it may perhaps be broadly said that this triumph is an expression of the weight of a determined central policy enforced at the periphery against what might be called the minor antagonism of the old-line opposition which has supported regulation as against suppression In the Navy as no doubt in the Army a large part of

Fig 892.—Venereal disease, United States Army since 1820, annual rates per 1,000 strength. (The Army Medical Bulletin No. 67)

(American troops only)

Note: American troops in China where not shown are included in Philippine Island figures.

Fig 893.—Admissions for venereal disease, annual rates per 1,000 strength, United States Army by country 1900–1940. (The Army Medical Bulletin No. 67.)

the improvement must be attributed to attention to preventive detail at the periphery In the Navy the autonomy of the ship and the fleet operating often in the worst imaginable conditions as regards milieu in the tropics and the Asiatic countries, the importance of the ship's medical officer the fleet medical officer and the rapport between them and the fleet command, must have special significance and this demonstration that it has reached its full effectiveness is especially welcome.

Several points deserve comment on principle. First, the rates presented are *incidence* or attack rates and there is nothing comparable with them in experience with respect to the civilian population. They are based, and the possibility of obtaining them depends, on the medical physical inspection possible only under the disciplinary control of the armed forces. In civil life a large part of the incidence of venereal disease disappears into the limbo of nonexamination. The second point concerns the use by the Army in the more recent statistics, of so-called *adjusted rate* which excludes those cases which appeared with venereal disease at their first assignment to camp, presumably acquired en route after examination at the induction center This, of course, results in a striking drop in incidence figures, but it raises the uncomfortable and probably as yet unanswerable question as to whether the armed forces have any responsibility for the condition in which their inductees arrive and if so, what forms of pressure they can bring to bear to protect them during the immediate preinduction period. That such responsibility could not with justice be placed solely upon the armed forces is clear but the desirability of their initiating an energetic movement for the correction of the discrepancies is, we believe, equally clear The third matter for comment is the special conditions encountered by the *Navy* Throughout its history the Navy has had a higher incidence of venereal disease in times of peace than in time of war because in war the personnel is distributed to ships and fleets which are on the move and for long periods of time out of access to venereal infective sources. That such condition of affairs need not necessarily prevail, and that tropical service or not, the Navy should be controlling the situation in time of peace with something approaching the circumstantial efficiency of war would seem to be at least a permissible deduction. Nonetheless, the greater difficulty of organizing the small unit groupings of the Navy must be admitted. In armed forces whether of the land or the sea, there will inevitably be a fraction of the medical and line personnel unacquainted with advances in venereal disease control practice, and if acquainted, disposed to differ because of limited personal observation of some limited local solution of problems which has little or no general application. The Navy in the present war has laid great stress on the educational responsibility of the individual officer with respect to his men, and has been placing increasing reliance on preexposure, especially mechanical prophylaxis, and on the most systematic advocacy if not enforcement, of early postexposure prophylaxis. The records on some individual ships are almost too good to believe and are convincing demonstration of the effect of locally applied force, energy and foresight in dealing with the infection problem.

The history of Army practice is particularly well displayed in Colonel Siler's diagram (Fig 892) The war peaks are obvious, but more important is the record following the Spanish American war and the Philippines insurrection, in which the influence of voluntary prophylaxis, instruction in sex hygiene, compulsory prophylaxis, monthly physical inspection and forfeiture of pay began to become apparent. The comparatively low figures in World War I high in contrast though they are with those of the present war are also expressions of a determined central policy initiated early in the conflict, and adequately implemented by sections 12 and 13 of the Selective Service Act, which provided control of extracantonment and leave conditions and the alcohol situation, which was slow in developing in the present conflict. Colonel Siler explicitly and repeatedly emphasizes what is coming to be regarded (Pappas 1943) as first principle of venereal disease control official recognition of the responsibility of unit commanders for the rate prevalent among their men. This again points the principle that the control of venereal disease is local and indeed an individual matter eye-to-eye and man to man. There can never be substitute in directive letters, general orders or statements of policy for the energetic and determined as well as enlightened medical and line officer

A Summary of Control Principles for the Armed Forces.—This has been attempted in Fig 893 and inasmuch as a large part of the volume of informational material, as well as the preponderance in man power comes from the Army side it may have a distinctly military flavor Nonetheless the emphasis

is nearly equally distributed. Venereal disease comes from the civil population. That portion of it which distributed venereal disease in former wars remained relatively stationary about points of troop concentrations. In this mobilization it moves with the troops, or the troops on leave move towards

Fig. 804.

SOME CONTROL PRINCIPLES FOR THE ARMED FORCES

1. Venereal disease comes from the civil population—but this does not relieve the military and naval authority from the duty of protection of personnel en route and on duty and an interest in public health.
2. Control problems are fundamentally local, with general phase, not the reverse.
3. Cooperation with the local health authority is vital.
4. Such cooperation requires
   a. Accurate contact tracing and other information freely exchanged;
   b. Centralized (venereal disease control officer) responsibility in major units and concentrations, on both sides (i.e., military or naval, and health authority);
   c. Frequent conference.
5. Suppression of opportunity for exposure to potential infection not mere regulation of prostitution, is the demonstrated, not just the rhetorically sound policy
6. Suppression should be encouraged and left to the civil authority as long as possible.
7. Venereal disease control officers in the armed forces should participate actively in public education and the securing of professional cooperation.
8. Within the armed forces themselves the following policy items are essential
   a. Central directive influence;
   b. Cooperation and sympathy between venereal disease control and general medical and line officers,
   c. Development of adequate personnel to obtain usable epidemiologic information within the corps itself
   d. Adequate planned prophylaxis, pre- (condom and kit), and post-exposure (station)
   e. Adequate forceful and repeated vivid instruction in small groups and man to man, not in occasional casual mass aggregates
   f. No "pro-slips"; contact-tracing based on source of infection (via the infected man);
   g. Study of the leave area and out-of-bounds; military police, shore patrol and Navy Act second or last;
   h. Willingness to have uniformed personnel appear in support of civil effort and court action where indicated
9. A positive attitude of responsibility placed on all concerned for the incidence of venereal disease in command or group—i.e., on the personnel to report infection (not necessarily exposure) and on line and commanding officers to account for their venereal disease rates and accept them as grading factors in promotion, etc. It is recognized that penalty too directly applied encourages concealment and self-treatment.
10. A positive attitude on morale factors. Don't just leave it to the chaplain.
11. Four additional suggestions
    a. That treatment for venereal disease be so far as possible conducted on duty-status basis (Pappas);
    b. That the post be made more attractive than the undesirable leave area ("barrios" of Philippine practice—Siler and sports-recreation principle advocated by Wenger);
    c. That training be conducted when possible in areas with low indigenous venereal disease rates (Wisconsin-Minnesota mobilization) and
    d. That extraordinary precaution and special preparation combining civil and military effort be devoted to venereal disease control in advance of occupancy (Wisconsin mobilization) and in tropical and certain foreign stations.

widely scattered sources with a new and disconcerting fluidity. Army conditions now begin to approach the "sea-gull" situation in the Navy in which the girls move back and forth from station to station with the fleet. This extends over the entire countryside for distances ranging up to a thousand

miles from the point at which an individual infection appeared, the general problem of control and makes doubly necessary the inter-state and inter municipal not to say national public health mechanism for the handling of the situation equally with the closest possible inter-digitation between the military medical organization and the civil public health authorities. The first duty, therefore, of a medical officer charged with responsibility for venereal disease is to accept himself and to sell to all concerned the principle of suppression as opposed to regulation and tolerance. He should not feel himself restricted in his approaches to the civil population, but should at the earliest moment cultivate the closest possible relations with it and particularly with its public health representative Much travel and constant conference and interchange without the stiffness but with the prestige encouraged by the uniform is a necessity In March, 1942 for the first time in its history the Surgeon General's Office of the United States Army announced that specifically qualified medical officers would be assigned to control and prevent the spread of venereal disease among our troops, and the Venereal Disease Division was placed in charge of Colonel Thomas B Turner formerly of the Johns Hopkins School of Public Health and a syphilologist and laboratorian of distinction. From this point onward the force of the jointly announced policy of the War and Navy Departments the Federal Security Agency and the State Health Departments (Venereal Disease Information, September 1940) gradually became a reality The delays heatedly discussed from various sources have not apparently seriously affected the ultimate good results, although the question again of an adjusted rate and nonresponsibility for preinduction infection arises to plague the inquirer Some of the delay was perhaps consequent on a disposition on the whole a wise one, to endeavor to proceed to the control of local situations by building up local support and enforcement in contrast with the use of the big stick and F B.I approach.

The value of planning which includes all agencies civil and military including the public health and police authorities, the beverage control, highway and automobile control, and similar authorities, was effectively illustrated by the pre-war Wisconsin and Minnesota mobilization in which, vested with the necessary constitutional authority the governors of the states concerned as an emergency measure were enabled to call together conferences of the interested authorities to set aside as segregated or controlled area, the entire region of mobilization as special public health district. The individual functioning state services were able to prepare the terrain for occupancy and to frighten off it is believed, wholesale influx of subversive influences. The results in the Wisconsin area: 60,000 regulars and National Guard troops, total of 78 cases of venereal disease admitted to hospital, only four of which could be definitely traced to infection received in the maneuver area, a rate of 0.65 cases per thousand per annum. A critique of these figures must take account of the relatively short duration of the maneuvers, which failed to reveal perhaps all infections acquired during them; the great activity of the troops which through sheer fatigue, limited their capacity for acquiring venereal disease, and the high morale of experienced soldiers and the pick of the National Guard, many of these men in middle life with family and personal responsibilities acting deterrents.

The Military Mechanism—Selective Service Contact Tracing, Power to Act.—The policy of the armed forces of the United States in the present war with reference to the acceptance of men with venereal disease began with an absolute "No, and then as man power pressure increased the gates were cautiously lifted and at the time of going to press the general policy of admitting selected persons with syphilis to the armed forces has had full acceptance An effort has been made to preserve the general principle that a man with venereal disease admitted must either have had or would after

induction be given an amount of treatment which an advisory group (the Venereal Disease Subcommittee of the National Research Council) felt willing to define as adequate treatment for his infection. This admits to service a relatively large body of usable material in the early and latent phases of the disease cripples if it does not outright do away with the malingering device of acquiring a venereal disease in order to avoid induction and subjects a large mass of human material to a better evaluation with respect to blood serology and spinal fluid and clinical examination, than it has ever received before. The exclusion of recognizable cardiovascular and neurosyphilis is absolute and its identification after induction is made the basis for medical discharge. This too may be subject to new directives.

The recognition by the Army of its share of the responsibility for the tracing of the infectious contact is one of the notable advances in the practice of the present war At the start, the Army's share in the identification of the source of infection consisted in making available to the local public health authority the prophylaxis slips made out by personnel visiting prophylactic stations after exposure. The worth of the information was small though in expert hands, by no means negligible. Intoxication, unwillingness to testify fuzziness of recollection, fear of medicolegal complications, all diminished the usefulness of the "pro slip" and it required a high order of expert contact tracer to "stack" these slips in such a way as to bring out the identities of important promiscuous and infection-distributing individuals. There was increasing reason to believe that the necessity for filing a "pro slip" deterred a large proportion of personnel from seeking prophylaxis after exposure, and emphasis on its use has accordingly steadily diminished With this decline has arisen a far more effective approach namely by way of the infected individual after his acquiring of a venereal disease is established at his post. The report of contact of venereal disease reproduced as Fig. 895 illustrates the use the Army has made of the developing knowledge of source of infection. The information is collected from several different types of adjunct personnel within the Army medical organization itself but particularly from corpsmen and noncommissioned officers, whose contact with troops is extremely close. In some instances, public health nurses in the employ of the civil health authority have participated in this work with notable or negligible results dependent on various circumstances. This form of report is addressed to the health officer a sign of the new cooperative relation between the civil and the military authorities

The Third Service Command, with which we have had special experience, and whose results have been effectively published (Norris, Doyle and Inkrant 1943), has illustrated number of important changes taking place in the venereal disease situation of our armed forces, and embodies demonstration of the effectiveness of military-civilian cooperation in control. For the sixteen months period, March 1942, to June 1943, 4,198 cases of venereal disease contacts (both gonorrhea and syphilis) were reported by the Third Service Command to the health departments of the states and cities concerned. Family (ife) contacts represented 9 per cent of the sources of infection casuals (friend, pick-up, no-fee-paid) 73 per cent of the contacts; and prostitutes including streetwalkers, brothel inmates and call-girls, represented only 18 per cent of the infectious contacts. The shift in the present war and American scene from professional to casual source of infection could not be more clearly illustrated. The age group distribution of the contact sources of infection presents disconcerting food for thought. One-third were between fifteen and nineteen years of age; 47 per cent in the early twenties (twenty to twenty-four), thus placing the problem statistically squarely in the lap of youth, and difficultly controllable youth at that. In supplementary report (Venereal Disease Information) of interest to control agencies, is the item of the foregoing report ... hich classifies the changes in the sites of encounter and exposure. tavern class, hich includes restaurant, caf and night club, is still the leading place of encounter for both clandestine contacts and prostit tes. The house or partment, nd hotel or rooming house have increased in relative frequency as places of exposure while tomobiles, brothels and

outdoors have decreased (recall seasonal factors). The brothel, which was the leading place of exposure for paid prostitutes in the 1942 series, is now in third place with hotel or rooming house first and home or apartment second.

With all the emphasis that has been placed on the importance of civilian cooperative effort, it will be clear that influence should precede pressure, and pressure precede force where the military and naval groups are convinced that civilian inadequacy underlies their excessive rates. Pressure consists in the repeated appearance and insistent repetition in the offices of the public health and other civilian authorities included in the "gang-up" of venereal disease control officers in uniform. Offers of cooperation in reporting, improved reporting, improved and intensified follow-up of unutilized reports, offers of witnesses for civilian-initiated repressive procedures (closing of liquor abuses, curfew and early closing laws, suppression of houses, repression of solicitation) are all preliminary steps. The next grade of pressure is the introduction with or without request of the civilian authority, but preferably with, of the Military Police and the Shore Patrol. The general practice is, of course, to turn over military personnel arrested by the civil authorities in compromising or vicious situations, to their local command, and the local civilian authority may not unreasonably expect assurance from the military that something is being done with such cases, and vice versa. The military authority may confidently point out to civil agencies by invitation or otherwise, conspicuous lacks in their attention to the leave situation and the protection and entertainment as a matter of patriotic duty, of personnel on leave or en route.

A next form of pressure and one preferably invoked by request rather than as threat and execution, is the out-of-bounds or off-limits type of order, which in present practice can issue from a variety of sources and cover small as well as large situations. This type of control is particularly exercised against districts, groups of establishments, individual establishments, and even regions along highways and so forth within the same local or state jurisdiction.

There exists also a separate Federal agency to which both civil and military authority can take appeal, and which proceeds to some extent also on its own initiative, though always seeking to cultivate local mechanisms and local sentiments. This is the Social Protection Division of the Federal Security Agency, whose organization and technic of procedure have been well described by its Director, Eliot Ness (Venereal Disease Information, 22: 456, December 1941). The Division is concerned with the protection of the community and particularly of its girls and young women, from prostitution and other related social hazards. It also stimulates the constructive treatment and care of girls and women detained by the police. In its long-term aspects it is an integral part of the total public welfare program of the country, and depends for its effectiveness upon the established agencies for public health, medical care, law enforcement, public assistance, recreation and child protection, and in turn supplements these agencies in its particular field. It devotes its energies particularly under four headings: repression of commercialized prostitution, the treatment of prostitutes including emphasis on rehabilitation, the protection of girls in defense areas, and cooperation with other agencies.

The May Act.—The big stick of venereal disease control by the armed forces was enacted as the May Act by Congress in July 1941. Confronted with an unalterable opposition on the part of the American public to the prohibition of alcohol, this act lacked at the start some of the most important

basic elements of control provided by the Selective Service Act of the previous war It came into existence late after many of the military and naval establishments were planned and quite fully developed it has a rather complicated mechanism of invocation within the armed forces themselves and places enforcement almost entirely in the hands of a badly over-worked agency the Federal Bureau of Investigation though its tremendous efficiency is fully recognized The result has been a relatively insignificant use of the act, and on these occasions mainly against important cantonment areas mostly in the South Its invocation is inevitably in contravention of the broadly constructive policy that action should be at the demand of local sentiment and with local support. Nonetheless, enactments such as the May Act are necessary evils, even though in their framing they may turn out to be jointed clubs.

Responsibility and Penalty —The armed forces have had to struggle with their special problems. The driving of venereal disease into concealment has been countered first by penalty in the form of forfeiture of pay (1912) for failure to take prophylaxis, as evidenced by absence of record of the fact in individuals developing infection This was reinforced by monthly physical inspection (colloquially but erroneously designated "short arm" inspection). During the period of World War I punitive regulation was supplemented by the placing of official responsibility on unit commanders for the venereal disease rates of their commands (1917) Towards the value of both of these measures, experienced students like Colonel Siler are distinctly inclined. Pappas rates the principle of responsibility of the unit commander as among the most fundamental in military venereal disease control On the other hand, there can be no denying that the trend of treatment toward shortened effective procedure and toward shortened but ineffective though symptom-concealing procedure (sulfonamides) is likely not only to nullify the inspection provision of compulsory practice but to make outside treatment and concealment of infection particularly easy as an escape from penalty This in its turn reacts on any attempt to make prophylaxis compulsory as revealed by the occurrence of infection in those who fail to seek it, and disturbs the entire mechanism of the use of station prophylaxis, the most effective instruments of venereal disease control in the catalogue. There is therefore an as yet undecided issue here which only subsequent experience can evaluate There seems reason to believe that the problem like all venereal disease control problems, has important local features and the nature of the command and locale, the character perhaps even the race of the troops concerned, the individuality of the responsible officers will make special solutions work at one point when they are ineffective at others. It is believed, therefore, that at this point particularly autonomy may well prevail under the aegis of the basic principle that the unit commander must assume responsibility for the venereal disease rate along with the general health standing and military efficiency of his command.

CHAPTER XXIV

THE CURRENT DEVELOPMENTS—PENICILLIN

The Pace of Discovery.—Two figures were coming into being as the third revision of this textbook was approaching completion—the one destined to become a giant, the other probably a dwarf. Intensive arsenotherapy was reaching its full stature in massive foreshortened treatment—its sole remaining drawback, toxicity. The promised (though not yet completely fulfilled) answer to toxicity is the advance of knowledge of the detoxicants, which can make the arsenic-heavy metal combinations safe. Just as safety seemed within reach, and arsenotherapy about to mount the giant's throne, a reactionless, safe antibiotic agent, penicillin, challenged its title to the sceptor. Though the rivals will for some time dispute the title, and the struggle perhaps end in a compromise arseno-penicillin handclasp, it is already growing clearer which will be the ruling giant, which the subordinated if not defeated dwarf. Even the drama of the occasion does not however, justify as yet calling the giant Penicillin the King. But at least we know that we can now cry "The king is dead—long live the King" and with this introduction, it will soon be possible for the reader to infer by space and type font, which way our personal beliefs on kingship are tending. His first problem then, is to decide how to conduct himself in the interregnum.

For the interregnum these reflections are suggested:

1. The established principles regarding syphilis and its behavior under treatment have not lost their meaning. Without them we might well be in a milling mob.

2. The arsenotherapeutic era warns us against the repetition of the serious mistakes of 1911–1920—the one-dose cure unachieved, the infectious relapse unrecognized, follow-up unknown, titered serologic tests as measurements of treatment response nonexistent, the spinal fluid warnings of asymptomatic neurosyphilis unsought for, neurorecurrence unforeseen, the variations in drug activity and behavior unsuspected, treatment allergy yet to be heard of, the causes and prevention of serious reaction guessed at, overlooked, slowly and painfully brought to light, with an irreducible residue of mortality confronting us almost until today.

3. The arsenotherapeutic era has set base lines and standards in curative and palliative performance in fractions of a per cent against which to measure new claims to therapeutic preeminence; has trained minds and organizations in logic, teamwork, planning and procedure, and in the evaluation of chemotherapeutic agents; has been combined with collateral methods (fever therapy for example) that will now in turn be integrated with the new discovery. It may be even so combined with the new to bring, for the first time, the one hundred per cent cure.

4. The arsenotherapeutic era has warned of the dangers of loose thinking—letting down the bars on standards, "pushing" a hoped-for result.

A short statement on arsenical detoxicants recently reported in the literature is given at the opening of this chapter.

5 The arsenotherapeutic era has taught, and it has in the same process set limits on the conclusive significance of time in the evaluation of results. Less than a lifetime now will decide the new order—less than a decade perhaps, because of what we know from the past.

6 For years to come there will be patients who have had the old treatment, whose decisions must be made for them on the basis of the old, plus the new

It appears then, that penicillin if and when enthroned, will literally climb to the seat on the shoulders of the sound, established and effective past of syphilotherapy And with these preliminary remarks we proceed to summarize the recent acquisitions in the field of the detoxicants.

Mode of Action of Arsenical Detoxicants.—For previous discussion of the subject of detoxicants, see Chapter IX. Among the more recently proposed detoxicants is, of course, ascorbic acid and its derivatives, which, as vitamin C, is assumed to have an influence on capillary fragility (as in scurvy) and upon perhaps the allergic state. McChesney Barlow and Klinck (1944) found not only that ascorbic acid, but other organic acids, including isoascorbic, d-gluco-ascorbic, lactic, pyruvic, succinic, malic, mandelic, aspartic, gluconic, β-ketoglucuronic acid and l-cystine, exercised a detoxifying effect on arsenical preparations. Significant protection was obtained in animals against the toxicity of neoarsphenamine. The effect is most favorable when the arsenical and the protective agent are injected intravenously in the same solution, but is nonetheless present when they are injected simultaneously at different sites. Ascorbic acid and para-aminobenzoic acid are of equal value as detoxicants for neoarsphenamine

Simultaneously with its detoxicating power must, of course, be considered the effect of the detoxicant on the spirillicidal action of the drug employed. Ascorbic and para-aminobenzoic acid and their congeners, so far as investigated, do not appear to rob the arsenicals with which they have been tested of their spirillicidal value, notwithstanding their detoxicating power The mode of action of detoxicants of this type is not yet clear The above-mentioned authors believe that most of the effect of the ascorbic acid is that of preventing oxidation, chiefly after injection. It is, of course, importa t further to find out whether a detoxicant acts by changing the affinity of the drug for tissue cells, which is offered by Hogan and Eagle (1944) as an explanation of the extraordinary differences in the toxicity of various arsenicals. It follows that the less toxic compounds and the more effective detoxicants prevent the linkage of the therapeutic agent with tissue cells and thus likewise make possible their rapid excretion.

The clinical application of para-aminobenzoic acid in protecting against the toxicity of trivalent and pentavalent arsenicals is only in its beginnings and the report by Rose, Travell, Solomon and Sandground certainly presents no convincing evidence of effectiveness so far as the methods tried are concerned Whether the knowledge accumulated in the animal in this group of detoxicants will be transferable to man remains to be seen.

Methyl Chalcone of Hesperidin.—This substance or group of substances act as an arsenical detoxicant by protecting against excessive capillary fragility which is assumed to underlie the most fatal of the grave complications of the use of the arsenicals, hemorrhagic encephalopathy

The substance is pparently an active ingredient of lemon juice and lemon peel, and was apparently shown by Warwa and Webb (1942) to decrease the fragility of capillaries and protect against localized hemorrhages. Methyl chalcone has been studied by Griffith (personal communication) with results apparently confirmatory of the capillary protective action, and Goldstein, Stolman, and Goldfarb (1945) applied the use of this substance experimentally to animals in combination with mapharsen. The results indicated a substantial protection of rabbits by the mapharsen-methyl-chalcone combination. These authors further showed that methyl chalcone of hesperidin does not impair the spirochetcidal activity of mapharsen in vitro. It was even suggested that the substance had some spirochetcidal effect over and above the action of the mapharsen.

Thus far no clinical report of the use of methyl chalcone of hesperidin in the treatment of syphilis has appeared.

PENICILLIN IN THE TREATMENT OF SYPHILIS

The Literature —It is not proposed here to review the already extensive literature accumulating about an antibiotic agent of such superb versatility as penicillin. Instead, the following references are cited for those who wish a

thorough-going and easily accessible review of the subject. A N Richards, as Chairman of the Committee on Medical Research of the Office of Scientific Research and Development (J A M. A. 122:235 1943) gives the early historical and clinical background with emphasis on the development of penicillin manufacture, investigation and use in this country The next authoritative statement is that of Keefer and associates of the Committee on Chemotherapeutic and Other Agents, Division of Medical Sciences, National Research Council (J A. M A 122 1217 1943) on whom was placed the responsibility for allocation of penicillin to medical investigators in the United States They described tersely the use of penicillin in the conditions in which it was to that date known to be effective. Syphilis was not studied, since the publication antedates the use of penicillin in syphilis by Mahoney and his co-workers An important symposium on the clinical use of penicillin and a discussion of anti microbial agents of biological origin (J A. M. A. 124:611–637 1944) presented the experience of Dawson and Hobby Herrell, Bloomfield, Rantz and Kirby and Dubos s analysis of the mechanism of action. This was followed in May 1944 by an excellent review of the literature through 1943 by Lieutenant G F Schmitt, M. C., USN(R) (Am. J Med. Sc., 207:601–678) with a bibliography of 126 titles which will give the average reader all he can absorb of technical detail, from culture media through therapeutics. This includes, however only a notation on the treatment of syphilis.

Because of the extremely important part played by the cooperation of the great pharmaceutical manufacturers of this country and their research laboratories in the development of penicillin manufacture, unusual weight attaches to the publications of these concerns on the subject. Any of the large well known pharmaceutical houses can be addressed by the physician for copies of brochures, collections of bibliographic references, news items and so forth, as may be desired.

Historical Summary —For those interested in dates, 1929 the year in which Alexander Fleming of London recognized the inhibitory effect of mold cultures upon cultures of staphylococci, can well compare with 1909 and 1910 which marked the Ehrlich-Hata Bertheim synthesis of "606" The discovery remained dormant for a time, 1932 being the date of confirmation of Fleming s discovery by Oxford investigators, and nine years elapsing between discovery and the making of penicillin available for therapeutic purposes, through the pioneering work of H. W Florey of Oxford and his associates. As pointed out by Richards (1943) Florey and Heatley s visit to the United States, under the auspices of the Rockefeller Foundation in 1941 marked the beginning of the tremendous wave of interest and productive activity which has set the United States, in all probability far ahead of the rest of the world in the manufacture and use of penicillin.

Because of the scarcity of the supply and the anticipated—and, in fact, demonstrated—tremendous importance of penicillin in the treatment of various types of war casualties, the responsibility for the development, manufacture and general allocation of penicillin has devolved upon the War Production Board. The currently available supply of penicillin devoted to investigative purposes has been under the control of the Office of Scientific Research and Development and the Committee on Chemotherapeutic and Other Agents of the National Research Council has, under the chairmanship of C. S. Keefer carried the responsibility for allocations to individual investigators and groups. After Mahoney and his co-workers had established the potential usefulness of

penicillin in the treatment of syphilis, the Subcommittee on Venereal Diseases of the National Research Council, under the chairmanship of Moore and subsequently a Penicillin Panel appointed by them, undertook the organization of a general program of study in the field of syphilis with allocations made for specific purposes to cooperating clinicians and their organizations throughout the country The plan of investigation for early syphilis involved a participation of 23 clinics working under allocated time-dosage schedules in the treatment of early syphilis, and 8 clinics with only general instruction, working on various aspects of late syphilis. The results, correlated and presented by

Courtesy of Dr John F Mahoney Senior Surgeon, U.S.P.H.S. Research Center Stapleton, Staten Island, New York.

J E. Moore for early syphilis, and John H Stokes for late syphilis, at the American Medical Association meeting in Chicago, June 1944 will be referred to subsequently as the Panel Research of the Office of Scientific Research and Development and the Committee on Medical Research

Penicillin in Syphilis.—The distinction of discovering the applicability of penicillin to the treatment of syphilis belongs incontestably to J F Mahoney Senior Surgeon United States Public Health Service the head of the Venereal Disease Research Center at the United States Marine Hospital, Staten Island, who with his associates R. C Arnold and A. Harris, published their original paper in December 1943 (Am J Pub Health 33 1387 and Ven. Dis. Inform.

24:355–357) Subsequent brief descriptions of the effect of penicillin on certain aspects of syphilis were later published by O'Leary and Herrell (Proc. Staff Meet., Mayo Clin. 19:20 1944) and by Bloomfield, Rantz and Kirby in the Symposium referred to above (J A. M. A. 124:927 1944)

Mahoney and his associates, after finding by limited animal experimentation that penicillin possessed spirillicidal activity for *Spirochaeta pallida*, transferred the work to man, because of the known lack of toxicity of the antibiotic agent. The early results in the animal phase of the general study to quote the authors, indicate that the time-dose relationship will prove to be as important in this therapy as in the use of other chemotherapeutic agents. Their four original patients were all males with characteristic *Spirochaeta pallida* identified by darkfield from single penile ulcers. Mahoney's method of studying the serologic behavior of the case by a battery of tests in which the gradual decline of intensity of reaction to negative over a period of observation could be observed, is well shown in his historic Case 1 whose chart is reproduced as Figure 896 The spirillicidal action of penicillin (*Spirochaeta pallida* disappeared by the sixteenth hour) the occurrence of Herxheimer-like reactions and the healing of lesions were coincidently demonstrated.

O'Leary and Herrell's case was that of a woman with a late syphilid of the nose and a concomitant neurosyphilis who was treated with penicillin by the continuous intravenous drip in contrast to the intramuscular route employed by Mahoney and the total dose was approximately one-fourth that employed by Mahoney Healing of the late syphilid and slight improvement in the spinal fluid were observed over a period of about six weeks. Bloomfield, Rantz and Kirby treated seven cases of early syphilis by intravenous drip with total doses approximating 1,000,000 Oxford units. Their findings confirmed Mahoney's observations with regard to spirillicidal and Herxheimer effect.

Against this background we now see projected the evaluation study brought to an admittedly only preliminary report, by the Panel Research summaries, spokesmanned by Moore and Stokes at the American Medical Association, in June, 1944 to which fuller reference must subsequently be made. As a preliminary to any comprehension of penicillin in the treatment of syphilis, Figure 897 attempts to summarize what the practitioner meeting this antibiotic agent for the first time should have as elementary informational equipment.

The Known and the Unknown on Penicillin in Syphilis.—It is now in order to place penicillin, so far as present knowledge permits, in the therapy of syphilis. This has been attempted in a manner to indicate so far as may now be anticipated, both the known and the unknown (Fig 898) It may of course, be anticipated that other penicillins or relatives of penicillin will come into existence. At the present time, only three of the relatively large group of antibiotics appear to possess spirillicidal activity but once the structural formula of penicillin becomes available and its synthesis is possible it may be anticipated that the chemotherapeutic history of the arsenicals, with its shifts of important elements and groups within the molecular structural formula, will repeat itself

Outstanding Problems in the Advent of Penicillin.—It hardly seems, with the goal of therapeutic efficiency if not absolute mastery of the infection by a reactionless agent, in sight, that any significant desirata remain. This, unfortunately is not the case. As intimated at several points in the discussion the present technics of penicillin administration leave much to be desired from the standpoint of the control of syphilis as a public health problem. The simul

Fig. 897

PENICILLIN FOR THE PRACTITIONER

A General Statement of th Facts

1 Produced by a fungus, *Penicill um notatum*, in amounts varying with strain, the extract used therapeutically is a partially purified product, the sodium, calcium or ammonium salt of the base, yellow powder "Pure penicillin is not vailable as yet. Pyrogens must be removed i manufacture.

2. Therapeutic activity is measured by th Oxford unit," an amount of penicillin capable of inhibiting to a defined degree the growth of a strain of *Staphylococcus aureus* Standard maintained and manufacturing quality controlled by the Federal Food and Drug Administration in the United States. The Oxford unit will probably be replaced by weight measurement of dosage of 1650 O.U. per milligram.

3. Manufactured by a number of concerns, there are discernible differences in lot behavior marked differences in price and undefined differences in potency Expiration dates are well inside the probable lif of the preparation.

4. Marketed in mpules in vacuo, i amounts of 5,000, 10,000 25 000, 100,000 and 1,000 000 O.U thought to be thermolabile (ceiling of 4 C.) but less so than nticipated, the sodium salt is easily soluble in distilled water physiologic salt solution, 5 per cent glucose. The first scheme is used in intramuscular the latter two i intravenous work. Calcium penicillin follows the same rules, more stable, rated as equal to sodium penicillin in effect.

5 For intramuscular injection, 50,000 O U can be administered in 1 cc. of water Potency of solutions at room temperature shown t be maintained for four days with current preparations (Kirby 1944) making icebox storage of solutions unnecessary but of ampules still desirable. One day supply may be mixed in summer

6. For intravenous injection, use 1,000 to 5,000 O.U per cc sterile saline For drip, 25-50 O.U per cc. of saline or 5 per cent dextrose solution.

7 Oral administration ineffective (destroyed by HCl), enteric coating erratic duodenal tube, wkward, not used destroyed in colon by an antagonistic substance. Subcutaneous absorption slow large loss. Inunction for topical use only Not advised for systemic therapy

8. Penicillin is poor tissue penetrator Eliminated rapidly largely by the kidneys (58 per cent first hour), most rapidly after intravenous, slower fter intramuscular injection Methods of biologic ssay so far have too large a margin of error for over-positive statements regarding blood levels, presence or absence of minut amounts.

9. A method of delaying the elimination of penicillin by the administration of p-amino-hippuric acid has just been reported (experimental in rabbits) (Beyer Woodward, Peters, Verwey and Mattis, Science 100 107 Aug 4 1944)

10 Because of rapid elimination, administration is currently by drip or intramuscular injection repeated t three-hour intervals round the clock, thus necessitating hospital or continuous nursing ttention. The total dose is fractioned mong the scheduled periods, usually equally but in some cases with initial reduction (in syphilis, to void Herxheimer effects) Inter jection intervals as long as twelve hours have been used, foreshadowing an ambulatory techniq (not yet recommended)

11 In defining penicillin dosage give in th following order the total Oxford units (or milligrams if sed when standard is made official); the fractioned dose per injection, the time interval between injection the time of the entire course or series; the route of administration. These facts with manufacturer name and lot number should be part of ll records. The same manufacturer product, if possible should be used in given case

12. In intravenous injection technic with slight risk of thrombosis the needle can be strapped but the drip technic (p. 317) is preferred. Give the first 200 cc rapidly then reduce rate t 30 t 40 drops per minut (dextrose).

13. In intramuscular injection technic, follow procedure of Chapter VIII (p. 304). Vary injection sit divide mounts over 2 cc. between the two buttocks; can be given subscapularly or into thigh or deltoid but not advised. Slight burning usually only reaction but in rare idiosyncrasy (probably due t impurities) or allergy may be deeply swelling. Moderate exercise promotes absorption; need not be urged.

Fig. 807 (*Continued*)

PENICILLIN FOR THE PRACTITIONER

A General Statement of the Facts

14. For intrathecal administration (intraspinal, intracisternal) 5,000 units per cc., 10,000 units per injection, once or twice daily (Bloomfield)
15. Reactions to penicillin are few and trivial and are suspected of being due to impurities. Do not confuse Herxheimer or therapeutic shock effects in syphilis. Allergy appears in workers in manufacture but thus far not clearly recognized in treatment (urticaria, "id" reactions on palms, eosinophilia of 20 to 30 per cent, exfoliative dermatitis, 2 cases) The commonest general reaction is urticaria with severe itching lasting 2 to 5 days (1 to 5 per cent of patients) with or without marked gastro-intestinal symptoms, not recurrent with retreatment or change of lot and manufacturer Fever with or without chills, headache or head-flush, tingling sensations in testes, skin burning, paronals, may occur While study of animals is not complete, visceral or vascular or nervous tissue injury has not, so far been recognized at therapeutic dosage in man.
16. Herxheimer or therapeutic shock effects occur in human syphilis at approximately the same time and with symptomatology to correspond with the expectancy for the trivalent arsenicals. See p. 240 The cutaneous eruptive exacerbation is less common than with the arsenicals.

taneous effect of the antibiotic on the gonococcus and *Spirochaeta pallida* introduces, along with the suggested advantage of a one-method treatment for two diseases, the rather serious problem of under treating syphilis in its initial stages, concomitantly present with gonorrhea A technic will have to be devised with probable emphasis on the syphilis follow-up of gonorrheal patients which will keep the masked syphilis from slipping through, to go on to infectious relapse and recurrence.

The existing intramuscular and intravenous technics for the use of penicillin in syphilis are unwieldy and require an amount of supervision that will, for a long time make them impractical for the large proportion of infected individuals, except at suitably equipped centers, until an ambulatory procedure is developed Whether this will stem from the possible feasibility of longer intervals between intramuscular injection whether it will arise from the development of new penicillin compounds of higher efficiency or different rates of absorption from the simple salts now available or whether it will be accomplished by the use of absorption-delaying vehicles or elimination-delaying agents, remains to be determined. When the patient can visit the doctor office once or perhaps twice in the twenty-four hours, the sun will be rising on the future of syphilis control by penicillin, though it will be setting behind the hard-worked doctor s back.

Mahoney has frequently stated informally that he anticipates the return of the treatment of syphilis from the hands of experts and organizations, to the office of the general practitioner In a speculative mood one might go even further than this, and imagine himself at the day when a "protamine-penicillin" will be administered at the start by the office nurse and throughout the continuance, to the finish of treatment by the patient himself Certainly physicians will no longer need to lay bare the embarrassment of their own conditions to their professional brethren, for few will lack the hardihood to carry out their own penicillin therapy

The Cost.—As this discussion is written, it will be difficult to apply penicillin on a large scale to the syphilis of clinic practice, and the common run of mankind. The price per hundred thousand units, ranging from about $4.00 to

Fig. [illegible]

PENICILLIN IN SYPHILIS

The Known and the Unknown as of July 1944

The Known	The Unknown
1. Spirillicidal *in vitro* and *in vivo*.	1. The mechanism is unknown; assumed from bacterial analogies to consist in (1) inhibition of multiplication, (2) direct action on a synthetic anabolic process within the spirochetal cell (as with sulfonamides [Dubos, Weiss 1944]) It is not a bacteriolysis as with phage.
2. Spirillicidal at all dosages clinically explored in man from 1 000 to 25,000 O U every 3 hours intramuscularly	2. The spirocheticidal dose bears no known relation to the curative dose (animals)
3. Organisms disappear from surface lesions in 6 to 60 hours, usually 12 to 24 hours at 25,000 O U	3. The clinical significance of the shorter and longer periods as compared with dosage is still unknown.
4. No penicillin-resistant organisms have been encountered as yet in man. Suggested in animals (Dunham, Hamre, McKee and Rake 1944)	4. Will penicillin resistance appear later? Will it be overcome by modification in dosage technic (*i.e.* shorter time intervals, larger single or total dose repetition, adjunct treatment with arsenicals, bismuth, fever)?
5. Treatment resistance is foreshadowed by serologic curves in certain patients.	5. Where no response is shown, has the patient a metabolizing defect (inability to utilize the penicillin) or a penicillin-resistant spirochete
6. A flare, Herxheimer or therapeutic shock effect follows the first administrations, about the time it occurs with the arsphenamines. Evidenced in blood serologic titer and cerebrospinal fluid as well as lesions and clinical symptoms.	6. Does this justify inference as to a delayed action intermediary mechanism between penicillin and the organism, as inferred by some for the arsenicals?
7. Therapeutic paradox is suspected but not proved.	7. What effect will it have on cirrhotic livers, early syphilitic aortitis, coronary disease?
8. *Penicillin follows the old rule—the* earlier in early syphilis treatment begins, the better the result. It is more effective in seropositive primary syphilis, than the arsenicals, by first reports.	8. *Can it be inferred from this and from* spirillicidal action and Herxheimer effect that penicillin can be thought of as an arsenical or superarsenical in the schemes of early syphilis treatment?
9. Results in early syphilis are demonstrably better the higher the dose (information up to 1,200 000 O U in 8 days) On trial are dosage schemes of 1 200,000 in 4 days, 2,400,000 in 8 days, 100,000 to 50,000 O.U. twice daily for 8–12 days.	9. The actual curative dose by weight is unknown.

Fig. 808 (*Continued*)

PENICILLIN IN SYPHILIS

The Known and the Unknown as of July 1944

The Known	The Unknown
10. Present information indicates that intramuscular administration is 5 to 6 times more effective in early syphilis than intravenous (range of 600,000 to 1,200,000 O U.) judged by relapses (Moore for Panel Research)	10. Is blood level maintenance important or is succession of peaks or spikes as satisfactory as continuous high level? Can an absorption-slowing vehicle or combination produce and prolong blood level spike, thus simplifying the round-the-clock frequency of aqueous solution injections? How far apart, with adequate individual doses (50 000 O U up) can injections be spaced? Can more rapid and sensitive blood level determination technic be found?
11. The accepted safe dose for early syphilis is not less, for the moment, than 2,400,000 O.U in 8 days. Proposed by Mahoney (USPHS) this is now Army-Navy standard. In early syphilis give maximums, not minimums. The time interval between doses has considerable elasticity not yet determined.	11. How large an amount will cure all or the nearest to all, is the needed knowledge—not how many how little will cure. Very little or none will cure some.
12. The penicillin relapse rates in early syphilis are thus far no greater or somewhat less at 1,200,000 O U. than in either standard combined, or in massive dose or other intensive arsenical-bismuth systems.	12. By what combination or intensification will this refractory margin be done away with, separating us from the 100 per cent cure—penicillin-mapharsen, penicillin-bismuth penicillin-fever; penicillin at higher dosage, shorter or longer intervals, for shorter or longer periods?
13. Penicillin-mapharsen (60,000 and 300,000 O U. plus 320 mg mapharsen in 8 days) has good record so far on both safety and relapse.	13. Do such combinations affect either therapeutic activity or reactivity of either agent—and do therapeutic activity and toxicity increase in different ratios?
14. Rabbit syphilis results so far indicate (a) single huge doses do not cure. (b) Repeated large doses at short intervals do not cure. (c) Repeated moderate or large doses at longer intervals over a longer period, do cure. Retarding vehicles (oil) require much larger doses, individual and total, for cure.	14. Does this mean that penicillin therapy will observe the arsenic-heavy metal principle of standard treatment days, that prolongation (of treatment) is as important as mass?
15. Treatment can be repeated if relapse or spontaneous recurrence in early syphilis occurs, at an equal (1,200,000 O U. or over) or larger dosage, with renewed response in most but not all cases but no decision yet on complete effectiveness.	15. Will such retreatment lead to an ultimate residue of penicillin-fast cases, to be avoided by huge initial treatment or much more prolonged moderate or high dosage treatment than at present in use? (See 14.)

PENICILLIN IN SYPHILIS

The Known and the Unknown as of July 1944

The Known

16. Penicillin shows signs of controlling malignant precocious tertiarism and arsenic-heavy metal treatment resistance.

17 Penicillin will reverse abnormal spinal fluids, even of Grade III in an undetermined proportion of cases to normal by total doses from 1 200,000 to 3,000,000 O U in single or 2 repeated sessions even after large amounts of standard treatment over long periods have failed. Standard treatment previously given does not seem to increase response to penicillin in late syphilis.

18. Under adequat (1,200,000 to 4,000 000 O U) dosage, penicillin continues to have clinical and serologic good effect for some time after the short courses are stopped. (Up to about 4 months?) Early relapse, especially mucocutaneous, begins to appear in about 90 days.

19 In early syphilis associated with pregnancy treated with 1 200,000 O U in 8 days (Lentz, Ingraham, Beerman nd Stokes) it is known that ( ) the *spirillicidal and lesion-healing effect* of penicillin i the same in other early syphilis (*b*) the child is adequately protected apparently (or cured) in large proportion of the few cases so far studied (born and remains seronegative or becomes so after birth) The mother serologic curve behaves as in early syphilis in general, but there is suggestion of *relapse tendency in some cases following childbirth* (observation period too short). No spirochetes so far found the umbilical vein scrapings. Penicillin in the umbilical vein blood after large dose given the mother *just before onset of labor* (Barksdale). Risk of inducing abortion (placental shock?) small but real, voidable by reducing initial dose.

The Unknown

16. Does penicillin insufficiently used (say below 600,000 O.U) induce immediate ( ) treatment allergy or *Unstimmung* as in malignant precocious tertiarism; (*b*) neurorecurrence (*c*) predispose t any type of late involvement over a longer period (questions raised for the arsenical in neurosyphilis)?

17 Will this mean control and prevention of neurosyphilis when applied in early syphilis? What is the optimum system for such effects—high initial dosage single course (2,400,000 O U or over up to 4,000,000 O.U. so far) or repeated less intense courses (not less than 1,200,000 O U each)? Will they be enhanced by simultaneous penicillin-mapharsen, penicillin-bismuth and penicillin-fever If the penicillin is ( ) reduced below 1,200,000 O U, or (*b*) held at 1,200,000 O.U or (*c*) raised to 2,400,000 O U or over? Do these combinations alter the action of penicillin, how and when is time relationships of the combination?

18. How long does the curative impetus last at various doses nd time schedules (*a* in intensive arsenotherapy malaria) and in various stages and types of the disease? Will penicillin be effective in preventing cardiovascular and visceral well as neurosyphilis, including especially so-called progression under treatment?

19. More time required to answer the questions involved. Is the adequate dose *for the mother-child combination* not larger even than the 2,400,000 O U *dose now ad ised for early syphilis?* Is the mother and child combination (in tero) curable easily as non-pregnant woman, or woman as easily (or more easily) the man. Where does the protection of the child take place; *i.e.* cure of the mother cure of child by mother (no penicillin in child?)? What effect has stage of beginning treatment in mother? What will be the results of treating pregnant women with latent syphilis. Does the child in tero help protect and treat" the mother (liter rise or relapse in mother blood after delivery)? I the placenta a penicillin barrier?

Fig. 898 (*Continued*)

PENICILLIN IN SYPHILIS

The Known and the Unknown
as of July 1944

The Known	The Unknown
20. Penicillin if used with caution at the start to avoid Herxheimer effects, produces rapid symptomatic improvement in congenital syphilitic infants, with roentgenologically demonstrable effects on epiphyseal and other bone lesions. The dose used thus far is the weight equivalent of an adult dosage of from 1,200,000 to 2,400,000 O U in 8–10 days, intramuscularly	20. Will it cure outright and in what proportion Will there be therapeutic paradoxical effects, especially in hepatosplenic involvement?
21. Penicillin heals late benign syphilids of the skin, mucosae and skeletal system at least as rapidly as the arsenicals but at a dosage (200,000 to 400,000) much too low to influence graver concomitant types of syphilis (e g neurosyphilis, especially Type III spinal fluids)	21. How much of the effect, e g on old osteomyelitis, is action on the pyogenic secondary invader rather than the primary syphilitic process?
22. Penicillin in late congenital syphilis (interstitial keratitis) acts equivocally sometimes dramatically favorably about as often disappointing. No dosage scale seems to give consistent results. Fever combinations may fail or succeed without rule. Other manifestations not yet reported.	22. What is the complex mechanism back of interstitial keratitis? Is the allergic factor important? The collateral infective or intoxicative factor?
23. The action of penicillin in latency and serologic fastness and in cardiovascular syphilis has not yet been studied	23. Experience opposes the expectation of more than "life insurance protection and 20–30 serologic reversal in such material.
24. Action of penicillin in neurosyphilis is separately summarized (see pp. 1260–1261)	24. Does penicillin penetrate the nervous system? Is intrathecal therapy preferable to intramuscular and intravenous? What is the status of fever penicillin combinations? All unanswered questions as yet.
25 Penicillin seems likely (*a*) to displace the arsenicals entirely if penicillin bismuth system proves effective. (*b*) It may displace all existing agencies for syphilis treatment (including massive dose systems) if the proportion of treatment failures after one year equals or falls below the massive dose and foreshortened arsenic-heavy metal systems, including equal effectiveness in preventing asymptomatic neurosyphilis.	25. How soon should the shift to penicillin be made? What will penicillin-bismuth do? (Safer than arsenic.) Will the penicillin-fever combination (drip technic) single or repeated, shorten and improve results? Will clinic and expert management become unnecessary (granted an ambulatory or office technic develops)? Will the patient learn to treat himself (à la insulin)? Can it be made usable by mouth? Can it develop prophylactic usefulness, local or systemic? How identify masked syphilis in cases cured of gonorrhea, leaving the underlying and developing syphilis insufficiently treated?

Fig. 808 (Continued)

PENICILLIN IN SYPHILIS

The Known and the Unknown
as of July 1944

26. Penicillin will not do the impossible—resolve scars or their effects; rebuild structural and functional wrecks; restore lost neurons; perform miracles in complex processes heretofore known to be erratic in response to treatment and involving metabolic, allergic, psychosomatic and other factors uncorrected or yet unknown or unexplored

FROM A.D. 1943 IT WILL TAKE A YEAR TO GUESS, TWO YEARS TO INTIMATE, FIVE YEARS TO INDICATE, A DECADE OR MORE TO KNOW WHAT PENICILLIN DOES IN SYPHILIS

$10.00 of the antibiotic alone, the cost for the present "standard" "cure" of 2,400,000 O U will be nearly a hundred dollars before any professional or clinical overhead has been considered. Notwithstanding the enormous increase in production of penicillin and the rapid drop in price, it will not be until the cost stabilizes at or below $2.00 per hundred thousand units, that it will be possible to discuss with the lower fee level private patient a satisfactory handling of his case at figures current in the present arsenotherapeutic regimen.

Problem of Partially Completed Arsenotherapy.—What to do with patients who have begun or partially completed treatment for an early or a late syphilis by standard arsenical and heavy metal methods will soon become a question. Those who demand and can pay for it, will doubtless receive penicillin in a dosage adequate as experience develops, to the type of infection they presented at the start. It will be some time before the worth of the previous arsenotherapy as a preparation for or a hinderance to the efficiency of the superimposed penicillin can be determined. Penicillin can now conceivably be substituted for repetitions of arsenic-heavy metal therapy of various types, and especially for the massive dose or intensive systems. Such a transition will probably take place with developing knowledge during the next two years, as the results of Penicillin Panel research are evaluated and published. It would seem that the hazardous methods of arsenotherapy should go first.

Penicillin in Latency.—A leading question too is that of the place of penicillin in the treatment of the overwhelming burden of monosymptomatic seropositive latency which constitutes seventy per cent of the load problem of public health treatment practice. On this, at this writing, little knowledge exists. The determination of what the older treatment did to improve the outlook of the latent syphilitic, as conducted by the Cooperative Clinic Group under the supervision of Moore was, within the limitations of the material, a masterpiece of rationalization. Only years of examination and reexamination of a stabilized material by a stable group of investigators following an initially planned series of schedules will provide the scientific answer to such a problem. Meanwhile we may anticipate all manner of unscientific approaches, beginning in all probability with the administration to every demonstrably latent syphilitic who can afford it, of the 2,400 000 O U dose of penicillin as for early syphilis. It will be a long time before any basis for the reduction of this maximum dose will appear as has indeed been the case in CCG USPHS standard-

ization of the treatment of late latency Early latency (first four years of the infection) may properly be considered eligible especially for the maximum penicillin dosage appropriate to early syphilis.

It is impossible to overemphasize, and it must be iterated and reiterated, that our basic knowledge of penicillin has the qualities of Swiss cheese—more holes than substance in many particulars. For example, it may appear as penicillin-treated persons are subjected to general medical study and go on with life that functional changes have occurred in important organs which have limited recuperative power One need only recall the lag in the study of the behavior of the liver under arsenotherapy to realize the importance of such considerations in the background.

The Importance of Follow Up.—As a final point for emphasis as penicillin moves to the front of the stage, the problem of follow-up deserves critical attention. Lacking even the impress upon his sense of responsibility made by the five-day drip and ten-day to twelve-week multiple injection methods, it will become more difficult than ever before to induce the quickly treated patient to let us evaluate penicillin results, and to control relapse and recurrence, with the inevitable continued dissemination of the disease. The problem of follow up was clearly recognized by the Penicillin Panel Research group, and already experience clearly shows that except under extraordinary precaution, effort and efficiency lapse and loss of supervisory contact may amount to 35 to 45 per cent of cases treated. If penicillin fails to hold its present creditably low record of mucocutaneous serologic relapse even under the higher dosage systems, a situation may well be created with respect to syphilis, comparable to that predicted by Pelouze and other authorities for gonorrhea, as a sequel of the sulfonamide regimen. This makes the more pressing the systematized study of larger dosage and therapeutic combinations of superior effectiveness in the research program of the present moment. It also strengthens the demand for adequate follow-up organization in clinics, adequate provision of follow-up service by the health authority for the practicing physician who may fall heir to this material, and adequate contact-tracing service to find and bring in for study as well as treatment, the new infections whose source may be the unrecognized penicillin failure.

In fact, while indulging in predictions, we may confidently venture another—that contact-tracing will grow rather than diminish in importance in the epidemiologic control of the disease. As public health experience increasingly demonstrates, the mere therapeutic abolishing of the problem of infectiousness does not solve the whole problem of the transmission of venereal diseases. Venereal disease, and conspicuously syphilis, is transmitted at two times in its course when the patient is out of therapeutic control—namely before he knows he has the infection, and after he believes himself cured or has been told that he is cured. Neither of these epochs in the transmissibility of the infection can be wholly reached by a spirocheticide though, of course, increased spirochaticidal permanence, so to speak, relieves the load of the second period of transmissibility Here, then, one sees penicillin face to face with the bed rock of venereal disease control only to find that it is not the drug or the antibiotic, but the struggle with sexual promiscuity that seems to be the ultimate determining force in the elimination of the venereal infections. The public health venereal disease front is shifting from treatment control to promiscuity control (see Chapter XXIII)

THE PENICILLIN PANEL RESULTS

It seems advisable in substantiation of some of the summarized material in the text figures, to quote directly from the Penicillin Panel Research reports of Moore Mahoney Schwartz, Sternberg and Wood on early syphilis, and Stokes, Sternberg Schwartz, Mahoney Moore and Wood on late syphilis, as published in the Journal of the American Medical Association. Since neurosyphilis holds numerical preponderance in the series and is by all odds the most important aspect of late syphilis clinically two summaries will be given in Figures 900 and 901 on penicillin in neurosyphilis, preceded by a résumé of general serologic effects (J.A.M.A 126 63-80 1944)

THE TREATMENT OF EARLY SYPHILIS

Early Syphilis.—The report on early syphilis by the Penicillin Panel contains important specific statements. Early syphilis was under investigation at the time of presentation of the report in 23 clinics and research centers, whose names are given in the published account. The material was limited to patients in whom *Spirochaeta pallida* could be demonstrated indubitably in active lesions. The five variables of route of administration; interval between injections, duration of treatment total dosage; and possible combinations of penicillin with other drugs, were dealt with by holding the first three factors constant, all cases being treated by the intramuscular route every three hours day and night to a total of 60 injections given intramuscularly in seven and one-half days. Four treatment schedules provided 20-fold dosage range. In a later investigation the time-variable was studied and systems calling for 300,000, 600,000 and 1,200,000 O U. in 30 intramuscular injections over a four-day period, were employed, but the results are not yet available. The total number of cases at the closing of the books of the Penicillin Panel on May 9th, 1944, was 1,587 patients with early syphilis, of whom 1,418 had records suitable for punch coding and machine statistical analysis.

The results of this study of early syphilis emphasized over and over the importance of adequate dosage. While, with total doses of 300,000 units and up, healing is as rapid or more rapid than with the arsenicals, and a trend towards serologic reversal begins within a period of about twenty days after the start of treatment within the entire range from 60,000 to 1,200,000 O.U., the evidence clearly indicates that less than 600,000 units should not be used in the treatment of early syphilis that this dosage is inadequate to display the best efficiency of penicillin, and that doses of 1 200,000 O U and over should be regarded as a starting point for practice subsequent to this report. The rate of serologic reversal is stated by Moore to be identical with that observed after arsenotherapy whether with an arsphenamine given at weekly intervals, or mapharsen given by various intensive methods Temporary positives are observed in some cases of originally seronegative primary syphilis, with reversion to negative. Within the brief observation period of this study serologic results are said to have been satisfactory in 93.9 per cent of seronegative primary syphilis. The efficiency of the mapharsen-penicillin combination has been mentioned in Figure 898 The incidence of relapse interpreted by rigid criteria with reference to reinfection and including serologic relapse is thus far the only measure of efficiency of penicillin. Clinical and serologic relapses occurred in 92 patients with seronegative primary syphilis in 3.8 per cent. In seropositive primary syphilis the incidence of clinical and serologic relapse was 6 per cent and in early secondary syphilis nearly 10 per cent. The relapses occurred as early as 29 days and as late as 291 days after the start of treatment with penicillin. Moore has stated informally that it occurred around the ninety-day observation period. Intravenously administered penicillin was shown by this study to be clearly less effective than penicillin by the intramuscular route.

Moore and his collaborators reported on the results of treatment in special forms of syphilis as follows of 13 patients with early syphilis who had positive spinal fluids before treatment, 11 of Group II and 2 of Group III showed improvement or disappearance of the abnormalities in ten to fifty days in 10 of the patients and no improvement in 3. In 10 cases of acute syphilitic meningitis, the majority treated with 1 200,000 O U in seven and one-half days, dramatic symptomatic relief occurred in all, and in the majority the spinal fluid abnormalities had disappeared or were rapidly improving Eight patients with treatment-resistant persistent dark-field positive cutaneous syphilids, persisting in spite of metal chemotherapy responded promptly to penicillin and behaved serologically as did patients with previously untreated early syphilis. Twenty infants with early congenital syphilis, treated in the majority of cases with 40,000 units per kilo body weight, corresponding to a total dose of 1,200,000 units in the adult, showed clinical and serologic responses analogous to those of acquired syphilis in the adult.

THE TREATMENT OF LATE SYPHILIS, CONGENITAL SYPHILIS AND NEUROSYPHILIS WITH PENICILLIN

It will be recalled that O'Leary and Herrell observed in their patient with concomitant late cutaneous and asymptomatic neurosyphilis, the healing of the cutaneous lesions and improvement in cell count, colloidal tests and total protein in the spinal fluid; changes subsequently shown by the Panel research to be among those characteristic of the effect of penicillin in neurosyphilis, as indeed it has been more or less characteristic of all forms of treatment capable of influencing neurosyphilis. Mahoney (personal communication) had observed in badly debilitated patient with paresis, treated early in his experience, most striking symptomatic improvement following the use of penicillin.

Fig. 880

PENICILLIN AND THE BLOOD SEROLOGIC REACTIONS

1. Some reduction in strength of serologic reactions is almost always obtainable by penicillin total dosage from 300,000 units up.
2. Effect more marked with higher titers.
3. A provocative increase in titer may be followed by drop, often seen in initially sero-negative primary syphilis about to become seropositive.
4. In early syphilis the curve of decline to normal under massive dose penicillin (1,200,000 to 2,400,000 O U) in eight days compares with that of massive dose arsenotherapy or is even more rapid. A patient with strong positive after ninety days is candidate for retreatment.
5. In late and latent syphilis, decline in titer occurs in from 30 to 60 per cent of cases, and provocative effect in 20 per cent. Up and down fluctuation occurs and the effect of penicillin serologic fastness is still unexplored.
6. A consistent rise in serologic titer after consistent decline is warning of relapse or non-cure, as with the arsenicals.
7. Improvement in blood serologic reactions tends to parallel spinal fluid improvement, though not necessarily so; and symptomatic improvement may occur independent of any improvement in the blood. Improvement in the blood may occur independent of any symptomatic response.
8. Complement fixation and flocculation tend to parallel each other in the serologic response of a test battery.

SEROLOGIC PRINCIPLES APPLICABLE TO As-Bi THERAPY SEEM TO FIT PENICILLIN ALSO

It was quickly established by the Panel Research that in gummatous manifestations of the skin, mucosae and bones, the action of penicillin is so striking and complete that it seemed unnecessary to collect larger material for the moment than the 21 cases provided by the cooperating clinics.

It was clear, insofar as the material covered the question, that satisfactory healing occurred in benign late syphilis with doses too low to have adequate therapeutic effect on important con-

The eight clinics cooperating in the study of late syphilis included those of Bellevue Hospital (Evan Thomas, M.D.), the Boston Psychopathic Hospital (Harry P. Solomon, M.D.), Cornell University (Walsh McDermott, M.D.), Johns Hopkins University (J. E. Moore, M.D.), the Mayo Clinic (P. A. O'Leary, M.D.), the University of Michigan, (U. J. Wile, M.D.), and the University of Pennsylvania (John H. Stokes, M.D.). Of these Johns Hopkins University and the University of Pennsylvania have been longest in the field, and provided the largest and longest observed material. At the University of Pennsylvania the work was organized on a subpanel basis with the cooperative participation of the following individuals and clinical departments: J. H. Stokes, M.D., H. Beerman, M.D., N. R. Ingraham, Jr., M.D. and J. W. Lentz, M.D., Institute for the Control of Syphilis and Department of Dermatology and Syphilology; V. S. Wammock, M.D. and O. M. Carrozzino, M.D., Division of Venereal Disease Control, Philadelphia City Department of Health and Philadelphia General Hospital; Service B, Pennsylvania Hospital, G. D. Gammon, M.D. and D. Scott, Jr., M.D., Department of Neurology; Willard Steele, M.D., Department of Ophthalmology; F. H. Adler, M.D., Professor; J. I. M. Scott, M.D., E. K. Rose, M.D. and H. H. Perlman, M.D., Department of Pediatrics and Children's Hospital; Joseph Stokes, J. M.D., Director; Department of Roentgenology, E. P. Pendergrass, M.D., Professor; and Department of Otolaryngology, Karl Houser, M.D., Professor.

Fig. 900

THE SPINAL FLUID UNDER PENICILLIN

1. Penicillin (sodium or calcium salt) has not yet been demonstrated in quantity in spinal fluid after intramuscular or intravenous administration. (cf meningitis, Rosenberg and Sylvester 1944)
2. The fact is of no established significance since the good responses are undoubted nonetheless; and it has not been proved that spinal fluid levels even in the arseno-therapeutic era had therapeutic significance.
3. A quantitative Wassermann reaction and total protein estimation are essential to interpretation.
4. The abnormal spinal fluid in late syphilis is improved in 74 per cent of cases of late symptomatic and asymptomatic neurosyphilis. Improvement is marked in 33 per cent.
5. The commonest change is a drop in cell count and total protein in 70 per cent of cases. Both may drop before an eight day course is ended. This is no measure or guide to efficient dose.
6. Relapse likewise begins with a consistent rise in cells or protein.
7. Cell count, protein, Wassermann and colloid tests all improve in 25 per cent of asymptomatic neurosyphilis and 10 per cent of paresis (largely 1,200,000 O.U. dosage)
8. Repeating a course may cause further improvement.
9. Grade III (preparetic) spinal fluids improve and may be reduced to normal after prolonged arsenical and heavy metal therapy has failed.
10. Spinal fluid provocative effects are suspected but not yet clearly demonstrated.
11. Patients with negative bloods and spinal fluids may undergo symptomatic improvement under penicillin.
12. The spinal fluid may remain unchanged despite marked symptomatic improvement.
13. Grade I and II spinal fluids seen in early syphilis usually improve rapidly (ten to fifty days)
14. Even grade III spinal fluid may ultimately be reduced completely to normal by as little as 1,200,000 O.U. in eight days, but such dosage is probably insufficient for routine use.
15. Spinal fluid response after penicillin continues for an unknown period after single course (1,200 000 to 3,000,000 O U)—possibly as long as four months.
16. Hence, in watching progress of neurosyphilis under penicillin, spinal fluid examination should be made not more than one month before and two weeks to one month after penicillin and every two to four months thereafter. A total of six examinations in the first year is advisable.
17. If the spinal fluid fails to improve or standstill after improvement occurs, judged by fluid findings at the fourth to fifth month, the patient should, unless symptomatically worse, be retreated with penicillin, not arsenotherapy. Relapse should be retreated with much larger dosage of penicillin; or fever therapy may be substituted or added.
18. The advisability of substituting penicillin for initial arsenotherapy (Unit courses, pp. 1038, 1049) or for fever in previous untreated cases, should be a matter for individual, if possible consultative decision. If the fluid is grade I or II, after previous treatment, penicillin should certainly be tried before fever and if grade III, it should probably be tried before fever.
19. Previous treatment with As, Bi or fever does not seem to influence the action of penicillin on abnormal spinal fluid.
20. In early syphilis under penicillin (2,400,000 O.U.) examine the spinal fluid early (after penicillin) and at three and six months. If normal at sixth month repeat in one year if possible. If abnormal, retreat with 4,000,000 O.U. and individualize case ... in (1 ...

THESE STATEMENTS ARE AS OF AUGUST 1944—NOT FINAL EVALUATIONS

comitant manifestations such as neurosyphilis. The danger of underdosage is therefore of significance here, and the necessity for complete investigation of the individual with benign late ... from all standpoints, very apparent. In fact, the gummatous late syphilis of the Penicillin Panel Research series yielded a number of cases of concomitant neurosyphilis.

With this statement disposing of the simple problem of benign late syphilis from the symptomatic standpoint, attention should be directed both to the broader delineation of therapeutic

effects on the reagin titer of the blood and on the spinal fluid, both of which, quantitatively studied, supply good indices of the efficiency of penicillin, and the action of penicillin in the more refractory late syphilis of the nervous system, interstitial keratitis, visceral and late congenital syphilis.

The material collected from the Panel clinics for the late syphilis study aggregated 192 cases, and differed from that available in early syphilis, in that no predetermined plan was employed by any investigator and each therefore more or less groped his way into his problem. The aggregate of 192 cases of even limited statistical eligibility had been observed for periods ranging from 8 to 214 days after the institution of treatment. It must be, as in the case of early syphilis, emphasized, iterated and reiterated, therefore, that such material provides only speculative basis for study in many respects and that no final conclusions should be drawn from it. The importance of neurosyphilis in the study is emphasized by the proportion of cases, 122 of neurosyphilis and 60 of other types.

It should also be emphasized that in the late syphilis study the dosage systems so carefully planned in the study of early syphilis have little or no counterpart. No less than 11 different types of treatment appeared in material of 192 cases. This limited any study of treatment effect to comparison of smaller and larger dosages, which gave suggestive but by no means conclusive results, especially qualified in the light of the variability of the observation period.

Fig. 901

SYMPTOMATIC NEUROSYPHILIS UNDER PENICILLIN

1. N eurorecurrences observed thus far
2. Early meningeal eurosyphilis response excellent.
3. Definite Herxheimer effects observed in lat neurosyphilis to be voided by reducing dosage at least one-half for first two to three days. Includes convulsions, myelitic symptoms, etc.
4. Simple dementated paresis, 80 per cent some improvement, 50 per cent improved 50 per cent; 27 per cent improved 75 per cent, 1 complete remission. Encephalogram improves, handwriting may return to normal in six weeks, dysarthria, disorientation, etc., may improve varying degrees up to 100 per cent. Influence of spontaneous remission factor not yet determined.
5. Deteriorated paresis, 33 per cent improved, none put into remission.
6. Tabes dorsalis in the aggregate, 20 per cent improved 50 per cent and more.
   ( ) Lightning pains, severe, one-half improved 50 per cent or more.
   (b) Primary optic atrophy mostly advanced, none made worse, one in seven improved (including spinal fluid).
   ( ) Charcot joint, no response, either preventive or curative.
   (d) Paresthesias, gait, etc., slight improvement.
7 Meningo-vascular neurosyphilis, 40 per cent improve 50 t 75 per cent.
8. Recent ocular nerve palsies (diplopia, ptosis) respond completely if treatment is begun early enough.
9 Optic papillitis and papilledema respond rapidly

Effect of Penicillin Treatment on Blood Serologic Reactions in Late Syphilis.—Penicillin causes reduction of syphilitic reagin titer in the blood in from 50 to 60 per cent of late cases. An initial Herxheimer-like or provocative rise is observed in about 20 per cent of cases. Only five seroresistant cases were treated—one made negative four improved. (See Fig. 899.)

Effect of Penicillin Treatment on the Abnormal Spinal Fluid.—The abnormal spinal fluid in neurosyphilis is improved in 74 per cent of cases in some degree; markedly in 35 per cent. The commonest change is drop in cell count and total protein (rated as grade 2 improvement on scale of five) occurring in 67 per cent of cases. One spinal fluid was rendered normal within the observation period. All four fluid findings improved in 25 per cent of the cases of asymptomatic neurosyphilis, and 10 per cent in paresis and taboparesis. (See Fig 900.)

Symptomatic Improvement in Neurosyphilis.—In simple dementated paresis, of 30 cases on which data were adequate for classification, 80 per cent improved to some degree. Nearly half improved 50 per cent or more, including 8 who improved 75 per cent, and one restored to normal. Deteriorated paresis; two of 10 improved 75 per cent, one 50 per cent, 7 no change. Tabes dorsalis three of 14 cases improved 50 per cent or more; of seven with lightning pains two were completely relieved, one improved 50 per cent, two improved 25 per cent, one remained unchanged

and one became worse. Of seven cases of primary (?) optic atrophy mostly advanced, none was made worse one improved. In meningovascular neurosyphilis, 40 per cent improved from 20 to 75 per cent.

Case Examples in Neurosyphilis.—Since nothing carries conviction to the doubter like the touch of the individual case certain serial spinal fluid and blood findings typical of the best responses observed by the Penicillin Panel groups are reproduced in Figures 902, 904 and 905 For the symptomatic results, two case histories are abstracted (Fig 906) and the improvement in the handwriting of a markedly demented paretic is shown during the six weeks following penicillin through the courtesy of G D Gammon, M D (Fig. 907)

Fig 903.

PENICILLIN PANEL INVESTIGATION

Case 3 (Penna.) Male, age 38, acquired syphilis. Primary optic atrophy in tabes, with euphoria, possible taboparesis. Fields show sector defect suggesting arachnoiditis or retrobulbar neuritic episode. Original spinal fluid, cells 182, Kolmer WR 4444, Pandy 4 plus, mastic 4448110000, improved to cells 29, Kolmer WR 0123, Pandy 3 plus, mastic 4438210000 by 2 Swift Ellis treatments.

Penicillin Treatment Series 1 — Total dose 1,600,000 units

Post penicilli	Quantit. Kline (blood)	Cells	CSF W. (kolmer)	Protein	Mastic
		Cerebrospinal fluid			
0 day	16 unit	29	0123	3 plus	4134110000
13		12	0012	2 plus	2211000000
78	2	10	0112	1 plus	2211000000

Began to lose ground visually with slight confusion and increased euphoria.

Penicillin Treatment Series 2 — Total additional dose 1,800,000

104	16	11	0112	20 mgm.	2211100000
164	Less than 1 unit	5	0012	20 mgm.	2211000000

Definit improvement in fields, acuity and mental stat

It true, of course that these cases put the best foot forward that the permanence of the result is still question and that it is of course difficult t evaluat symptomatology but which elements of the subjective nd the influence of suggestion, rest, practice (in eye station and pupil test) enter but t is clear t le st that penicillin i capable of exerting marked and indeed surprising influence on neurosyphilis of resistant types, including Grade 3 spinal fluid findings. Again, it ca not be expected that penicillin will do the impossible restore lost neurons or do away with scar or t effects.

The Effect of Treatment Systems in Neurosyphilis.—Because of the lack of a uniform plan it was perhaps risky to attempt such a study in a material of this type Two stati tical summations seemed possible however one of the influence of smaller dose as contrasted with larger dose treatment and the other of the response under penicillin of spinal fluids with low as contrasted with relatively high cell counts. None of the results are beyond challenge

They suggest that in late syphilis, especially neurosyphilis, smaller doses, if not grossly inadequate (as in the inadequate 300 000 O U dosage for combined late benign cutaneous and asymptomatic neurosyphilis) may have the good effects of a therapeutic push in the right direction which may perhaps be improved by repetition, as compared with the expected better effects of

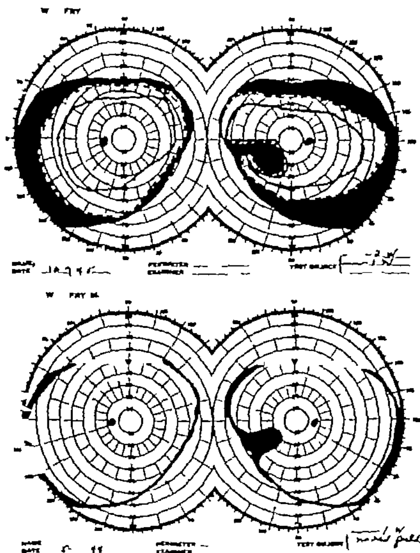

Fig 303.—Visual fields of Case 8, Pennsylvania penicillin series. Improvement with decrease in sector defect shown. Clinical history and spinal fluid findings given in text under above case history number

initial large dosage. It is understood that the term, lower dosage scale, approximates 1,200,000 units, repeated if improvement is delayed or ceases entirely and that 4,000,000 O U represents the larger dosage scale, both being administered in approximately eight to ten days. It is at least suggested that the patient's resistance and defensive responses can be stimulated or utilized by

the lower dosage scale The figures on response in relation to cell count, suggest that moderate to high cell count cases tend to react somewhat better than cases with low cell counts, a conclusion in keeping with experience under the older methods of treatment.

The material studied provided no basis for inferences regarding the combined effect of fever therapy and penicillin or of intrathecal penicillin therapy A breakdown of the material on the basis of the intensity of routine and fever treatment received before penicillin was begun indicated that the good effects of penicillin were obtainable without respect to previous arsenic and heavy metal or indeed of fever therapy

What advice would we offer the practitioner then, confronted with a case of asymptomatic or symptomatic neurosyphilis at the threshold of the penicillin era? Here we believe that the question of individualization is paramount. It is useless to expect responses from dead or gravely damaged structures. It

Fig. 904.

PENICILLIN PANEL INVESTIGATION

Case 11 (Twena.) Male, *age* 18, *congenital syphilis*, discovered at age 6, treated with 30 neoarsphenamine injections a year for 11 years. Typical stigmas, neurologic signs including A-R pupils, anisocoria, partial ptosis left eyelid, weakness left 7th nerve, sluggish reflexes.

Penicillin Treatment Series 1 — Total dose 1,200,000 units

Post penicillin	Quantit. Kline (blood)	Cerebrospinal fluid. Cells.	CSF Wass. (Kolmer)	Protein.	Mastic.
0 days	16 units	32	1244	4 plus	3334410000
13	4	16	0123	1 plus	2111100000
52	4	6	0011	plus-minus	1111000000
140	Less than 1 unit	1	0000	30 mgm.	1110000000

Ptosis disappeared under Penicillin

is equally clear that penicillin produces effects fully equal to the best of preceding chemotherapy It may therefore well be suggested that penicillin in a 4,000,000 O U total dosage be considered eligible treatment for asymptomatic and symptomatic neurosyphilis with the proviso of adequate follow-up, and that such treatment can be substituted for the unit arsenotherapy summarized in Figures 703 704 If the response is not satisfactory fever therapy and not a return to arsenotherapy would seem to be the proper procedure The study of fever in combination with penicillin has just begun, and no opinions on its effectiveness can be offered. Penicillin does not influence the course of therapeutic malaria, so that the combination is usable, even though initial confusion, rather than illumination as to effects is the result to be expected.

Effect of Penicillin in Late Congenital Syphilis.—This is confined almost entirely to the observation of 14 patients with interstitial keratitis who, as previously indicated presented an equivocal though at times dramatically

favorable response. Patients with marked corneal and other ocular damage were included, and too much was expected in the way of results from such material. Of 14 cases, 6 showed improvement—3 of grade 4 on a scale of 1 2, 3 4 one of grade 3, and two of grade 2 Six showed no improvement, and two were definitely worse. When improvement occurred it was apt to be

Fig 906.

SYMPTOMATIC RESULTS IN TWO PATIENTS WITH NEUROSYPHILIS

U of P 34-W-F-Paresis-symptomatic-Grade III CSF Patient could not write or do housework. Had auditory hallucinations, personality changes, disorientation, tremor of tongue, hands and mouth, slurred speech. On second day of penicillin therapy had Herxheimer reaction with right-sided convulsions becoming generalized. After twenty-four hours, penicillin reinstituted at half dose to total 1,200,000 units without untoward effect. By sixteenth day completely oriented, memory speech, tremor improved, electroencephalogram improved. In four months patient tremor-free, speech and writing normal, well oriented. hallucination-free, and satisfactorily performing housework including marketing with points and driving car Clinical improvement not accompanied by spinal fluid improvement.

J. H. Hosp. 42 M-Paresis-symptomatic. In August, 1943 shell exploded near patient who developed mispronouncing of words, garbled speech, uncertain gait, tremor of hands, difficulty in writing Received 48 arm and hip injections. Became boastful, speech rambling, tremors more pronounced; handwriting worse and calculation poor Unimproved during hospitalization after 50,000 Oxford units per dose of penicillin to 4,000,000 units total. Clinical improvement three weeks post-penicillin with loss of tremors, improved handwriting and speech. Passed examination as pipe fitter CSF did not accompany clinical improvement. Neurologist considered him mentally improved, but not t original level.

dramatic. One patient previously energetically treated with chemotherapy and fever without results was given 1 200,000 O U in eight days. He was relieved of photophobia by the third day and a week after penicillin returned to work for the first time in many months. He has remained well, improvement continuing up to the stage of stationary residue. Another improved grade 4

and 104 days after penicillin flared and recovered again without further treatment. A *persistently seronegative congenital syphilitic with characteristic* stigmas, made no response and in fact became worse under 1,200,000 O U One of McDermott's patients, a fever failure, received a total of 4,845,000 O U in two courses without results. Thomas secured improvement in a case on *4 000 000 O U over 25 days, 20,000 O U every three hours.* Moore has excellent serial color photographs of a favorable case One of his cases likewise improved on 3,970 000 O U in 21 days, observed for 159 days.

Effect of Penicillin on Other Eye Lesions.—Klauder (personal communication) has been able to demonstrate with a slit lamp the Herxheimer effect in a case of syphilitic iritis (not included in this series) Two cases of optic neuritis on 2,000,000 and 3 000 000 O U both showed improvement. O'Leary's case improved 100 per cent on retreatment. Two cases of iritis improved

PENICILLIN

Fig 907 —Improvement in handwriting of simple demented paretic patient approximately n weeks following penicillin treatment. The signature before treatment is given above the word "penicillin. (Courtesy George D Gammon, M.D.)

100 per cent, but one relapsed and required an iridectomy for beginning glaucoma, after failing to respond to retreatment.

What should one say to the eye man confronted with the question of using penicillin in conditions here included? First, if it is possible do all the trying out of other methods of treatment before penicillin is invoked, if the impulse to mix the treatment after penicillin is begun is likely to be irresistible Recall that the eye is a stamping ground for other than specific syphilitic effects, some of which may be favorably influenced by penicillin but others may prove entirely unresponsive if they are not actually made worse Furthermore it should be recalled that it is too early to use penicillin in therapeutic tests for a possible syphilitic factor in all sorts of eye conditions, including otherwise undiagnosed tumors of the orbit and so forth The case should be reasonably clear for syphilis before penicillin is used if it is to be made a basis for the interpretation of penicillin effect.

The Effect of Penicillin on Eighth Nerve Deafness and Visceral Lesions.—This interesting but puzzling problem was left in the air by this investigation. The Ménière syndrome in a congenital syphilitic with eighth nerve deafness failed of improvement. One woman of thirty-one with undoubted stigmas improved definitely but not markedly on 1,200 000 O U Other cases (two in this series) failed to improve. The probabilities are against rather than for a striking good effect in this type of material

Miscellaneous cases permitted the observation of the recedence of a tumor like gummatous mass in the liver under penicillin therapy with equivocal and less definable results in the hepatosplenic complex. Charcot hip failed to respond and a new Charcot joint developed in the patient after penicillin (following injury) Rapidly progressing gangrenous balanitis, always a terror to the therapist and the patient, healed with a loss of less than a third of the corpus spongiosum on 300,000 O U

Herxheimer Effects in Late Syphilis.—It must again be emphasized from this, as from other studies, that penicillin is not a wholly reactionless drug. The disposition to pour it about like water in syphilis may lead to serious trouble especially from therapeutic shock and also from therapeutic paradox ical effect. The former is important under the usual rule that an active syph ilitic process in a vital structure may be gravely and even fatally damaged by the impact of a large dose or series of doses at the start of treatment. Most Herxheimer effects, however seem controllable by reduction in dosage from the first twenty four to forty-eight hours of an eight-day series without loss of ultimate effect. There is some question whether there are not delayed Herx heimer effects such as are suggested by spinal fluid and blood serologic curves, and the initially unfavorable but ultimately favorable course of some lesions (eye nervous system for example)

Of 182 cases, 24 per cent sustained reactions interpretable as Herxheimer or therapeutic shock effect. In four Pennsylvania cases, reactions thus inter preted in the nervous system included transverse myelitic symptoms in one case Jacksonian convulsions lasting twelve hours in another· exacerbation of lightning pains, and mania and hallucinations.

Early Syphilis in Pregnancy

The Penicillin Panel research report by Moore mentioned 58 pregnant women with early syphilis who had been treated but without evaluation of results. This topic was made a special interest of the University of Pennsyl vania group and the subject of a special report. At the deadline for the close of the investigation, 26 cases were collectable from the cooperating clinics includ ing Pennsylvania, with 10 deliveries, 6 at term. The mothers became darkfield negative in four to twelve hours, with 2 mucocutaneous relapses in 12 receiving 600,000 O U and none in 12 receiving 1,200,000 O U to date of close of the investigation Seven of 21 on whom data were available became seronegative within 76 to 148 days.

Of the infants, 10 delivered, all are living, three seronegative on the cord blood at birth, 4 seropositive, and 3 with no data. Five became seronegative under observation 8 of 10 had negative bone roentgenograms. Scrapings of the umbilical vein walls were negative to the darkfield in 5 instances, not per formed in the remainder Figure 908 reproduces the quantitative serologic curves for mother and child in 7 cases, which are part of the group reported by Lentz, Ingraham, Beerman and Stokes from the University of Pennsylvania,

observed for the longest period. It is too early to judge whether the mothers who were not seronegative at the time of delivery will ultimately become so or not. Observation since the deadline rather tends to suggest that there is a distinct tendency in the mother's curve to rise following the delivery as if the child had had, so to speak, while *in utero*, an inhibitive effect. There seems little or no question of the high degree of protection afforded to the child, which has been after all, the chief objective of the treatment of syphilis in pregnancy in the arsenical era. Under conditions almost certain to result in infection of the child *in utero*, had penicillin been ineffective, not a single miscarriage, stillbirth or clinically syphilitic infant resulted. Of course, only prolonged observation will establish clearly the absence of the disease in the mothers or the infants who have become seronegative after birth, or who are seronegative at the time of birth. The roentgenographic confirmation of the freedom of these children from syphilis is of almost greater weight than their serologic findings, and makes the outlook, so far as the child is concerned, quite promising Since the dosage employed, 1,200 000 units at 25 000 units

over 4 hours (the dose being reduced in the first twenty four to forty-eight hours as a result of our observation of two cases of threatened abortion on maximum dosage) is, in the light of our present conceptions in the treatment of early syphilis, probably inadequate for the cure of the mother in the highest possible proportion of cases even though it may protect the child, it should be advanced to 2 400 000 O U and patients who have received 1,200,000 O.U should unless clearly and lastingly seronegative, be retreated with the larger dosage

It should be noted that the earliest cases do not include as yet (a) latent syphilitic mothers, (b) pregnancies in which treatment was begun before the fifth month. The permeability of the placenta to penicillin is still undetermined Barksdale reported failure to find penicillin in the cord blood in 3 cases (J.A.M.A. in discussion) in which the mother was given a large dose intravenously at the time of delivery but a small amount was found in a subsequent case (personal communication)

INFANTILE CONGENITAL SYPHILIS

Nine congenitally syphilitic infants were treated by the University of Pennsylvania group Three have been followed long enough (99 97 70 days) to

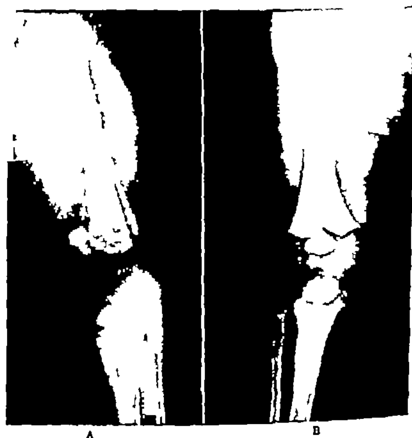

Fig 909 —A, Before penicillin. B, After penicillin

show the type of clinical and serologic response which may be obtained (Fig 908) They may well be rated remarkable. The two infants who showed defaulte

roentgenographic changes of osteochondritis and periostitis resumed normal bone development (Fig 909)

The total dosage employed in 6 of the 9 infants ranged from 13,000 to 16 000 O U per pound (28,600 and 34,200 O U per kilo respectively) given intramuscularly in fractions at four hour intervals, round the clock for eight days. After observing one supposedly Herxheimer reaction at 19 000 O U in the first forty-eight hours (cyanosis, dyspnea, nasorespiratory tract obstruction) the practice of using half doses for the first forty-eight hours seemed advisable and there is good reason to believe that a longer reduction period would be desirable in gravely diseased infants. Lentz, Ingraham, Beerman and Stokes strongly urge the need for expert pediatric care of the infant regardless of the apparently good general tolerance of penicillin exhibited in their series Two deaths were the result of medical complications (congenital heart, infectious diarrhea) not the penicillin.

The Most Recent Penicillin Panel Results in Early Syphilis

We are deeply indebted to Dr J E. Moore and the Penicillin Panel of the National Research Council for the opportunity to present here in advance of publication in the literature, the latest tabulations prepared by Moore, cover

Fig. 910.

GROSS OVERALL RESULTS OF PENICILLIN IN EARLY SYPHILIS
(As of August 1 1944)

Total dose of penicillin (units) intramuscularly	Duration of treatment (days).	Total cases treated.	Maximum observation period (days)	Treatment failures.	Gross percentage failure (these figures meaningless except for comparison)
60,000	7½	31	294	15	48 4
300,000	7½	306	290	34	11 1
600,000	7½	673	294	23	3 4
1,200,000	7½	483	250	10	2 0
2,400,000	7½	100	112		
60,000 and 320 mg. mapharsen	7½	45	185	3	6 6
300,000 and 320 mg. mapharsen	7½	114	140	3	2 6
Penicillin Intravenously					
1 1.2 million	5–6	29		4	13 8
300,000	4	41	56		
600,000	4	101	112		
1,200,000	4	107	112	1	
2,400,000	4	39	42		
Total Cases Treated		2072			

ing penicillin treatment results in early syphilis as of August 1 1944 To quote Moore s explanatory letter

"Figure 910 is of value only in showing (1) the total number of cases so far treated in each dosage group, (2) the probable (but not yet proved) advantage of penicillin plus mapharsen, especially in the 300,000 unit group, (3) the cases treated in four days with as yet too short observation periods for any results, (4) the probable (but not yet proved) disadvantages of the intravenous route, and (5) the absolute inadequacy of 60,000 units total dose.

*Figure 911 is the one which really counts. Enough cases and elapsed observation time are available in only three groups t permit figuring cumulative percentages, and in them only to the 140th day after treatment. The maximum observation periods in the three dosage groups tabulated (and others) are shown in Fig. 910, but the number followed after the 140th day is as yet too small for statistical significance. In Figure 911 the final column is only a guess, but may be a good one.

Fig. 911

PRELIMINARY RESULTS IN EARLY SYPHILIS OF 60 INTRAMUSCULAR INJECTIONS OF PENICILLIN GIVEN EVERY 3 HOURS FOR 7½ DAYS

(As of August 1 1944)

Total dose of penicillin (units)	Number cases treated.	Number cases followed 115–140 days.	Cumulative per cent failure 115–140 days.	Cumulative per cent becoming seronegative 115–140 days.	Cases failing after 140 days.	Probable eventual cumulative per cent failure.
300,000	306	65	26.1 (17 failures)	48.4	7	60
600,000	673	95	13.4 (10 failures)	57.4	4	20–30
1,200,000	495	77	7.6 (5 failures)	71.8	2	10–15

Gross number followed too small to permit percentages.

The reinforcing power of mapharsen in lower total doses of penicillin should be borne in mind where the amount of penicillin available is limited by any circumstances and might even be considered as reinforcement at the low dosage employed for the penicillin therapy of gonorrhea reasonably suspected of being likely to mask a coincident syphilis, as in some conditions prevailing among the armed forces in some theaters, especially the Orient. The excellent record of 1 200 000 O U encourages the hope that 2,400,000 O U will leave a negligible margin of relapse in early syphilis.
